approaches and dynamic finite element analyses are explained. In addition, an actual application, a crash problem of car structures, is explained because adhesively bonded joints have been recently introduced to car structures and the design of the joints subjected to impact loads has become very important.

### 29.1 Introduction

In actual applications of adhesively bonded joints, there are many cases in which joints are subjected to impact loading. For instance, weldbonding joints, in which spot welding and adhesive bonding are combined, are widely used in the body structures of cars (see ► Chap. 46, “Automotive Industry”). Joints are subjected to impact loading when the cars are crashed in accidents. Adhesively bonded joints are also used in aircraft structures in these days, and impacts should be considered to design the airframe because bird-strike accidents may occur. Therefore, design for impact loads of adhesively bonded joints has become important, and a proper design method is required.

Other problems, in which impact occurs in a lower velocity range than those of car crash or bird strikes, has also become important. Dropping impact failure of mobile phones is one example. In mobile phones, there are several joints bonded with adhesives or pressure sensitive adhesives (PSAs). When a mobile phone drops and collides with the floor, an impact loading occurs and is applied to the structure, although the impact velocity and the maximum stress are relatively lower than in the case of higher velocity impacts. Thus, impact problems have a very wide range in impact velocity or loading rate, and methodologies depend on the type of loading rate.

Figure 1 shows the relation between types of impact, strain rates occurring in materials subjected to impacts, and typical experimental methods. Impact conditions can be categorized in three ranges: low velocity, medium velocity, and high velocity. In the low velocity range, problems cannot be treated as impact but as vibration. In the

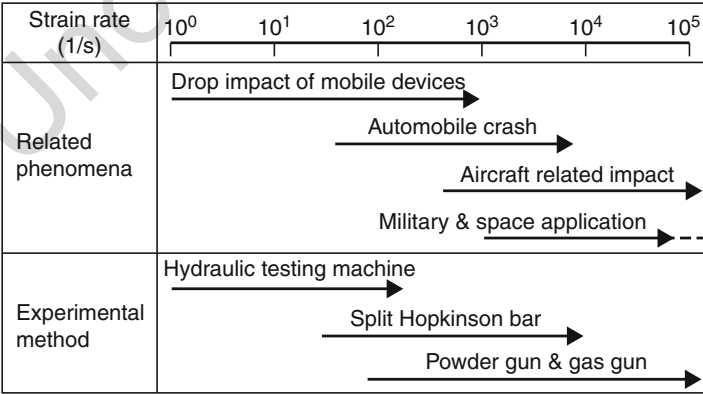

Fig. 1 Types of impact related phenomena, strain rates, and experimental methods

medium velocity range, stresses and strains propagate as waves in materials. In the high velocity range, a body collides with another body faster than the sound velocity of the bodies, and the sound velocity increases up to the impact velocity. The increase occurs due to the density and temperature increase by compression of the bodies. The stress waves higher than normal sound velocity are called “shock waves.” The above mentioned examples of cars, aircrafts, and mobile phones are included in the problems of medium velocity impacts that are mainly treated in this chapter.

The design process of adhesively bonded joints subjected to impact loading is basically the same as that to static loading. These processes include experimental investigations of material properties and failure criteria, stress analyses, and strength prediction by applying failure criteria to the analyzed stresses. The difference between impact and static cases is in the stress analysis considering stress wave propagations, the dependency of stress–strain relations, and the strength of materials. Experimental methods for impact phenomena are shown in ► Chap. 21, “Impact Tests.” In this chapter, the introduction of dynamic problems, stress analyses, and strength predictions are mainly discussed.

## 29.2 Stress Waves

Dynamic mechanics of materials is different from the static. In dynamic cases, inertia forces occurring in bodies should be considered. This is equivalent to solving the kinetic equation at each point in the bodies. In dynamic conditions, the stress value at a point changes with time, and the stress transmits in the solid. The stress variation in time and space domains is called “stress waves” (Goldsmith 2001).

The governing equations of stress waves propagating in three-dimensional space denoted with vector ( $\mathbf{x}$ ) are as follows:

$$\rho \frac{\partial^2 \varphi(\mathbf{x}, t)}{\partial t^2} = (\lambda + 2G) \nabla^2 \varphi(\mathbf{x}, t), \quad (1)$$

$$\rho \frac{\partial^2 \psi(\mathbf{x}, t)}{\partial t^2} = G \nabla^2 \psi(\mathbf{x}, t), \quad (2)$$

where ( $t$ ) is time, ( $\varphi(\mathbf{x}, t)$ ) is the field of dilatational waves, ( $\psi(\mathbf{x}, t)$ ) is the field of shear waves, ( $\rho$ ) indicates density of the solid, ( $\lambda$ ) and ( $G$ ) are the Lamé constant and the shear modulus of the solid, respectively, ( $\nabla$ ) and ( $\nabla^2$ ) are nabla and Laplacian operators. Since Eqs. 1 and 2 are wave equations, they can be expressed with velocities ( $c_1$ ) and ( $c_2$ ) as:

$$\frac{\partial^2 \varphi}{\partial t^2} = c_1^2 \nabla^2 \varphi, \quad (3)$$

$$\frac{\partial^2 \psi}{\partial t^2} = c_2^2 \nabla^2 \psi, \quad (4)$$

where  $(c_1)$  is  $(\sqrt{(\lambda + 2G)/\rho})$ , and  $(c_2)$  is  $(\sqrt{G/\rho})$ . In ordinary solids,  $(c_1)$  is greater than  $(c_2)$ . Therefore, dilatational waves can propagate faster than shear waves in the solids.

## 29.3 Material Properties Under High Strain-Rate Conditions

Constitutive relations (stress–strain relations) of materials are greatly dependent on stress and strain rates. Therefore, the dependency should be considered for precise simulation of impact phenomena. Constitutive relations and their loading-rate dependencies are shown in this section.

### 29.3.1 Constitutive Relations of Metals

Most metals show elasto-plastic behavior when they are loaded. They behave as linear elastic materials in low stress conditions, and plastic materials in high stress conditions over their yield points or proof stresses. The yield point is determined by yield criteria, and the plastic deformation over the yield point is described by flow rules. A flow rule in three-dimensional space can be obtained from the deformation and translation of the yield surface, which is expressed by work hardening of one-dimensional loading if the material is isotropic. Therefore, expression of work hardening is very important and can determine the flow rule. There are several models expressing work hardening, as shown in Fig. 2. Elastic and perfect plastic models are models for materials having no work hardening. The linear hardening model can describe a work hardening of constant rate with respect to plastic strain. As nonlinear models, power hardening model, Ludwik type hardening model, and Swift type hardening model are frequently used (Johnson and Mellor 1973).

**Fig. 2** Stress strain curves with or without work hardening

In impact conditions, the loading rate is quite high, so that the plastic behavior of metals is much influenced. In order to describe the loading-rate dependency, several models have been presented. The Johnson–Cook model, shown in Eq. 5, is a model by which Ludwik type hardening and loading-rate dependency can be expressed (Johnson and Cook 1983).

$$\sigma = (\sigma_0 + B\epsilon^n) \left\{ 1 + C \ln \left( \frac{\dot{\epsilon}^p}{\dot{\epsilon}_0} \right) \right\} \left\{ 1 - \left( \frac{T - T_r}{T_m - T_r} \right)^m \right\} \quad (5)$$

where ( $\sigma$ ) and ( $\sigma_0$ ) are stress and yield stress, respectively, ( $\epsilon$ ) is stress, ( $\dot{\epsilon}_0$ ) is a standard strain rate, ( $\dot{\epsilon}^p$ ) is the rate of equivalent plastic strain, ( $T$ ) is the temperature of the material, ( $T_r$ ) is room temperature, and ( $T_m$ ) is the melting point of the material. Parameters ( $B$ ), ( $C$ ), ( $m$ ), and ( $n$ ) should be determined experimentally. This model is suitable for high-rate deformations or high velocity impacts in which the temperature of materials increases due to the collision and the material constants change (Mayer 1990). The Cowper–Symonds model can also express high-rate condition by means of increasing the yield point of a material subject to impact (Cowper and Symonds 1952). The model can be shown as follows:

$$\frac{\sigma_d}{\sigma_s} = 1 + \left( \frac{\dot{\epsilon}^p}{D} \right)^{\frac{1}{P}} \quad (6)$$

where, ( $\sigma_d$ ) is the dynamic yielding stress, ( $\sigma_s$ ) is the static yielding stress, ( $\dot{\epsilon}^p$ ) is the rate of equivalent plastic strain, and ( $D$ ) and ( $P$ ) are parameters determined experimentally. Both the Johnson–Cook model and the Cowper–Symonds model are widely used for impact analyses and are included in many packages of finite element methods (FEMs).

### 29.3.2 Constitutive Relations of Plastics

Plastics are in the glassy state and linear elastic at low temperatures. The nature of plastics changes to a viscoelastic state around the glass transition temperature ( $T_g$ ) and to rubbery state in temperature range higher than  $T_g$ . Thus, the constitutive relations change from linear elastic to rubber elastic via viscoelastic. Since high loading-rate conditions are equivalent to low temperature conditions in terms of the temperature time superposition principle, plastics tend to become brittle in high loading-rate conditions.

Plastics are very often used in temperature ranges lower than their  $T_g$ s, so that their constitutive relations used for analyses should be linear elastic. However, strictly speaking, their moduli have a weak dependency to loading rates. If the dependency is a problem for impact analyses, the variation of moduli should be compensated. For this purpose, viscoelastic models are sometimes used to express the loading rate dependency (Sato and Ikegami 2000).

The situation of adhesives is different from that of ordinary plastics because adhesives are often plasticized to increase their ductility and cannot be treated as simple linear elastic materials. In this case, elasto-plastic models should be applied. Goglio, Peroni et al. have investigated the constitutive relation of a ductile epoxy adhesive at high strain rates using the split Hopkinson bar method (Goglio et al. 2008). The adhesives showed large plastic deformation that was much better fitted with a poly-linear model than the Johnson–Cook model and the Cowper–Symonds model.

---

## **29.4 Stress Analysis of Adhesively Bonded Joints Subjected to Impact Loads**

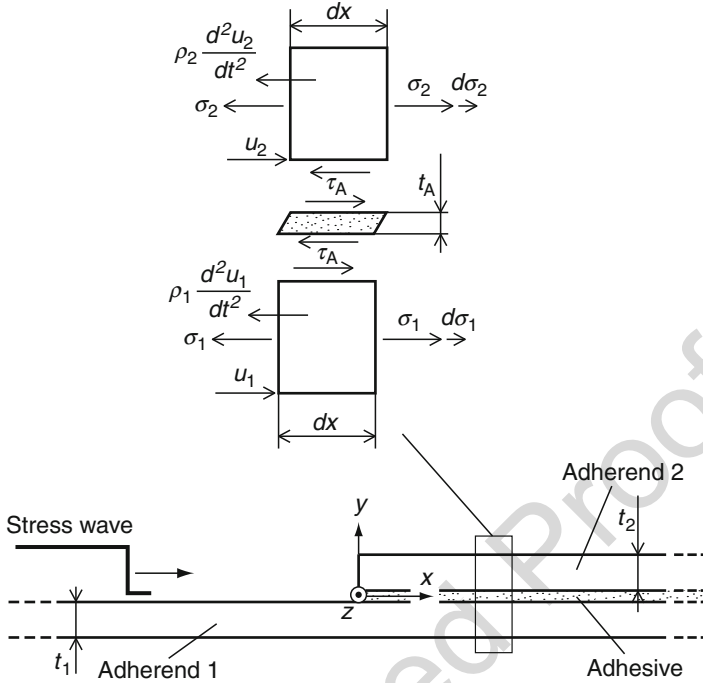

### **29.4.1 Theoretical Approach**

A correct stress analysis is necessary to estimate the strength of adhesively bonded joints. Much research on the problem has been carried out since the first theory emerged: Volkersen's shear lag model (Volkersen 1938). Since the stress distribution in joints depends on dimensions, types of materials and particularly the configuration, suitable designs to reduce stress concentration has been pursued. Stress analysis using FEM has a history of over 30 years, and almost all joint configurations have been investigated already with the method. For instance, Adams and Peppiatt conducted FEM analysis of lap joints and compared them with the closed forms of Goland–Reissner model (Adams and Peppiatt 1974). Other research treated the joints considering the elasto-plastic or viscoelastic properties of adherends and adhesives. However, dynamic analyses of the joints are still rare because they are more difficult than the static ones. The difficulty is due to the fact that a dynamic analysis needs repeated calculations and consumes much of computer resources.

### **29.4.2 Infinite Lap-Strap Joints**

Sato expanded the Volkersen's model to a dynamic model considering the inertia force effect of the adherends and derived series solutions of the governing equations for infinite lap-strap joints, which had boundary conditions simpler than single lap joints (Sato 2009). For ordinary adhesively bonded joints, cured adhesive resins are lighter than adherend materials, and the adhesive thickness is very smaller than that of adherends. Therefore, the inertia force of the adhesive layer is negligible and is thus not considered in the model.

Figure 3 shows the load equilibrium and deformation compatibility for the dynamic Volkersen's model of a lap-strap joint having a half-infinite length. The joint configuration has only one discontinuity at the edge of the joint, and its boundary condition is easier to treat than other joint configurations such as finite length single lap joints because stress reflection occurs only at the edge.

**Fig. 3** Equilibrium condition in infinite lap-joint (Sato 2009)

The force equilibrium of the half-infinite length lap-joint in the case of a dynamic condition can be determined considering the inertia forces  $(t_1 W \rho_1 \frac{\partial^2 u_1}{\partial t^2})$  and  $(t_2 W \rho_2 \frac{\partial^2 u_2}{\partial t^2})$  of the adherends as follows:

$$t_1 W \frac{\partial \sigma_1}{\partial x} + W \tau_A = t_1 W \rho_1 \frac{\partial^2 u_1}{\partial t^2}, \quad t_2 W \frac{\partial \sigma_2}{\partial x} - W \tau_A = t_2 W \rho_2 \frac{\partial^2 u_2}{\partial t^2}, \quad (7)$$

where  $(t_1)$ ,  $(t_2)$ ,  $(\rho_1)$ , and  $(\rho_2)$  are the thicknesses and densities of adherend 1 and adherend 2, respectively;  $(W)$  is the width of the joint; and  $(u_1)$ ,  $(u_2)$ ,  $(\sigma_1)$ , and  $(\sigma_2)$  denote the longitudinal displacements and normal stresses of adherends 1 and 2, respectively. Moreover,  $(\tau_A)$  is the shear stress of the adhesive layer, and  $(t)$  denotes the time since the beginning of loading. The normal strains of adherends 1 and 2 are denoted as  $(\epsilon_1)$  and  $(\epsilon_2)$ , respectively, and the shear strain (engineering strain) of the adhesive layer is denoted as  $(\gamma_A)$ . With  $(u_1)$  and  $(u_2)$ , the strains can be written as

$$\epsilon_1 = \frac{\partial u_1}{\partial x}, \quad \epsilon_2 = \frac{\partial u_2}{\partial x}, \quad \gamma_A = \frac{u_2 - u_1}{t_A}, \quad (8)$$

where  $(t_A)$  is the thickness of the adhesive layer.

The constitutive relations of the materials comprising the joint can be described as follows:

$$E_1 \epsilon_1 = \sigma_1, \quad E_2 \epsilon_2 = \sigma_2, \quad G_A \gamma_A = \tau_A, \quad (9)$$

where ( $E_1$ ) and ( $E_2$ ) are the Young's moduli of adherends 1 and 2, and ( $G_A$ ) is the shear modulus of the adhesive layer. Therefore, the governing equations of the dynamic Volkersen's model are given as follows:

$$\frac{\partial^2 u_1}{\partial x^2} + \frac{G_A}{E_1 t_1 t_A} (u_2 - u_1) = \frac{\rho_1}{E_1} \frac{\partial^2 u_1}{\partial t^2}, \quad \frac{\partial^2 u_2}{\partial x^2} - \frac{G_A}{E_2 t_2 t_A} (u_2 - u_1) = \frac{\rho_2}{E_2} \frac{\partial^2 u_2}{\partial t^2}. \quad (10)$$

When the thicknesses, moduli, and densities of the adherends are equal, they can be denoted by ( $t_s$ ), ( $E$ ), and ( $\rho$ ), and Eq. 10 can be written as

$$\frac{\partial^2 \tau_A}{\partial x^2} - \frac{2G_A}{E t_s t_A} \tau_A = \frac{\rho}{E} \frac{\partial^2 \tau_A}{\partial t^2}. \quad (11)$$

This equation is a simple modification of the governing equation of the Volkersen's model. It is obtained by adding the inertia force to the static equation. Although the governing equation of the static Volkersen's model is an ordinary differential equation, that for the dynamic Volkersen's model is a partial differential equation.

The boundary conditions for the model are defined as the situation in which a given stress wave transmits from adherend 1 into the joint, as shown in Fig. 4. If a strain gage is bonded on adherend 1 far from the joint end, the strain variation due to the stress wave propagation can be measured. In this case, the information of the progressive stress wave can be obtained, but have no information on the stress wave reflection occurring at the joint end.

The stress at the edge of adherend 2 is zero because this edge is a free surface. At the points of infinite distance ( $(x = \infty)$ ) in adherends 1 and 2, the displacements are zero because no stress wave reaches there within finite duration. When adherend 1 is virtually cut at the edge of the joint, the displacement of a virtual interface on the left part of adherend 1 can be expressed as the superposition of a displacement caused by the free-edge reflection of a progressive stress wave ( $\sigma_p(x - c_1 t)$ ) in adherend 1 and a displacement caused by a stress ( $\sigma_1(0, t)$ ) at ( $x = 0$ ). Note that ( $\sigma_p(x - c_1 t)$ ) is the stress distribution in the left part of adherend 1 due to a progressive wave. No stress wave reflection at the joint end is considered. In contrast, ( $\sigma_1(0, t)$ ) is the real stress

**Fig. 4** Boundary condition for infinite lap-strap joint (Sato 2009)

variation at the joint end. Therefore, all boundary conditions can be written as follows:

$$\begin{aligned} u_1(0, t) &= -2 \int_0^t c_1 \frac{\sigma_w(\xi)}{E_1} d\xi + \int_0^t c_1 \frac{\partial u_1(x, \xi)}{\partial x} \bigg|_{x=0} d\xi, \frac{\partial u_2(x, t)}{\partial x} \bigg|_{x=0} = 0, \\ u_1(\infty, t) &= 0, \quad u_2(\infty, t) = 0, \end{aligned} \quad (12)$$

where  $(\sigma_w(t) \equiv \sigma_p(0 - c_1 t))$  and  $(\xi)$  is a variable for the time integration. The function  $(\sigma_p())$  indicates the shape of a stress wave in the space domain  $(x)$ . In contrast,  $(\sigma_w())$  is a function in the time domain  $(t)$  and indicates the stress variation with respect to time caused by a stress wave propagation without reflection at  $(x = 0)$ . Therefore,  $(\sigma_w(t) \neq \sigma_1(0, t))$ .

Equations 11 and 12 are transformed into complex number domain  $(s)$  by the Laplace transform and are combined to the following equation:

$$H(0, s) = \frac{T_A(0, s)}{\Sigma_w(s)} = \frac{G_A c}{Et_A} \cdot \frac{4}{s + 3\sqrt{s^2 + 2c^2 k^2}}, \quad (13)$$

where  $(T_A(0, s))$  and  $(\Sigma_w(s))$  are the Laplace transforms of  $(\tau_A(0, t))$  and  $(\sigma_w(t))$ , respectively,  $(H(0, s))$  is the transfer function between  $(\Sigma_w(s))$  and  $(T_A(0, s))$ ,  $(k)$ , and  $(c)$  are given as follows:

$$k = \sqrt{\frac{G_A}{Et_s t_A}}, \quad c = \sqrt{\frac{E}{\rho}}. \quad (14)$$

This transfer function has enough information between the input stress waves and the stress fluctuation at the joint end that is the stress concentration point in the static case.

When a unit impulse stress wave is applied to the joint, the shear stress variation  $(\tau_{A \text{ imp}}(0, t))$  at the adhesive edge can be expressed as follows:

$$\tau_{A \text{ imp}}(0, t) = L^{-1}(H(0, s)) = \frac{G_A c}{Et_A} L^{-1} \left( \frac{4}{s + 3\sqrt{s^2 + 2c^2 k^2}} \right). \quad (15)$$

Here, a function  $(W(s))$  is defined as

$$W(s) \equiv \frac{4}{s + 3\sqrt{s^2 + a^2}} \wedge a = \sqrt{2}ck. \quad (16)$$

This function can be modified as

$$W(s) = \frac{4}{s} \sum_{n=0}^{\infty} \frac{(-1)^n}{3^{n+1}} \sum_{m=0}^{\infty} \frac{(-1)^m (n + 2m - 1)!!}{2^m \cdot m! \cdot (n - 1)!!} \left( \frac{\sqrt{2}ck}{s} \right)^{2m}. \quad (17)$$

233 The function  $(\Omega(\sqrt{2}ckt))$ , which is the inverse Laplace transform of  $(W(s))$ , can  
 234 be written as

$$\Omega(\xi) = \frac{4}{3} \sum_{m=0}^{\infty} \frac{(-1)^m}{2^m \cdot m!} \cdot \frac{\xi^{2m}}{(2m)!} \sum_{n=0}^{\infty} \left(-\frac{1}{3}\right)^n \frac{(n+2m-1)!!}{(n-1)!!}. \quad (18)$$

235 A function obtained by the inverse Laplace transform of the transfer function of a  
 236 dynamic system is equivalent to the impulse response of the system. Therefore, the  
 237 shear stress variation at the adhesive edge  $(\tau_{A \text{ imp}}(0, t))$  by a unit impulse stress wave  
 238 can be written as the following equation.

$$\begin{aligned} \tau_{A \text{ imp}}(0, t) &= L^{-1}(H(0, s)) = \frac{G_{AC}}{Et_A} L^{-1} \left( \frac{4}{s + 3\sqrt{s^2 + 2c^2k^2}} \right) \\ &= \frac{G_{AC}}{Et_A} \Omega(\sqrt{2}ckt). \end{aligned} \quad (19)$$

239 The indicial response  $(\tau_{A \text{ ind}}(0, t))$ , which is the response when a unit step stress  
 240 wave is applied to the joint, can be written as

$$\tau_{A \text{ ind}}(0, t) = \frac{G_{AC}}{Et_A} \int_0^t \Omega(\sqrt{2}ck\xi) d\xi = \sqrt{\frac{G_{AC}t_s}{2Et_A}} \int_0^{\sqrt{2}ckt} \Omega(\chi) d\chi. \quad (20)$$

241 The impulse response and the indicial response are shown in Fig. 5, where  $(\Omega())$  is  
 242 calculated approximately by the summation of terms in the series signified by the  
 243 symbols (m) and (n) up to 100.

**Fig. 5** Impulse and indicial response of shear stress at the edge of adhesive layer (Sato 2009)

The shear stress variation ( $\tau_{A \text{ val}}(0, t)$ ) at the adhesive edge caused by a given applied stress wave ( $\sigma_w(t)$ ) can be calculated by using the convolution integration of its impulse responses as follows:

$$\begin{aligned}\tau_{A \text{ val}}(0, t) &= \int_0^t \tau_{A \text{ imp}}(0, t - \xi) \cdot \sigma_w(\xi) d\xi \\ &= \frac{G_{AC}}{Et_A} \int_0^t \Omega(\sqrt{2}ck(t - \xi)) \cdot \sigma_w(\xi) d\xi.\end{aligned}\quad (21)$$

In addition, ( $\tau_{A \text{ val}}(0, t)$ ) can also be expressed by a convolution integral of its indicial response and applied stress wave as follows:

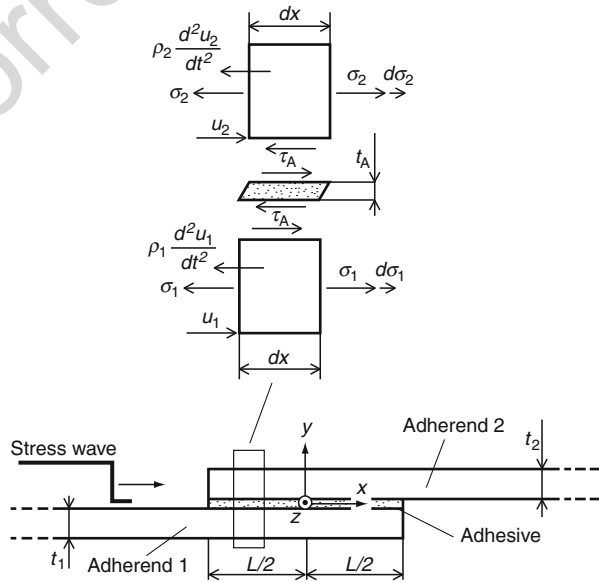

$$\tau_{A \text{ val}}(0, t) = \tau_{A \text{ ind}}(0, t) \sigma_w(0) + \int_0^t \tau_{A \text{ ind}}(0, t - \xi) \cdot \frac{d\sigma_w(\xi)}{d\xi} d\xi. \quad (22)$$

### 29.4.3 Single Lap Joints

Equation 10 can be also used to calculate the dynamic stress analysis of single lap joints. Unfortunately, boundary conditions for single lap joints are too difficult to be treated mathematically. Therefore, an example with a numerical solution is shown in this section.

The boundary conditions of a single lap joint shown in Fig. 6 can be written as:

**Fig. 6** Load balance in a single lap joint (Sato 2008)

$$\begin{aligned}
u_1|_{x=-\frac{L}{2}} &= -2 \int_0^t c_{s1} \frac{\sigma U(\lambda)}{E_1} d\lambda + \int_0^t c_{s1} \frac{\partial u_1(x, \lambda)}{\partial x} \bigg|_{x=-\frac{L}{2}} d\lambda, \frac{\partial u_2}{\partial x} \bigg|_{x=-\frac{L}{2}} = 0, \frac{\partial u_1}{\partial x} \bigg|_{x=\frac{L}{2}} = 0, \\
u_2|_{x=\frac{L}{2}} &= - \int_0^t c_{s2} \frac{\partial u_2(x, \lambda)}{\partial x} \bigg|_{x=\frac{L}{2}} d\lambda,
\end{aligned} \tag{23}$$

where ( $\sigma$ ) is the amplitude of stress wave, ( $U(t)$ ) is the unit step function, ( $c_{s1}$ ) and ( $c_{s2}$ ) are the longitudinal stress wave velocities of adherends 1 and 2, respectively, defined as ( $c_{s1} = \sqrt{E_1/\rho_1}$ ) and ( $c_{s2} = \sqrt{E_2/\rho_2}$ ).

Equations 10 can be transformed to discrete equations using the central difference for space and the backward difference for time shown as:

$$\begin{aligned}
&\frac{u_1(x_{n+1}, t_n)}{(\Delta x)^2} - \left( \frac{2}{(\Delta x)^2} + k_1 + \frac{c_{s1}}{(\Delta t)^2} \right) u_1(x_n, t_n) \\
&+ u_1(x_{n-1}, t_n)(\Delta x)^2 + k_1 u_2(x_n, t_n) = \frac{c_{s1}}{(\Delta t)^2} (-2u_1(x_n, t_{n-1}) + u_1(x_n, t_{n-2})) \\
&\frac{u_2(x_{n+1}, t_n)}{(\Delta x)^2} - \left( 2(\Delta x)^2 + k_2 + \frac{c_{s2}}{(\Delta t)^2} \right) u_2(x_n, t_n) \\
&+ u_2(x_{n-1}, t_n)(\Delta x)^2 + k_2 u_1(x_n, t_n) = \frac{c_{s2}}{(\Delta t)^2} (-2u_2(x_n, t_{n-1}) + u_2(x_n, t_{n-2}))
\end{aligned} \tag{24}$$

where ( $k_1 = G_A/(E_1 t_1 t_A)$ ) and ( $k_2 = G_A/(E_2 t_2 t_A)$ ). Stepwise time integration of Eq. 24 under the boundary condition shown in Eq. 23 gives displacement vectors ( $u_1$ ) and ( $u_2$ ) at each time step. Based on the results, distribution of shear stress ( $\tau_A$ ) can be calculated by the finite difference method.

Figure 7 shows a calculated result of shear stress distribution in the adhesive layer of a single lap joint subjected to a step load of 1 MPa in amplitude, using a MATLAB program (Sato 2008). Here, the single lap joint is 40 mm in lap length, 4 mm in thickness of the adherends, which are made of aluminum alloy having a tensile modulus of 72 GPa and the density of  $2.8 (\times) 10^3$  kg/m<sup>3</sup>. The thickness and the shear modulus of the adhesive layer are 0.1 mm and 1.0 GPa, respectively. It is shown in Fig. 7 that the stress near the load input side (Position =  $-L/2$ ) increases initially, and the stress at the opposite side (Position =  $L/2$ ) increases with a delay, which is due to the duration of stress wave propagation between the sides. At the load input side, there is stress oscillation, but it decays soon.

## 29.4.4 Finite Element Analysis

### Theoretical Background

The finite element method for solids is based on the principle of virtual work (Zienkiewicz 1971), and it is given by:

**Fig. 7** Shear stress distribution and variation along bondline of a single lap joint calculated based on the dynamic Volkersen's model (Sato 2008)

$$\int_V \sum_i \sum_j \sigma_{ij} \delta \epsilon_{ij} dV = \int_S \mathbf{q} \cdot \delta \mathbf{u} dS + \int_V \mathbf{b} \cdot \delta \mathbf{u} dV \quad (25)$$

where  $(\sigma_{ij})$  and  $(\delta \epsilon_{ij})$  indicate stress tensor and virtual variation of strain tensor, and  $(\mathbf{q})$ ,  $(\mathbf{b})$  and  $(\delta \mathbf{u})$  are surface force, body force applied to the solid and virtual displacement occurring in the solid, respectively. The subscripts (V) and (S) indicate total volume and total surface of the solid, respectively. Suffixes (i) and (j) denote the direction of (x), (y), and (z) axes. The principle of virtual work has the same meaning as the equilibrium equation which is one of the fundamental relations in solid mechanics. Note that the components of strain vector are not tensor strains, but engineering strains. Though stress and strain are tensor quantities, the vector notation is convenient to calculate virtual work. Equation 25 can be simplified by inner product of vector, and it is shown as follows:

$$\int_V \boldsymbol{\sigma} \cdot \delta \boldsymbol{\epsilon} dV = \int_S hf \mathbf{q} \cdot \delta \mathbf{u} dS + \int_V \mathbf{b} \cdot \delta \mathbf{u} dV. \quad (26)$$

A displacement vector  $(\mathbf{u})$  in a finite element is associated with the nodal displacement vector  $(hf\mathbf{a})$  of the element via the shape function matrix  $(hf\mathbf{N})$  of the element as follows:

$$\mathbf{u} = \mathbf{N}\mathbf{a}. \quad (27)$$

291 The strain vector ( $\boldsymbol{\epsilon}$ ) in the finite element is also associated with the nodal  
 292 displacement vector ( $\mathbf{a}$ ) via the strain–displacement relation matrix ( $\mathbf{B}$ ) of the  
 293 element as follows:

$$\boldsymbol{\epsilon} = \mathbf{B}\mathbf{a}. \quad (28)$$

294 Therefore, Eq. 26 can be approximated by the following:

$$\sum_V \boldsymbol{\sigma} \cdot \mathbf{B}\delta\mathbf{a}\Delta V = \sum_S \mathbf{q} \cdot \mathbf{N}\delta\mathbf{a}\Delta S + \sum_V \mathbf{b} \cdot \mathbf{N}\delta\mathbf{a}\Delta V. \quad (29)$$

295 Since Eq. 29 is an identical equation which is independent on ( $\delta\mathbf{a}$ ), the equation  
 296 can be modified as follows:

$$\sum_V \mathbf{B}^T \boldsymbol{\sigma} \Delta V = \sum_S \mathbf{N}^T \mathbf{q} \Delta S + \sum_V \mathbf{N}^T \mathbf{b} \Delta V. \quad (30)$$

297 When the constitutive relation of the solid is linear elastic, stress vector ( $\boldsymbol{\sigma}$ ) is  
 298 given by:

$$\boldsymbol{\sigma} = \mathbf{D}\boldsymbol{\epsilon} = \mathbf{D}\mathbf{B}\mathbf{a} \quad (31)$$

299 where ( $\mathbf{D}$ ) is local stiffness matrix. Equation 29 can be modified using matrix ( $\mathbf{D}$ ) and  
 300 is shown as follows:

$$\sum_V \mathbf{B}^T \mathbf{b}^f \mathbf{D} \mathbf{B} \mathbf{a} \Delta V = \sum_S \mathbf{b}^f \mathbf{N}^T \mathbf{b}^f \mathbf{q} \Delta S + \sum_V \mathbf{b}^f \mathbf{N}^T \mathbf{b}^f \mathbf{b} \Delta V. \quad (32)$$

301 The left term in Eq. 32 includes nodal displacement vector ( $\mathbf{a}$ ), and it can be  
 302 extracted from summation. Thus, the final form of the equation for the finite element  
 303 method is obtained:

$$\mathbf{K}\mathbf{a}' = \mathbf{F} + \mathbf{B} \quad (33)$$

304 where, ( $\mathbf{K} = \sum_V \mathbf{B}^T \mathbf{D} \mathbf{B} \Delta V$ ), ( $\mathbf{F} = \sum_S \mathbf{N}^T \mathbf{q} \Delta S$ ), ( $\mathbf{B} = \sum_V \mathbf{N}^T \mathbf{b} \Delta V$ ), and ( $\mathbf{a}'$ ) is the  
 305 total nodal displacement vector of whole the structure, and it is the sum of local  
 306 displacement vectors ( $\mathbf{a}$ ) defined in each element. Solving Eq. 33 gives ( $\mathbf{a}'$ ), and  
 307 then ( $\boldsymbol{\epsilon}$ ) is calculated using Eq. 28. The stress ( $\boldsymbol{\sigma}$ ) is obtained using Eq. 31.

308 For dynamic conditions, few modification of the static equation is necessary. That  
 309 can be done by adding the term of inertia force to the equation following  
 310 d'Alembert's principle. Equation 25 is modified to the following:

$$\int_V \sum_i \sum_j \sigma_{ij} \delta \epsilon_{ij} dV = \int_S \mathbf{q} \cdot \delta \mathbf{u} dS + \int_V \mathbf{b} \cdot \delta \mathbf{u} dV - \int_V \rho \ddot{\mathbf{u}}' \cdot \delta \mathbf{u} dV \quad (34)$$

311 where ( $\ddot{\mathbf{u}}'$ ) is acceleration vector. Therefore, Eq. 33 becomes:

$$\mathbf{K}\mathbf{a}' = \mathbf{F} + \mathbf{B} - \mathbf{M}\ddot{\mathbf{a}}' \quad (35)$$

where  $(\ddot{\mathbf{a}}')$  is total nodal acceleration vector of the structure, and  $(\mathbf{M} = \sum \rho \mathbf{N}^T \mathbf{N} \Delta V)$ . The symbol  $(\mathbf{M})$  is called the mass matrix.

For solving Eq. 35, explicit schemes for time integration are efficient and their use is increasing in many applications such as crash analysis of car bodies in the last two decades. The equation of explicit schemes is given by:

$$\ddot{\mathbf{a}}'_n = \mathbf{M}^{-1} (\mathbf{F}_n + \mathbf{B}_n - \mathbf{K}\mathbf{a}'_n). \quad (36)$$

To obtain  $(\mathbf{a}'_{n+1})$ , additional calculations have to be carried out using the central difference as follows:

$$\ddot{\mathbf{a}}'_{n+0.5} = \ddot{\mathbf{a}}'_{n-0.5} + \Delta t_n \ddot{\mathbf{a}}'_n \quad (37)$$

$$\mathbf{a}'_{n+1} = \mathbf{a}'_n + \Delta t_{n+0.5} \ddot{\mathbf{a}}'_{n+0.5'} \quad (38)$$

where  $(\Delta t_{n+0.5} - t_{n-0.5})$  and  $(\Delta t_n = \Delta t_{n+0.5} - t_{n-0.5})$ . As seen in Eq. 36, if a lumped weight matrix for  $(\mathbf{M})$  is used, inverse matrix calculation can be omitted. In addition, there is no need to store the entire matrix  $(\mathbf{K}^{-1})$  which includes many fill-ins or zeros after the forward elimination, and calculation of only  $(\mathbf{K}\mathbf{a}'_n)$  is a less memory consuming process. Because of such advantages, explicit schemes have recently become the only choice to treat huge-scale applications. As a matter of fact, crash analysis of whole car structures, which is one of the biggest calculation these days, can be completed using only a personal desk-top computer of high performance within few weeks. Many packages of explicit finite element analysis are commercially available now. The disadvantage of explicit scheme is the necessity of using a lumped matrix for  $(\mathbf{M})$ . Using a lumped matrix decreases the accuracy of results, and the use of high-order elements is also ineffective. Finer meshes are more suitable for explicit schemes than high-order elements.

### Examples of Dynamic Analysis for Adhesively Bonded Joints

Sawa et al. (1996) have conducted dynamic finite element analysis of adhesively bonded joints using an explicit solver: DYNA3D (Lawrence Livermore National Laboratory, Livermore, USA). The stress distribution and fluctuations of stresses in laminated plates subjected to perpendicular impacts were calculated, and it was found that a singular stress occurred at the edges of the interfaces and the stress increased with an increase of the ratio between the Young's moduli of the adherends and the adhesive. Higuchi et al. (2002a) conducted stress analysis of single lap joints subjected to impact bending moments and to impact tensile loads (Higuchi et al. 2002b). They found that the maximum principal stress in the joints increased as the Young's modulus of the adherends increased, although the phenomenon is opposite to static cases. They also investigated the influence of the Young's moduli of adherends on the stress distribution in a single lap joint

having different adherends (Sawa et al. 2003). Sawa et al. have also conducted several impact analyses of butt joints of hollow cylinders (Sawa et al. 2002) and verified the numerical results experimentally (Sawa et al. 2003). They also analyzed the case of impact bending moments applied to butt joints (Higuchi et al. 2003). The dynamic response of single lap joints subjected transverse impacts has been also studied by Yaidya et al. using LS-DYNA 3D (Vaidya et al. 2006).

## 29.5 Impact Strength Evaluation of Adhesively Bonded Joints

To predict the strength of adhesively bonded joints, strength criteria should be applied to the stress values obtained by analyses. Several types of strength criteria applicable to dynamic problems are explained below. In addition, an example of an actual application is also shown in that section.

### 29.5.1 Failure Criteria for Adhesively Bonded Joints

#### Stress–Strain Criteria

Stress–strain criteria are the most popular for strength evaluation of materials. They can be applied to strength predictions of adhesively bonded joints. If the stress or strain value at a point in a solid is greater than a particular threshold level, the solid is regarded to be broken. In the case of a linear elastic material, the stress–strain curve is perfectly linear, and the stress criterion is equivalent to the strain criterion. In contrast, stress criteria cannot be used for elastic perfect plastic materials because the proper threshold level of stress cannot be selected, and strain criteria are applied for this situation instead.

In a continuum, combined stress states are usual, and there are six components in each stress and strain. Strictly speaking, strength criteria should be functions of all the components. The simplest criterion for combined stress conditions are the maximum stress function shown in the following equation.

$$\max(\sigma_1, \sigma_2, \sigma_3) = \sigma_y, \quad (39)$$

where  $(\sigma_1)$ ,  $(\sigma_2)$ , and  $(\sigma_3)$  are principal stresses, and  $(\sigma_y)$  is the tensile strength of the material. This criterion can be used for brittle materials such as glass, ceramics, and hard plastics, including brittle epoxy adhesives.

If adhesives are ductile, strength criteria based on shear stress components are often used with analogies to metals. For example, the maximum shear stress criterion called the Tresca's criterion (Tresca 1869) or the maximum shear-strain energy criterion called the Mises' criterion (von Mises 1913) are well known, and they can be shown as follows:

(The maximum stress criterion)

$$\max\left(\left|\frac{\sigma_1 - \sigma_2}{2}\right|, \left|\frac{\sigma_2 - \sigma_3}{2}\right|, \left|\frac{\sigma_3 - \sigma_1}{2}\right|\right) = \tau_y \quad (40)$$

where  $(\tau_y)$  is the pure shear strength of the material.

(The maximum shear-strain energy criterion)

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 2\sigma_Y^2 \quad (41)$$

where  $(\sigma_1)$ ,  $(\sigma_2)$ , and  $(\sigma_3)$  are principal stresses, and  $(\sigma_Y)$  is the pure tensile strength of the material. It is well known that plastic behaviors of metals are independent of hydrostatic pressures, and only deviation components of stress can affect yielding. The maximum stress criterion and the maximum shear-strain energy criterion are function of only the deviation components. In reality, the plastic behavior of ductile adhesives is slightly different from those of metals due to the generation of micro cracks or craze. Therefore, hydrostatic pressure can affect the plastic behavior of adhesives, but the effect is not so significant.

Since the strain rate is very high when impact loading is applied, ductile adhesives can become brittle and have a higher strength. Thus, the change should be introduced to the strength criterion to predict the proper strength. Highly ductile adhesives show the tendency of increasing the maximum stress without the loss of plastic deformation, thus becoming very brittle. For brittle adhesives, the maximum stress criterion may be applied increasing the strength parameters with respect to strain rates based on the impact tests. Sato and Ikegami, however, showed that the maximum shear-strain energy criterion is more suitable than the maximum stress criterion even for brittle adhesives (Sato and Ikegami 1999). In this case, parameters for the criterion such as  $(\sigma_Y)$  increased two times in the impact condition of about  $10^{11}$ – $10^{13}$  Pa/s in stress rate (see Chap. 21, “Impact Tests”).

### Stress Singularity Criterion

The disadvantage of stress–strain criterion is the presence of very high stresses in the adhesive layer at the ends of joints, which are often higher than the strength of the adhesive in bulk. The phenomenon is called “stress singularity,” and this occurs when elastic materials are assumed for adhesives and adherends, and joints have sharp edges at the ends. The stresses at singularity points can be infinite in elastic analyses. Such an infinite stress is not real because materials have a finite strength. However, it is sure that very sharp stress concentration must occur near the singularity points. An option for overcoming the problem is considering stress relaxation due to the inelastic behavior of adhesive layers. The other method is strength prediction using stress singularity parameters (Hattori et al. 1988). However, research on stress singularity of adhesive joints in dynamic conditions has been very few so far. Thus, further intensive studies are required.

### Fracture Mechanics and Cohesive Zone Model

At the tip of a crack in a solid, very sharp stress concentration occurs as well as stress singularity points. Thus, stress or strain criteria cannot be applied to these cases, and

fracture mechanics is used instead. Since almost all joints have no crack initially, the methodology of fracture mechanics cannot be applied directly to them. In contrast, fracture mechanics has an advantage because it can predict crack propagation. This aspect is useful to predict not only the initial failure, but also the final fracture of joints. The fatigue life of joints can also be treated by this method.

When fracture mechanics is applied to joint strength prediction, the presence of initial cracks should be assumed, and the stress distribution near the crack tip is analyzed. Then, based on the stress distributions obtained by the analysis, stress intensity factors or energy release rates should be calculated, although this process is not simple and easy. Another way is the virtual crack extension method (VCEM), by which the energy release rate can be calculated with small efforts (Parks 1977). Since cracks tend to propagate along the interface between adhesive layers and adherends, it is easy to apply VCEM to these problems. Therefore, to predict the strength of adhesively bonded joints, energy release rates are more used than stress intensity factors.

Applying fracture mechanics to impact problems has other difficulties. Local finer meshes, which are often used near stress concentration points in static finite element methods, are not suitable for dynamic calculation because the step of time integral depends on the smallest mesh size in the analytical model, and total calculation time increases drastically even if only one small mesh is used. Therefore, finite element analysis for fracture mechanics, which needs finer meshes near the crack tips for calculating the stress intensity factors, consumes time and computer resources.

A novel method called cohesive zone model (CZM) has been introduced for the calculations of fracture mechanics. This model has high applicability to dynamic calculations. In the method, adhesive layers or interfaces are modeled with springs having a particular load–displacement relation called “traction-separation law,” and the fracture mechanical characteristics are described by the model. A rule of CZM is that the area surrounded by the traction-separation curve should be equal to the fracture toughness (critical energy release rate) of the joint. The shape of traction-separation law is arbitrary. Proper shape should be selected among several types such as bilinear or trapezoidal curves shown in Fig. 8, so that the predicted strength can agree with experimental results.

**Fig. 8** Types of traction-separation laws

The cohesive zone model has the advantage that initial crack and fine meshes are not necessary. In addition, CZM fits well explicit schemes. Thus, the method is suitable for dynamic analysis of adhesively bonded joints, and actual application has been started (see Sect. 6.1). The disadvantage of the model is the arbitrary selection of traction-separation law. Trial and error process is necessary to reach satisfactory results (see ► Chap. 25, “Numerical Approach: Finite Element Analysis” for more details on CZM).

## 29.6 Applications

Joint design considering impact loading is still rare in industries, but the number of cases has been gradually increasing over the last decade. Needs for impact analysis is recently increasing in several areas such as automotive and electronic industries. In addition, the progress of computers facilitates impact analyses. Small models can be analyzed with a desktop computer in these days. Several cases of joint design for impact loads are shown in the following sections.

### 29.6.1 Crash of Car Structures

Ordinary car structures comprised of steel panels, and they have been mainly joined by spot welding. Recently, a novel joining method called “weldbonding” has been applied to luxury cars. This is a combination method of spot welding and adhesive bonding to increase the torsional stiffness, fatigue life, and damping of the body. When a car built by “weldbonding” is crashed, the impact strength of joints bonded with the adhesive is very important because the joined steel panels should be largely deformed and absorb the kinetic energy. Early fracture of the joints leads to a smaller absorbed energy by the body. In addition, joint failure should be avoided in terms of product liability law. From these reasons, impact problems of adhesively bonded joints in car structures become important and are widely studied over the world.

Harris and Adams (1985) have examined the impact strength of lap-shear joints bonded with ductile adhesives. They also made open-ended cylinders of steel and aluminum alloy joined by spot welding and weldbonding with one of the ductile adhesives used for the lap-shear tests, and tested them under axial impact loading. The results indicated that the weldbonded joints had a small failure area and higher energy absorption than those joined only by spot welding.

Fay and Suthurst (1990) have been experimentally investigated the deformation and energy absorption of steel box beams joined by weldbonding. The results showed that the properties greatly depended on the configurations and spot intervals, although weldbonding is an effective method to absorb large kinetic energy. This research emphasized the necessity of a strength prediction method that can be applied to weldbonded joints. Recently, Belingardi et al. (2005) have investigated box-beams configurations suitable for impact loading. They prepared specimens of different configurations bonded with an adhesive and tested them using a drop-

weight testing machine. The integrity of specimens and their energy absorption highly depends on the configurations.

Nossek and Marzi (2009) have developed a CZM base method to predict the impact strength of adhesive joints for car structures. A trapezoidal traction-separation law was adopted. In this case, they expanded the CZM model from mode I condition to mode II and combined both stress conditions. In this study, the fracture toughness of adhesive joints was measured using tapered double cantilever beam (TDCB) specimens, and the strain-rate dependency of the adhesive was described by the Johnson–Cook model determined by impact tests of bulk adhesive. In addition, the impact test of a U-shape specimen bonded adhesively was carried out, as shown in Fig. 9 . The adhesively bonded part between the U-shape frame and the panel was partially separated in the experiment, and the deformation of the plate was well simulated by the finite element analysis based on their CZM method, as shown in Fig. 10 . Marzi et al. 2009a have measured the mode I fracture toughness of joints and investigated its stress-rate dependency using butt joint specimens and TDCB specimens. They presented a novel joint configuration called end-loaded shear joint (ELSJ) shown in Fig. 11 and measured mode

**Fig. 9** Experimental setup for impact test of U-shape specimen (Nossek and Marzi 2009)

**Fig. 10** U-shape specimen after impact test and simulated result (Nossek and Marzi 2009)

II fracture toughness (Marzi et al. 2009b). These fracture toughnesses were applied to their mix-mode CZM criterion shown in Fig. 12, interpolating between the mode I and II traction-separation laws in the mixed-mode conditions, and a precise prediction method for adhesively bonded car structures was established. Marzi et al. applied the mixed-mode CZM criterion to the crash simulation of a floor pan model for cars bonded adhesively (Marzi et al. 2009c), and compared the prediction to experimental results (Marzi et al. 2008) shown in Fig. 13. The deformation of the floor pan specimen could be appropriately simulated by the finite element analysis based on the CZM model.

## 29.7 Conclusions

Research on the impact strength of adhesively bonded joints has been recently carried out very often. As mentioned above, the reason is due to the increase of demand from industries and the progress of computer technologies. The tendency seems to continue

**Fig. 11** Configuration of end-loaded shear joint (Marzi et al. 2009b)

**Fig. 12** Traction-separation law for mixed-mode criterion (Marzi et al. 2009c)

**Fig. 13** Deformation of floor pan specimen and simulated results (Marzi et al. 2009c)

in the near future. For the purpose, the integration of finite element analyses and strength criteria becomes important. Approaches using cohesive zone models are very promising for actual applications such as car structures because the approaches are suitable for finite element analyses based on explicit schemes. In contrast, closed-form approaches are necessary from an academic point of view and should be also taken for the impact problem of adhesively bonded joints to understand the nature of joint mechanics. Unfortunately, only few studies on the closed-form analyses have conducted already, so that more research should be done in the future.

There are many remaining topics on impact phenomena of adhesively bonded joints, which should be solved in the future. One of rising and promising research areas is impact problems of composite materials bonded adhesively. This analysis will be more important due to the increase of composite aircrafts, although it has difficulties of high impact velocity and the anisotropy of composite materials. In contrast, lower impact velocity will also become more important. Dropping impact problem of mobile phones has been analyzed (Akiba et al. 2006), but joining parts in the structure was not modeled. Even in low impact velocities, the modeling of adhesive joints is still a big problem and a material for research.

**Abstract**

A study into the vibration characteristics of adhesively bonded single-lap joints has been carried out to investigate the effect of joint geometry and temperature variation on overall system damping. Concepts of vibration damping are introduced, and it is shown how to determine the damping of a system. The methodology of calculating the damping of even a simple bonded element in the form of a lap joint from material and geometric parameters is shown to be complex. The vibration damping of bonded joints has been extended into an experimental program using four different adhesives. These were AV119, a one-part epoxy; 9245, a structural bonding tape; 3532, a two-part polyurethane; and Hysol XEA 9359.3, a two-part structural adhesive. High-strength steel adherends were used to manufacture single-lap joints of varying overlap lengths. The specimens were vibrated flexurally and the damping values calculated using the free decay method. In this investigation, the damping of the adhesive layer dominates the damping of the specimens rather than the damping of the adherends. An optimum overlap ratio was found at approximately 0.25 in this study. The adhesives were tested under varying temperature conditions to illustrate the dominance of the glass transition temperature on the damping of the specimen.

It has been shown that the damping of a structure is unlikely to be improved by using adhesive bonding as a joining method.

**30.1 Introduction**

There are several reasons for controlling the vibration response of a structure. Health and safety may be adversely affected if people are subjected to excessive vibration and acoustic radiation from the vibrating surfaces. Also, equipment subject to external vibration may not perform as specified, or an item of vibrating equipment may cause adjacent machinery to perform in an unsatisfactory way. If resonant or near-resonant conditions occur in a structure, fatigue may cause cracks and eventual failure. The reduction of unwanted vibration, usually by damping, is an integral part of good engineering practice, and improvements are constantly sought. It is therefore important to understand the mechanics of damping and what factors, such as materials, temperature, frequency, and structural form, affect the amount of damping that might be expected from a structure.

Structural damping has become a very important property in many modern applications. For example, passenger comfort in vehicles often can be improved by increasing structural damping, while during the launch phase of a spacecraft, damping is essential to avoid damage to electronic components and other delicate parts. In the early days of the US space program, there were typically 90–100 failures on each satellite launched, 64% of these being due to vibration. By adding damping, resonant vibration amplitudes were halved, and there was a 20% overall performance improvement by reducing failure in electronic circuits. Current launch vehicles have to maintain satisfactory levels of damping. Where this is inherent within the structure, this is a bonus. Since most satellite

structures are made of composites which contain a lot of adhesive bonds, it is important to understand what levels of damping originate from what source. Structural damping is damping inherent to the bulk material from which the system is formed. It can also be present in joints or discontinuities and is caused by the presence of high local stresses. Damping can also be due to a variety of external effects, such as acoustic radiation. In its simplest case, vibration can be seen as steady state or freely decaying as shown in Fig. 1. If the excitation frequency coincides with a resonance frequency, then the amplitude of vibration can be magnified as shown in Fig. 2. If the damping is high, the transient decays more quickly, and the resonance amplitude is smaller. In practice, more complex situations exist in which there are several modes of vibration and hence several resonance frequencies. The excitation may not be sinusoidal as commonly depicted, but the same basic principles apply. The total energy dissipated by a structure in vibration is the sum of the energies lost in the structural material, the joints between members, and by radiation to the surroundings. Acoustic radiation may be high for thin

80 sheets of aluminum, composite, of honeycomb panels at ground level, but it will be  
81 much lower at high altitudes where the air pressure and density are low (Maheri et al.  
82 2008). Bolted and riveted joints usually allow some slip under load which results in  
83 energy loss by Coulomb friction. But if the joints are welded or brazed, there is no slip  
84 and so no energy dissipation. For many structures, it has been found necessary to add  
85 damping, often by using viscoelastic damping treatment in the form of a high damping  
86 polymer sandwiched between a thin metal film and the structure. Optimizing the  
87 parameters to achieve the optimum level of damping is quite complex, and the reader  
88 is referred to the books by Mead (1998) and Nashif et al. (1985) for a definitive  
89 explanation. From the successful use of these damping treatments, it might be expected  
90 that adhesively bonded joints, which are typically a sandwich of a polymeric layer  
91 between two metallic adherends, might also provide high damping.

92 The use of an adhesive with a high damping capacity can increase the damping of  
93 a bonded joint (Hildebrand and Vessonen 1997). However, high damping in an  
94 adhesive is usually associated with relatively low stiffness and strength. Hence, a  
95 balance between vibration amplitude and static strength and stiffness needs to be  
96 considered. An adhesive is a substance capable of usefully holding two surfaces  
97 together by surface attachment. An adhesive must have two fundamental character-  
98 istics. First, it must at some stage possess the properties of a fluid in order to  
99 thoroughly wet out the two surfaces to be bonded. Second, it must (when cured)  
100 have the properties of a solid to resist the tensile and shear forces that may be applied  
101 to separate the two surfaces. Adhesives are widely used in industry for joining  
102 surfaces as they offer a simple and strong form of joint, with better stress distribution  
103 and fatigue resistance than conventional joining methods (e.g., bolts, rivets, and  
104 welds). In motorcar body design and manufacture, there are considerable advantages  
105 in using adhesives in conjunction with weld bonding or sometimes in using adhe-  
106 sives alone. An adhesive offers a much reduced structural weight, with no loss of  
107 strength in terms of structural rigidity and impact performance, corrosion resistance,  
108 ease of joining dissimilar materials, and more flexibility in the design of body shape.

109 Adhesive bonding appears to provide attractive solutions for achieving joints  
110 with high damping. Tough structural adhesives (e.g., modified epoxies and poly-  
111 urethanes) have excellent strength and good damping properties due to their visco-  
112 elastic behavior. Multi-material structures usually contain a significant number of  
113 adhesively bonded joints, but the damping of such structures is not well understood.

114 Temperature is usually considered to be the single most important environmental  
115 factor affecting the properties of damping materials. The effect on damping is that three  
116 distinct regions can be observed. The first is the "glassy" region, where the material  
117 takes on extremely low values for the loss factor. The second region, the transition  
118 region, is characterized by having the loss factor achieve its maximum value. This  
119 temperature, at which the loss factor is a maximum, is known as the glass transition  
120 temperature ( $T_g$ ), which is the region where a polymer changes from a hard material to  
121 one that is softer or more rubbery. For cross-linked amorphous polymers such as resins,  
122 the cure or post-cure temperature governs  $T_g$ . Sometimes,  $T_g$  can be increased by  
123 raising the cure or post-cure temperature. Structural adhesives as a family of polymers  
124 are almost invariably used at temperatures below their  $T_g$  (Adams et al. 1997). The

**Fig. 3** Alpha (1), beta (2), and gamma (3) transitions in a typical polymer (From Adams and Singh 1995)

third region is the rubbery phase where the loss factor takes on a low value and varies slowly with temperature. Some low-stiffness rubbery adhesives are generally used above their  $T_g$ , which is typically about  $-50^\circ\text{C}$ . Most polymers have two or three regions in which the damping peaks, as shown schematically in Fig. 3.

The objective here is to understand the damping properties of joints bonded with various adhesives and to see how this might affect the overall damping of a structure. Some variables to be examined are the effects of adhesive properties, joint geometry, and temperature on the overall damping performance of a joint.

Finally, it must be remembered that damping is only of use in reducing vibration levels when the excitation frequency is at or near a resonance frequency.

## 30.2 Damping Definitions

Damping can be defined in a number of ways, and those commonly used are described as follows:

### 30.2.1 Specific Damping Capacity (SDC), $\psi$

This is defined as the ratio of energy dissipated per cycle ( $dW$ ) to the maximum elastic energy stored per cycle ( $W$ ), per unit volume as shown in Fig. 4. Thus,

$$\psi = dW/W \quad (1)$$

the ratio usually being expressed as a percentage. While the SDC is a material property, it also applies to structures in that  $dW$  represents the total energy dissipated, whether this is in the materials or by acoustic radiation, friction, etc., while  $W$  is the maximum vibratory stored energy in the structure. For this reason, it is a more useful and practical definition when assessing the overall damping of a structure (Lin et al. 1984).

**Fig. 4** Definition of specific damping capacity (SDC)

### 30.2.2 Logarithmic Decrement, $\Delta$

The logarithmic decrement is found by measuring the rate of decay of a freely vibrating system at its resonance frequency once the excitation force has been removed. It can be found from a trace of vibration amplitude against time and relates the ratio of the  $n$ th to the  $n + N$ th cycle amplitudes by

$$\Delta = \frac{1}{N} \ln \frac{u_n}{u_{n+N}} \quad (2)$$

where  $u_n$  is the amplitude of the  $n$ th cycle and  $u_{n+N}$  is the amplitude of the  $n + N$ th cycle. A complete description of this method can be found in the Appendix.

### 30.2.3 Damping Ratio, $\zeta$

The damping ratio is the ratio of the actual damping in the system to the critical damping level for that same system. The system is said to be critically damped when  $\zeta = 1$ , overdamped when  $\zeta > 1$ , and underdamped when  $\zeta < 1$ .

### 30.2.4 Loss Factor, $\eta$

The loss factor is frequently used for damping in elastomers. The higher the loss factor, the higher the damping.

The equation below summarizes the relationship between each of these damping measurements:

$$\eta = \frac{\psi}{2\pi} = \frac{dW}{2\pi W} = \frac{1}{Q} = 2\zeta = \frac{\Delta}{\pi} = \tan \delta \quad (3)$$

where

- $\eta$ , loss factor
- $\psi$ , specific damping capacity
- $dW/W$ , ratio of dissipated energy and stored energy
- $Q$ , Q-factor
- $\zeta$ , damping ratio
- $\Delta$ , logarithmic decrement
- $\tan \delta$ , tangent of the phase angle

## 30.3 Estimation of Damping Level in a Bonded Structure

In a vibrating structure, the overall damping level for a particular mode of vibration will depend on the materials, the geometric form, and the mode of vibration. For most structures, it is unlikely that a single damping value exists which applies to all modes of vibration especially if (anisotropic) composite materials are used (Lin et al. 1984; Maheri et al. 2008). It is convenient to use the specific damping capacity (SDC), which was defined above, as the unit of damping. For a structure, we have

$$\text{SDC} = \text{Total energy dissipated} / \text{Maximum energy stored}$$

during a cycle of oscillation. For a vibrating bonded assembly, the stored energy will mainly be in the general structure with a small amount being stored in the adhesive. The question is how to calculate the energy dissipated and how to relate this to the total energy stored.

Most bonded joints will be used to connect thin metallic or composite sheets or panels, and the predominant mode of vibration will be in bending. This is a complex situation to analyze. The energy dissipation,  $dW_{\text{adhesive}}$ , in the adhesive is equal to the maximum energy stored in the adhesive (the energy stored per unit volume integrated over the volume) multiplied by the SDC,  $\psi$ , of the adhesive. Thus,

$$dW_{\text{adhesive}} = \int_{\text{volume}} \psi \tau^2 / 2G \quad (4)$$

where  $\tau$  is the shear stress and  $G$  is the shear modulus of the adhesive. The shear stress distribution in the adhesive layer is far from simple (Adams et al. 1997), whether the joint is loaded in tensile lap shear or in bending. If the shear stress is constant across the adhesive width,  $b$ , and thickness,  $t$ , and if, as with most polymers, the SDC is not a function of cyclic stress, then, for an overlap length  $l$

$$dW_{\text{adhesive}} = \frac{\psi_{\text{adhesive}} bt}{2G} \int_0^l \tau^2 dx \quad (5)$$

It would appear that the energy dissipated should be proportional to the adhesive thickness, so that thick joints might be best for high damping. However, it is known from mechanics that as the thickness of the adhesive layer is increased, the maximum shear stresses are reduced. For joint strength, that might be an advantage, but since the damping depends on the square of the shear stress, a reduction in shear stress, even though it is over a bigger volume, may not produce a significant increase in joint damping. Volkersen's shear lag theory (Adams et al. 1997) says that the peak shear stress at the joint end is inversely proportional to the square root of the adhesive thickness,  $t$ . A fourfold increase in  $t$  will reduce  $\tau$  by a half, and, since the energy stored is proportional to  $\tau^2$ , the dimension change will be largely canceled out as far as the energy dissipation is concerned. Of course, the reduced shear stress will be extended further into the overlap, thus increasing the volume integral, but the point being made here is that increasing the volume of the joint may not produce a corresponding increase in energy dissipation. In bending, the position is similar in that the energy dissipation is primarily at the ends of the overlap. For both tension and bending, increasing the overlap length has no influence on the energy dissipated in most cases.

The higher the shear modulus of the adhesive, the higher and more concentrated at the edge are the stresses. It might therefore be expected that the damping of a high modulus adhesive will be low in the joint form. But remember that the energy stored per unit volume is proportional to  $\tau^2/2G$ , and if a high value of  $G$  gives a high value of  $\tau$ , then the energy dissipated is greater. Since the energy dissipated is directly proportional to the energy stored, we have a complex situation and one which is not amenable to accurate solution by simple algebra. However, it is possible to give an indication of the trends by making some simplifying assumptions, and this is done below for the two examples given.

In the first example, a single-lap joint is loaded in cyclic tension, and in the other, a similar joint is loaded in free-free flexure. But it must be remembered that these are very much simplified examples. Probably the only satisfactory approach is to use a numerical solution.

### 30.3.1 Single-Lap Joint in Tension

Using the dimensions given in Fig. 5, and applying a load  $P$ , then the stress  $\sigma$  in the adherends is given by

**Fig. 5** Lap joint dimensions. Overlap ratio is  $l/L$

$$\sigma = P/bd \quad (6)$$

Ignoring the overlap, the energy stored,  $W$ , is given by

$$W = \sigma^2 bd(L - l)/2E = (L - l)P^2/2Ebd \quad (7)$$

where  $E$  is Young's modulus of the adherends. In the adhesive layer, the shear stress,  $\tau$ , is usually not uniform (Adams et al. 1997), but we will in this case assume it to be the average shear stress given by

$$\tau = P/bl \quad (8)$$

and so the energy stored in the adhesive layer,  $W_{\text{adhesive}}$ , is

$$W_{\text{adhesive}} = P^2 t/2Gbl \quad (9)$$

The energy dissipated is then  $W_{\text{adhesive}} \psi_{\text{adhesive}}$ , and the overall SDC of the joint is the ratio of the energy dissipated in the adhesive layer to the total energy stored (from Eqs. 7 and 9, so

$$\psi_{\text{overall}} = \psi_{\text{adhesive}} t d E / l (L - l) G \quad (10)$$

Using some typical dimensions as  $t = 0.1$  mm,  $d = 1.6$  mm,  $l = 40$  mm, and  $L = 200$  mm and values of  $E = 200$  GPa (steel) and  $G = 40$  MPa (polyurethane), we have

$$\psi_{\text{overall}} = 0.125 \psi_{\text{adhesive}} \quad (11)$$

which indicates a lower level of damping than in the bulk polymeric adhesive.

### 30.3.2 Single-Lap Joint in Flexure

A vibrating beam is one of the simplest forms of system with distributed mass and stiffness. The motion is governed by a well-known (see Mead 1998; den Hartog 2008) fourth-order partial differential equation of the form

$$\frac{\partial^4 v}{\partial x^4} = \alpha^4 \frac{\partial^2 v}{\partial t^2}$$

(12)

where  $v$  is the displacement in the  $y$  (transverse) direction,  $x$  is the distance along the beam,  $t$  is time, and  $\alpha$  is a constant that incorporates the beam geometry and material properties.

The solution to this equation is of the form

$$v = (P \cos \alpha x + Q \sin \alpha x + R \cosh \alpha x + S \sinh \alpha x)(T \cos \omega t + U \sin \omega t)$$

(13)

where  $P$ ,  $Q$ ,  $R$ ,  $S$ ,  $T$ , and  $U$  are constants defined by the boundary conditions in space and time, and

$$\omega = 2\pi F$$

(14)

where  $F$  is the frequency of oscillation.

For a beam vibrating freely (no end restraints), the natural frequencies and the corresponding mode shapes can be defined. Figure 6 gives the mode shapes and the nodal positions for the first five modes of vibration. The constant  $B$  is used to define the natural frequency using the equation (den Hartog 2008)

**Fig. 6** Mode shapes of a free-free beam with the nodal positions and B values shown

$$F(Hz) = \frac{B}{\ell^2} \sqrt{\frac{12 \sum EI}{m}} \quad (15)$$

where  $\ell$  is the length of the beam,  $\sum EI$  is the sum of the products of Young's modulus and the second moment of area for each layer about the neutral axis, and  $m$  is the mass per unit length. For a uniform beam:

$$\sum EI = E \frac{bd^3}{12} \quad (16)$$

where  $b$  is the width of the beam and  $d$  is the thickness. Also, for a uniform beam,  $m = \rho bd$  where  $\rho$  is the density. Thus

$$F(Hz) = \frac{Bdc}{\ell^2} \quad (17)$$

where  $c = \sqrt{E/\rho}$  = velocity of extensional waves in the beam.

The mode shapes shown in Fig. 6 are for a uniform beam. A lap joint has a thicker portion in the middle part of the beam, so it is necessary to use more complex mode shapes than the ones shown. For this reason, the following analysis is restricted to mode 1, and even this has to be simplified. It will therefore be assumed that there is a constant bending moment,  $M$ , carried over the overlap portion and that this bending moment decreases linearly from the edge of the lap to the free end of the beam.

For such a system, the shear stress in the adhesive peaks at the overlap edges and decreases to zero at the midpoint. For a soft adhesive such as a polyurethane, the shear stress,  $\tau$  varies linearly with distance  $x$  along the joint in the form

$$\tau = \tau_0 - kx \quad (18)$$

where  $\tau_0$  is the shear stress at one end of the joint and  $k$  is a constant such that  $\tau = -\tau_0$  at the other end. For an epoxy adhesive or for long joints, the shear stress distribution is nonlinear and peaks at the ends of the joint, but this is too complex to solve except numerically. Integrating through the volume as before for this linearly varying shear stress gives

$$W_{\text{adhesive}} = btl(\tau_0)^2/6G \quad (19)$$

For the free length of the adherend vibrating in flexure, the energy stored per unit length is  $M^2/2 EI$ , where  $I$  is the second moment of area. Letting the bending moment vary as

$$M = kx \quad (20)$$

and noting that  $M = 0$  at  $x = 0$  and  $M = M_0$  at the joint end ( $x = (L - l)/2$ ), the energy stored in bending in the adherends can be estimated to be

$$W_{\text{adherends}} = M_0^2(L - l)/6EI \quad (21)$$

Numerical analysis using an in-house program gives that for  $M_0 = 4 \text{ Nm}$ , the shear stress at the overlap ends,  $\tau_0$  is about 4 MPa. Inserting these values into the equations for energy stored gives

$$\psi_{\text{overall}} = 0.016\psi_{\text{adhesive}} \quad (22)$$

It can therefore be seen that the actual damping of the lap joint in bending is only about 1.6% of the damping of the polymeric adhesive for the parameters given above. Because of the interactions between the various parameters, this calculation should be regarded as giving an indication and cannot be extrapolated to other situations.

The above attempts at calculating the damping of adhesively bonded lap joints may look complex. Others have attempted the same but using even more complex analysis. The reader is referred to Mead (1998), He and Rao (1992a, b), and Saito and Tani (1984). The problem with these analyses is that they are far too difficult to use in most practical situations. Saito and Tani did, however, predict that there is an optimum overlap ratio (OR) of 0.2 for maximum damping.

## 30.4 Experimental Evidence of Damping in Joints

Because there is very little reliable data on damping in adhesively bonded lap joints, it has been necessary to use previously unpublished data from an in-house program at the University of Bristol by the author and his students.

### 30.4.1 Materials Used

Four different adhesives were tested, details of which can be found in Table 1. The adhesives were AV119, a one-part epoxy manufactured by Hexcel; 9245, a structural bonding tape (SBT) manufactured by 3M; 3532, a two-part polyurethane also manufactured by 3M; and Hysol XEA 9359.3, which is a two-component structural adhesive that exhibits high peel and high tensile lap shear strength.

In order to investigate the contribution of the adhesive damping in the specimen, a high-strength low-damping steel was used for the metallic parts of the lap joints (Adams 1972a, b).

### 30.4.2 Joint Manufacture

A simple lap joint consists of two sheets joined together with an overlap and is a very common joint design in industry. The joints were manufactured using an alignment jig that ensured a total joint length which could be manufactured of 200 mm with a

t.1

307 width of 25 mm. The total length of the specimens was kept constant, but the overlap
308 was varied by using different adherend lengths. A typical joint is shown in Fig. 5.

309 To ensure a good bond, careful procedures were followed for preparation of the
310 jig and bonding surfaces. The bonding surface of the adherend was first grit-blasted
311 before thorough cleaning with acetone. Both sides of the specimen were grit-blasted
312 to avoid bending of the adherends by releasing or introducing residual stresses. The
313 jig and spacers were also cleaned with acetone before spraying with a release agent.
314 This prevented problems with clamping following the cure process. Next, adhesives
315 were prepared and applied to the bonding surface as evenly as possible. The joints
316 were then cured under pressure in a hot press according to the manufacturer’s
317 specification. Once fully cured, the joints were cooled slowly to room temperature.

318
**30.4.3 Vibration Test Apparatus**

319 When measuring damping, it is important to ensure that it is only the damping of the
320 system under investigation (in this case a lap joint) that is measured and that other
321 sources of damping are eliminated as far as possible. To some extent, this is a matter of
322 judgment, but there are some obvious principles to follow. In particular, it is necessary
323 to eliminate extraneous sources of damping. Many authors use cantilevered speci-
324 mens that have unwanted damping in the clamp by micro-slippage. Others use
325 accelerometers to measure the motion; unfortunately, accelerometers deliver their
326 signals via leads that cause damping. It is essential to prove the apparatus by showing
327 that its inherent damping is an order of magnitude less than the specimen damping.
328 This is best done by testing a low-damping material such as a high-strength aluminum
329 alloy. One of the authors (RDA) has had a lot of experience in measuring damping in a
330 wide variety of materials and has designed suitable apparatus according to the task in

hand (see, e.g., Adams and Percival 1969; Adams and Fox 1972; Adams and Bacon 1973; Adams and Lloyd 1975; Guild and Adams 1981).

For lap joints, it is best to use flexural (bending) vibration as this is the most likely form of vibration such joints will be subject to. In the investigation reported here, a free-free beam method was used to study the damping behavior. To measure the damping properties of a material, it is necessary to vibrate the specimen at a known frequency and a known resonant mode of vibration. The apparatus uses permanent magnets attached to each end of the specimen and placed within the fields of flat coils. This apparatus is a modification by Adams and Singh (1995) of the Guild and Adams (1981) apparatus. A signal generator provided an output that was passed through a power amplifier to give an alternating current to one coil, exciting the beam into vibration. The motion of the second coil induces an output voltage proportional to its velocity. The damping of the system was calculated by the “free decay” method (described in the Appendix).

#### 30.4.4 Temperature Testing of Joints

The damping properties of some of the beams were measured within the temperature range 20–100 °C. Heating was undertaken in an oven with the heating rate kept constant and slow to ensure that, as far as practicable, the entire specimen was at the same temperature. Faster rates of heating would cause a temperature gradient to exist across the adhesive layer, producing unreliable data. At temperatures above the glass transition temperature of the adhesives, lap joints become unstable in bending, particularly for short overlaps.

#### 30.4.5 Results and Discussion

The SDC values of the adhesives studied, determined by both the free decay method and bandwidth at 20 °C, are shown in Fig. 7. For joints of the same overlap ratio (OR), defined as the ratio of the adhesive bond length to the total length of the joint (0.125), the 9245 and 3532 adhesives provide considerably (about 20 times) higher damping than the structural epoxy AV119. Even so, the epoxy adhesive increases the damping by about five times over that of the hard steel adherends alone. Similar epoxies give an SDC of about 10%, so the reduction factor is about 0.05. Measurements of the damping of the 9245 material give an SDC of about 300% (Kadioglu 2000). For the 9245 lap joints, the reduction factor is therefore about 0.03, which is of the same order as that for the epoxy adhesive.

However, Fig. 7 gives a simplistic and possibly misleading picture, and it will be shown below that changing the OR or the temperature can significantly alter this balance.

**Fig. 7** Specific damping capacity values for 25 mm overlap joints (OR is 0.125)

**Effect of Overlap Ratio**

The effect of OR on the damping capacity of various adhesively bonded joints is shown in Figs. 8 and 9. In the work reported here, the OR was varied from 0.1 to 1. A sandwich beam is one in which the overlap covers the entire length of the specimen, so the OR is 1. Compared to the damping capacity of a single gauge steel beam, it is reasonable to assume that the adhesive dominates the damping characteristics of a lap joint. It might therefore be expected that the optimum OR would be that of a sandwich beam ( $OR = 1$ ), as this type of joint contains the largest volume of adhesive. However this is not the case as can be seen in Figs. 8 and 9. It is clear there is an optimum OR of about 0.25 for the first mode of vibration.

Park (1996) experimentally concluded that the damping is maximized if a viscoelastic layer is located at the region of maximum displacement. All the tests investigated here were for the first mode of vibration. However, the region of maximum displacement is located at the ends of the specimen for a lap joint in flexural vibration. Peel forces are created by the offset of the loading across the overlap region. It would therefore appear a sensible conclusion that having these shear and peel stresses nearer the center of the beam can increase the damping capacity. It is clear that a balance exists between the damping effect provided by the volume of adhesive and the damping effect of the position of the shear and peel stresses. Note that the areas of greatest energy dissipation are at the edges of the adhesive bond, where local shear and peel stresses are a maximum for lap joints in the first mode of vibration. The results of this study show that an optimum OR is

**Fig. 8** Variation of SDC with OR for 3532 and 9245 adhesives

**Fig. 9** Variation of SDC with OR for AV119 joints

present at around 0.25. Saito and Tani (1984) showed theoretically that an optimum OR of about 0.2 exists for the first mode of vibration and that there should be an increase in natural frequency with OR. Their predictions are confirmed by the results shown in Fig. 9, but Park's prediction is contradicted.

**Fig. 10** Variation of frequency (Hz) with OR for AV119 (series 1) and 9245 (series 2) single-lap joints in their first free-free mode of flexural vibration

Tests also showed an increase in natural frequency with OR as is demonstrated in Fig. 10. In vibrating systems, the resonant frequency is proportional to the square root of the ratio of the stiffness to the mass. Although a longer overlap increases the mass in proportion to the doubled thickness of the overlap, the bending stiffness of the overlap increases as the cube of this doubled thickness. Low-stiffness adhesives such as 9245 can shear in the adhesive thickness so these do not get the full (cubed) bending stiffness. The stiffer epoxy adhesive therefore shows a slightly stronger increase in frequency with OR, but the differences are small.

**Effect of Temperature**

Polymers are very susceptible to temperatures that leave metallic elements relatively unaffected. The reason for this is that the microstructural properties of polymeric materials result not from atomic interactions, as in metals, but from molecular interactions.

The results for AV119 and Hysol in the temperature range 20–90 °C are shown in Fig. 11. From the manufacturer’s data, AV119 is expected to have a Tg of around 120 °C, and the results demonstrate a smooth curve through the transition region with an expected peak around 120 °C. The other structural adhesive, Hysol, indicates the existence of a Tg at around 60 °C from the trend curve. Manufacturer’s data suggests a Tg of 85 °C.

It is important to note that structural adhesives as a family of polymers are usually used at temperatures below their Tg (Adams et al. 1997), except the rubbery

**Fig. 11** Variation of damping with temperature for two epoxy adhesives. Series 1 is AV119 and series 2 is Hysol 9359.3

adhesives such as 3532. It is unlikely, therefore, that temperature can be used as a device to enhance damping for structural adhesives.

**Effect of Bondline Thickness**

Joints made using 3532 and AV119 both exhibited an increase in SDC with increase in glue line thickness. This trend is illustrated in Figs. 12 and 13. The trend is clearly more significant in the case of the 3532 joints, where quadrupling the glue line thickness leads to a doubling of measured SDC. For AV119 joints, only a small increase is observed. This is not unexpected, as it has already been established that the use of a stiff adhesive such as AV119 does not significantly increase the overall damping of the system. Therefore the act of increasing the amount of an adhesive that has negligible damping effect will itself also have a negligible effect.

Furthermore, the fact that increasing the glue line thickness of the AV119 by almost a factor of 10 results in only a negligible damping increase suggests that joint geometry is not the dominant factor in determining the effect of glue line thickness on damping. If it were, then we would expect similar rates of damping increase with joint thickness regardless of adhesive used. Instead it is the consequent increase in adhesive material present that plays the dominant role, and thus when an adhesive of low shear modulus is used, the observed damping increase is large, whereas when a stiff epoxy is used, there is very little effect.

**Fig. 12** Variation of SDC (%) with bondline thickness (mm) for AV119 epoxy adhesive

**Fig. 13** Variation of SDC (%) with bondline thickness (mm) for 3532 polyurethane adhesive

### 30.5 Perspective

Figure 14 shows how the damping of a wide range of composites and structural metals varies with cyclic stress. It can be seen that composites fall in the range 0.5–12% SDC which is toward the higher end of the range of structural metals.

**Fig. 14** SDC versus cyclic stress for a wide range of materials

The results for lap joints, made using low-damping steel substrates, are in the same range as structural composites. The structural epoxy AV119 is at the bottom of this range, and it is only the rubbery adhesives that show any significant damping. The overall contribution of the adhesively bonded joints to damping in a structure is therefore expected to be small or negligible and claims that

**Fig. 15** Variation of damping with amplitude for a variety of joining methods for a composite beam in flexural vibration. The control sample was brazed

bonded structures can provide high damping should be taken with a large grain of salt. The essential point is that the energy dissipated in the adhesive is in a very small volume, whereas the energy stored in the structure is very much higher, so the overall damping is small.

Figure 15 shows some results from Brearley et al. (2005) for a bonded beam structure which was vibrated in free-free flexure. The beam was made of two equal U-shaped sections joined by rivets, bolts, an adhesive, and by brazing. It is clear that the bonded beam had a damping level only just above that of the brazed beam, and it was much less than the beams which could rely on friction at their joints.

### 30.6 Conclusions

The general concept of vibration damping in vibrating structures and how it can be used to limit vibration amplitudes has been discussed. The various damping parameters have been defined, and their relationship is given. Equations that can be used to measure damping in steady-state vibration or under free decay have been presented.

Simple equations for calculating the damping of a lap joint in tension and bending have been developed, and it was predicted that the damping of the whole specimen would be much lower than that of the adhesive alone.

As there is very little experimental data available in the literature, the damping of a variety of adhesively bonded single-lap joints has been measured and presented by the authors. From the results collected, the following conclusions can be made:

1. An optimum OR of around 0.25 exists for adhesively bonded single-lap joints in flexural vibration.
2. Damping from adhesives in vibrating structures is small and much less than the adhesive alone. It should not be expected that adhesive bonding can be used to enhance the damping of a structure.

## Appendix

### Damping Measurement by the Free Decay Method

This is a relatively simple method of measuring the damping of a freely vibrating system. The logarithmic decrement (log dec.),  $\Delta$ , is measured from an amplitude-time graph and is based on measuring the rate of decay of the free vibrations. This method is only suitable for measuring low damping and free vibration.

During the experiment, readings are recorded by measuring the time taken for the amplitude of the waveform to decrease from  $A_1$  to  $A_2$  (Fig. 16).

The relationship between log dec. and the damping ratio can be found by consideration of the equation for damped oscillation:

$$x = Ae^{-\zeta\omega t} \sin(\omega_d t + \theta)$$

$$A_1 = Ae^{-\zeta\omega t} \text{ and } A_2 = Ae^{-\zeta\omega(t+\tau_d)}$$

The log dec. is defined by

**Fig. 16** Variation of amplitude with time for a damped system

$$\Delta = \ln \frac{A_1}{A_2}$$

$$\Delta = \ln \frac{Ae^{-\zeta\omega t}}{Ae^{-\zeta\omega(t+\tau_d)}}$$

$$\Delta = \ln(e^{-\zeta\omega t + \zeta\omega(t+\tau_d)}) = \zeta\omega\tau_d$$

Noting that  $\tau_d = \frac{2\pi}{\omega_d} = \frac{2\pi}{\omega\sqrt{1-\zeta^2}}$

Therefore  $\Delta = \frac{2\pi\omega\zeta}{\omega\sqrt{1-\zeta^2}}$

And so if the damping ratio is small,  $\zeta \rightarrow 0$  and so

$$\Delta = 2\pi\zeta = \ln\left(\frac{A_1}{A_2}\right)$$

A more accurate result can be obtained by considering the decay over a number of peaks. The log dec. is then

$$\Delta = \frac{1}{N} \ln\left(\frac{A_1}{A_{N+1}}\right)$$

where  $N$  is the number of peaks calculated using the formula  $ft = N$ , where  $f$  is the frequency of oscillation, and  $t$  is the time taken for the amplitude to decay from  $A_1$  to  $A_2$ .

The first edition of *Handbook of Adhesion Technology* has been very well accepted by the adhesion community with over 25,000 downloads per year. This was the main motivation for the preparation of this 2nd edition. Also, there has been a general increase of the scientific and industrial community in this technology, which justifies an update. There are more papers published every year, there are new journals related to the field, there are more national and international conferences, and there are more applications. A revolution is currently taking place in the transport industry where fuel is being replaced by electric power. This change means that lighter structures need to be manufactured with the use of light materials and more efficient joining methods such as adhesive bonding. But, the use of adhesive bonding is not limited to the transport industry, and there are several other applications described in this handbook such as the use of adhesives in medicine.

This 2nd edition of *Handbook of Adhesion Technology* is a complete revision of the 1st edition with an update of the methods that have been investigated recently, which are now fully accepted by the adhesion community. Themes that are now included in more detail include, for example, hybrid adhesives used for automotive applications, ecofriendly surface treatments, damage mechanics, joint durability prediction, functionally graded joints, adhesive selection for space applications, and, lastly, trends in bioadhesion. There is also a new chapter related to the application of adhesives in the oil industry. Besides these content changes, there has been a complete revision of all chapters in terms of text, figures, tables, and references for a more didactic character of this reference book.

The editors would like to thank the authors for their patience with the preparation of this handbook. Finally, the editors especially thank Dr. Christoph Baumann, Ms. Tina Shelton, and Ms. Monika Garg, Springer editors, who helped enormously toward the success of this handbook.

Uncorrected Proof

Adhesives have been used for thousands of years, but until 100 years ago, the vast majority was from natural products such as bones, skins, fish, milk, and plants. Since about 1900, adhesives based on synthetic polymers have been introduced, and today, there are many industrial uses of adhesives and sealants. It is difficult to imagine a product—in the home, in industry, in transportation, or anywhere else for that matter—that does not use adhesives or sealants in some manner.

Adhesion technology is nowadays a common approach to many joining situations. There are many books and several international journals dealing with this subject. However, when the end-user needs to apply this technology, he does not have the time or the resources to thoroughly study the various technologies related to adhesives and sealants. It is not practical to go through volumes of text and product information looking for the specific methods or processes to apply. However, such information should be close-by if the need arises. The *Handbook of Adhesion Technology* is intended to fill a gap between the necessarily simplified treatment of the student textbook and the full and thorough treatment of the research monograph and review article. The subject is treated very comprehensively and with the most up to date information so that the end-user has in a single book a proper guidance and fundamental knowledge required for many adhesive bonding or sealing applications.

The *Handbook of Adhesion Technology* is intended to be a book of reference in the field of adhesion. Essential information is provided for all those concerned with the adhesion phenomenon. Adhesion is a phenomenon of interest in diverse scientific disciplines and of importance in a wide range of technologies. Therefore, this handbook includes the background science (physics, chemistry, and materials science), engineering aspects of adhesion, and industry specific applications. It is arranged in a user-friendly format with ten main sections: theory of adhesion, surface treatments, adhesive and sealant materials, testing of adhesive properties, joint design, durability, manufacture, quality control, applications, and emerging areas. The sections contain each about five chapters written by internationally renowned authors who are authorities in their fields.

This Handbook is intended to be a reference for people needing a quick, but authoritative, description of topics in the field of adhesion and the use of adhesives and sealants. It is intended for scientists and engineers of many different backgrounds who need to have an understanding of various aspects of adhesion

technology. These will include those working in research or design, as well as others involved with marketing services. It is expected to be a valuable resource for both undergraduate and research students.

The editors would like to thank the authors for their patience with the preparation of this Handbook. Finally, the editors especially thank Christoph Baumann and Tina Shelton, Springer editors, who helped enormously toward the success of this Handbook.

## About the Editors

**Lucas F. M. da Silva** is currently Associate Professor with Aggregation at the Department of Mechanical Engineering of the Faculty of Engineering of the University of Porto and Director of the Integrated Master in Mechanical Engineering. He obtained his Ph.D. in bonding of composites from the University of Bristol (UK) in 2004. He leads the Adhesives Group, composed of post-docs, Ph.D. students, and M.Sc. students. He has published 206 ISI papers (174 as author and 32 as editor) and 23 books (9 as author and 14 as editor) mainly on adhesive joint mechanics. His papers were cited 4690 times and correspond to an h-index of 37 (SCOPUS, 06/02/2018).

One of his papers obtained the SAGE Best Paper Award 2010 and Donald Julius Groen Prize 2010 (both awards given by the Institution of Mechanical Engineers). He received in 2013 and 2018 the Award of Scientific Excellence by the Faculty of Engineering of the University of Porto.

He is editor-in-chief of *The Journal of Adhesion*, *Proceedings of the Institution of Mechanical Engineers, Part L: Journal of Materials: Design and Applications*, and *University of Porto Journal of Engineering*. He is also co-editor of two Springer book series (*Advanced Structured Materials* and *Springer Briefs in Engineering: Computational Mechanics*). He is member of the editorial board of *International Journal of Adhesion and Adhesives* and *Journal of Adhesion Science and Technology*. He is reviewer of 60 ISI journals.

He organizes international conferences on adhesive bonding (*Structural Adhesive Bonding* every odd year and *Industrial Applications of Adhesive Bonding* every even year) and materials (*Materials Design and*

Applications every even year), and founded the Portuguese Adhesion Society that belongs to European Adhesion Societies Group (EURADH).

He has seven pending patents. He developed a software for designing adhesive joints available online (*jointdesigner*). He is consultant of several international companies (e.g., Alstom, Nagase Chemtex, John Deere).

**Andreas Öchsner** is Full Professor for lightweight design and structural simulation at the Esslingen University of Applied Sciences, Germany. Having obtained a Diploma Degree (Dipl.-Ing.) in Aeronautical Engineering at the University of Stuttgart (1997), Germany, he spent the time from 1997 to 2003 at the University of Erlangen-Nuremberg as a research and teaching assistant to obtain his Doctor of Engineering Sciences (Dr.-Ing.). From 2003 to 2006, he worked as Assistant Professor in the Department of Mechanical Engineering and Head of the Cellular Metals Group affiliated with the University of Aveiro, Portugal. He spent 7 years (2007–2013) as a Full Professor at the Department of Applied Mechanics, Technical University of Malaysia, where he was also Head of the Advanced Materials and Structure Lab. From 2014 to 2017, he was a Full Professor at the School of Engineering, Griffith University, Australia, and Leader of the Mechanical Engineering Program (Head of Discipline and Program Director). His research interests are related to experimental and computational mechanics, cellular metals and thin structures and interphases. He has published over 450 scientific publications, comprising 13 research monographs, 23 book chapters, and four teaching books on finite element methods. He obtained more than 3000 citations in Google Scholar. He is the general Chairman of 12 international conferences on computational and experimental engineering (ACE-X series) and 14 international conferences in the area of heat and mass transfer (DSL series). His editorial work comprises posts as editor-in-chief of the international journal *Continuum Mechanics and Thermodynamics* (Springer), editor-in-chief of the Springer book series on Advanced Structured Materials, and editor of *SpringerBriefs in Applied Sciences and Technology: Computational Mechanics*.

His research activities were recognized in 2010 by the award of a higher doctorate degree (D.Sc.) by the University of Newcastle, Australia.

**Robert D. Adams** got his first degree, in Mechanical Engineering, from Imperial College, London, in 1962, and his Ph.D. from Cambridge University in 1967 and an Sc.D. in 2017. He was awarded a D.Sc. (Eng) from London University in 1986. Most of his academic career (1967–2005) was at Bristol University where he was made Full Professor in 1986. He was Head of the Department of Mechanical Engineering from 1994 to 1998 and Graduate Dean from 1998 to 2004. In 1991, he was awarded the Visiting Foreign Franqui Chair and Medal at the Free University of Brussels (VUB). He is now an Emeritus Professor of Applied Mechanics at the University of Bristol and a Visiting Professor at the Universities of Oxford and Oxford Brookes. He has published and edited several books and published about 200 papers in international refereed journals.

In 2011, he was awarded the R.L. Patrick Fellowship of the US Adhesion Society. He is active in organizing conferences and publishing and was a founder member of EURADH and WCARP, the main European and World series on Adhesion. He has been joint editor-in-chief of the *International Journal of Adhesion and Adhesives* since 1999. His main research area is on adhesively bonded joints, and he pioneered the application of finite element analysis for determining the stresses, strains, and strength of such joints. In addition to his adhesives research, he has also worked extensively on vibration properties in composites and developed low-velocity impact tests for nondestructively testing composites and sandwich structures.

adhesive. There appears, however, to be a critical relative humidity, and only if this is exceeded are joints significantly weakened; evidence is that this is about 65%. The most harmful effect of water is potentially at the interface between the adhesive and adherend; however, surface treatment of metallic adherends can much improve water durability. Accelerated aging using elevated temperatures and humidities can provide information on the environmental resistance of different systems but does not easily correlate to aging in natural conditions. The entry of water into the adhesive layer can conform to the simple Fickian model, which just depends on two parameters (diffusion coefficient and solubility coefficient), but in some cases it is non-Fickian. Current state-of-the-art environmental degradation modeling of bonded joints involves multi-physics finite element analysis combined with progressive damage modeling. Essentially, this involves three main steps. The first step is modeling moisture transport through the joint in order to determine the moisture concentration distribution in the joint as a function of time. The second step involves evaluation of the transient mechanical-hygrothermal stress-strain state resulting from the combined effects of hygrothermal effects and applied loads. The final step involves incorporation of damage processes in order to model the progressive failure of the joint and hence enable the residual strength or lifetime of a joint to be predicted.

---

### 31.1 Introduction

Water, either as liquid or vapor, attacks all adhesive joints, and this is a major problem which limits the use of adhesives. Water is a problem because of its ubiquity and its high polarity. Water enters adhesives and alters their properties, but a potentially greater problem is attack by water on the adhesive interface. There are two main challenges in addressing the problems caused by the interactions between water and adhesive joints. The first is to reduce the deleterious effects of moisture on the joints, and the second is to develop an accurate method of predicting the effects of environment on the long-term in-service performance of joints. Both of these challenges have been the subject of extensive research, resulting in major advances in recent years, although there is still scope for further improvements. With structural adhesive joints to metals, it is now well established that loss of joint strength can be minimized by selection of a suitable pretreatment. It has recently been demonstrated that multi-physics finite element modeling combined with a suitable progressive failure criterion is an effective and powerful method of predicting the effects of environmental aging on bonded joints.

This chapter first discusses the effect that absorbed water has on the strength of adhesively bonded joints. The influence of adherend surface treatment, applied stress, and adhesive type on the environmental degradation of bonded joints is demonstrated. Methods of modeling the environmental degradation of adhesively bonded joints using coupled hygro-mechanical finite element (FE) analysis are then described.

**31.2 Behavior of Structural Joints to Metals in Wet Surroundings**

**31.2.1 Effect of Humidity**

There are many cases in the literature of adhesive joints with metallic adherends and rigid adhesives being weakened by exposure to wet surroundings, and a common feature is the shape of the plot of joint strength against time. Joint strength falls most rapidly at the beginning and eventually slows down to a very low or zero rate. Although the shapes of curves are similar, there are variations in the initial rates of strength loss and in the fraction of strength which is lost.

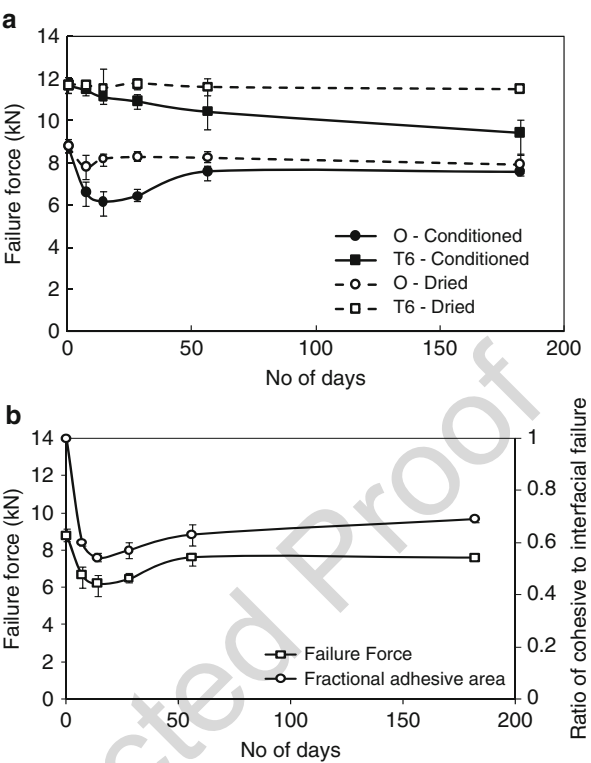

Experiments by Brewis et al. (1980a, b, c, 1981, 1987) exposed joints with aluminum adherends and a range of structural adhesives at 50 °C and 100% relative humidity (r.h.), and control specimens were either stored in the laboratory or at 50 °C and 50% r.h. The patterns which emerged are fairly typical, and they are illustrated in Fig. 1. It can be seen that on exposure to air at 100% r.h. and 50 °C, joint strengths initially fall, typically by 40–60%, but then tend to level out. In contrast little or no weakening is seen when joints are aged at 50% r.h. and 50 °C.

When joints exposed at 100% r.h. for 5,000 h are then stored for a further 5,000 h at 50% r.h., a significant part of the strength is recovered. This is shown by the triangular point and dotted line in Fig. 1. This indicates that the mechanism responsible for the decrease in joint strength at high humidity is at least partly reversible, which is demonstrated even more clearly in Fig. 2a. This figure shows the results from testing single-lap joints made from 7,075 aluminum alloy which had been

**Fig. 1** Strength of joints in aluminum alloy bonded with a nitrile-phenolic adhesive on exposure to wet air at 50 °C. ○ 50% r.h. □ 100%r.h. Δ Joints which have been exposed at 100%r.h. for 5000 h and then stored for a further 5000 h at 50% r.h (After Comyn et al. (1987). Crown copyright)

**Fig. 2** Effect of conditioning in deionized water at 50 °C on 7075 aluminum alloy/FM73 adhesive (Cytec Engineered Materials Ltd.) single lap joints. **(a)** Comparison of annealed (O) and heat treated (T3) adherends and recovery on drying. **(b)** Correlation between failure force and percentage of apparent interfacial failure (After Mubashar et al. (2009a))

anodized using the AC DC process described in Sect. 2.2 (Mubashar et al. 2009b). As well as demonstrating almost complete recovery of initial strength on drying, this figure also shows that adherend strength has a significant effect on joint behavior. The T6 heat-treated alloy exhibits a steady decline in strength with aging time, whereas the untreated alloy shows an initial steep decline in strength on aging, which then recovers. The main difference between the heat-treated and untreated alloys is that the yield strength is significantly lower in the latter, resulting in yielding of the adherend at the ends of the overlap when dry joints are tested. This results in greater rotation of the joint and higher peel stresses in the adhesive at the ends of the overlap. After short periods of exposure to moisture, the adhesive is significantly plasticized in the area of highest stress at the ends of the overlap, but most of the adhesive still has low moisture content, and hence overall joint behavior is little changed. On longer-term exposure, the adhesive becomes increasingly plasticized, reducing joint rotation and the magnitude of peel stresses.

It was also seen in the work of Comyn et al. (1987) that the use of a primer with a nitrile phenolic adhesive produced a marked improvement on dry and humid aged strengths and that the amount of failure at the adhesive-metal interface increased with time of exposure at 100% r.h. The latter observation is further illustrated in Fig. 2b, which shows a correlation between the joint strength and the proportion of apparent interfacial failure, as determined from digital image analysis of the fracture

surfaces. Surface analysis technique showed that what appeared to be interfacial failure from optical analysis of the fracture surfaces was actually failure in the primer close to the oxide layer. This explains why the loss in strength is largely reversible, as true interfacial failure involving thermodynamic displacement of the adhesive by water, as described in Sect. 4, would be irreversible.

Although joints are weakened by exposure to air of high humidity (e.g., 80–100% r.h.), it has been frequently observed that joints can withstand exposure at lower humidities (e.g., 50% r.h. or less) for long periods without weakening. In experiments on epoxide adhesives, Brewis et al. (1980a, c, 1981) found no significant weakening of joints after exposure for 10,000 h at about 45% r.h. and 20 °C. Figure 3 shows that joints with a range of adhesives (Ashcroft et al. 2001) are not significantly weakened on exposure to a natural hot/dry climate for up to 6 years. Here the average temperature was 25 °C and the average r.h. 55%. The adhesive symbols used in the legend of the figure are explained in Table 1.

Such information led to the proposal from Gledhill et al. (1980) that there must be a critical concentration of water in the adhesive, and corresponding relative humidity in the surroundings, which demarcates conditions under which weakening will occur, from those under which it will not. In a joint which is absorbing water, there may be an outer zone where the critical water concentration is exceeded, and this zone can be regarded as a crack in the bondline which can be dealt with by fracture mechanics. The hypothesis was tested by testing butt joints bonded with an

**Fig. 3** Strength of unstressed double lap joints on exposure to a hot/dry climate for up to 6 years (After Ashcroft et al. (2001). Crown copyright)

ME120k	Modified epoxy	120 °C	Film, knitted nylon carrier

**Fig. 4** Dependence of joint strength upon relative humidity, after 10,080 h exposure (After Brewis et al. (1990))

epoxide immersed in water at 20, 40, 60, and 90 °C and also in air at 20 °C and 55% r.h. All the water-immersed joints became weaker, and it could be shown using the fracture mechanics approach that the strengths of the joints could be correlated if the critical concentration of water in the adhesive was 1.35%.

Brewis et al. (1990) attempted to locate the critical conditions for some aluminum joints bonded with an epoxide adhesive. Surface preparation of the aluminum alloy adherends was by sandblasting; this was chosen because of the poor durability of sandblasted joints, a factor which was thought would give rapid results, which would be particularly sensitive to changes in relative humidity. Joints stored for up to 1,008 h did not weaken with increasing r.h. A slight weakening was evident after 2,016 h, and this became greater after 5,040 and 10,080 h. After 10,080 h, the locus had a kink at 65% r.h. (Fig. 4). This corresponds to a critical water concentration of water in the adhesive of 1.45%, a value which is very similar to that of Gledhill et al. (1980).

Micro- and nanoparticles are commonly added to adhesives as reinforcements to improve the strength of the adhesive joint under mechanical and environmental loads. These particles may act as sites for water absorption in the adhesive layer. Barbosa et al. (2015) used natural cork microparticles to improve the toughness of a brittle epoxy adhesive. The adhesive was mixed with 1% cork, and moisture absorption and desorption were experimentally observed at room temperature and 50 °C in water. No appreciable difference between the moisture diffusion rates was observed for the adhesive samples with and without cork microparticles. However, less variation in mechanical properties of the adhesive with cork microparticles were observed when compared to the original adhesive sample. Most of the mechanical strength of both types of adhesive samples recovered after drying the moisture-conditioned specimens. Sadigh and Ali (2016) mixed reduced graphene oxide (RGO) particles in an epoxy-based adhesive, Araldite 2011, to improve the strength of unconditioned and moisture-affected adhesive butt joints. The addition of RGO nanoparticles improved the strength of unconditioned adhesive joints by 22% when 0.5 wt. % fraction particles were added. However, the addition of nanoparticles changed the failure mode of the adhesive butt joints to interfacial failure from a cohesive failure. The joints were then conditioned in distilled and seawater for 30 days, after which the adhesive layer was saturated. The strength of the adhesive butt joints with 0.5 wt. % RGO decreased by 10% and 40% from the exposure to distilled water and seawater, respectively. In comparison, the strength of the conditioned adhesive butt joints without RGO nanoparticles decreased by 16% and 36% after conditioning in distilled and seawater, respectively. Thus a major improvement in the joint strength in conditioned adhesive butt joints was not seen with the addition of RGO nanoparticles.

Under combined hygrothermal loading, adhesive joints with dissimilar adherends have shown large decreases in strength. Korta et al. (2015) experimentally and numerically investigated adhesive joints between dissimilar material adherends, including carbon fiber composite, aluminum, and steel. The adhesive joints were subjected to hygrothermal cycling testing according to automotive industry standards. It was found that the joints debonded under the applied hygrothermal cyclic loads without the application of mechanical loads. The major reason for debonding was found to be the difference in the coefficient of thermal expansion of the dissimilar adherends. It has been observed that the moisture uptake of some composites may be decreased by increasing the amount of reinforcing fibers. This was observed during the durability study of FRP/steel adhesive joints (Heshmati et al. 2016). Moisture conditioning of the adhesive, CFRP, and GFRP specimens was performed for up to a year at 20 °C and 45 °C in water and at 45 °C, 95% r.h. It was reported that the maximum moisture uptake of GFRP composite material decreased by 40% by increasing the fiber volume from 46% to 62%. The change in the overall stiffness of the adhesive joint was found to be negligible owing to the insignificant effect of moisture on longitudinal properties of unidirectional composites. Low permeability adherends were also considered a reason for an insignificant loss of stiffness of the adhesive joints.

### 31.2.2 Surface Treatment

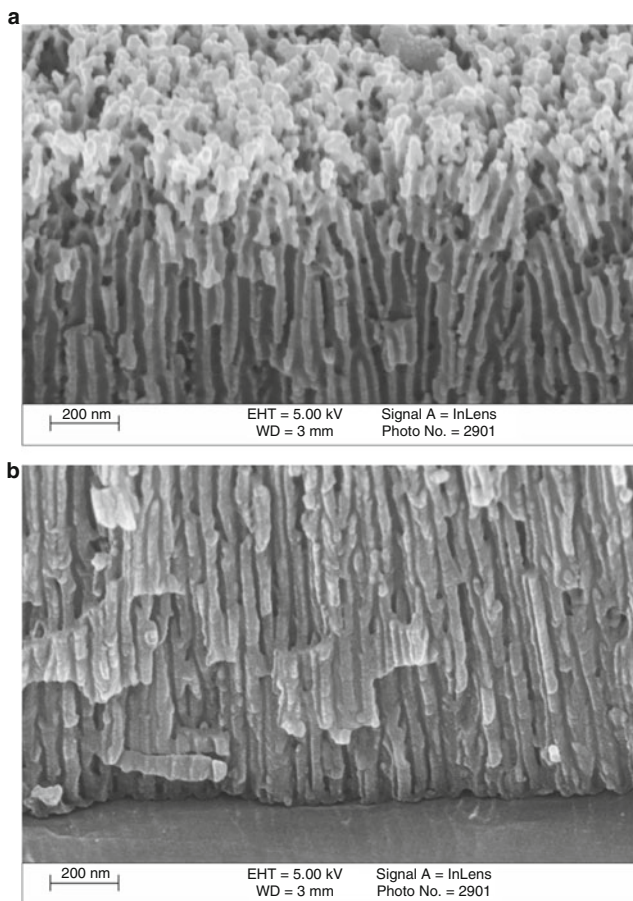

Surface treatment of metals is the most effective way of optimizing the resistance of joints to water. A graphic illustration of the effect of surface treatment on the wet durability of adhesive joints to aluminum was given by Butt and Cotter (1976), and their data are shown in Fig. 5. The surface treatments employed were etching in chromic-sulfuric acid, alkaline etching, solvent degreasing, and phosphoric acid anodizing. Before exposure the different treatments gave identical joint strengths, but exposure at 43 °C and 97% r.h. produced differences. Here the degreased adherends performed worst, and those etched in chromic-sulfuric acid did best. In this case phosphoric acid anodization gave a poor performance, but this is unusual.

The surface pretreatment of aluminum alloys for adhesive bonding has been reviewed by Critchlow and Brewis (1996). The literature in the period 1976–1991 on the wet durability of aluminum joints bonded with epoxide adhesives has been reviewed by Armstrong (1997). Critchlow and Brewis (1995) have also reviewed surface treatments for the titanium alloy Ti-6Al-4V.

One of the most effective pretreatments for bonding aluminum is chromic acid anodizing (CAA); however, there are health and safety concerns and environmental issues with the use of hexavalent chromium in this process, which is also highly complex and time-consuming. This has led to extensive research into alternative procedures. One of the most promising alternatives is the “AC DC” method proposed by Critchlow et al. (2006) (see ► Chap. 7, “General Introduction to Surface Treatments”). This is a mixed sulfuric-phosphoric acid anodization in which there is an initial AC anodizing stage which cleans the surface and produces an open porous oxide structure, suitable for bonding, as shown in Fig. 6a. This is followed by a DC

**Fig. 5** Effect of high humidity (97% r.h. at 43 °C) on the strength of aluminum joints bonded with an epoxide polyamide adhesive (After Butt and Cotter (1976)). Surface treatments are ○ chromic-sulfuric acid etch, □ alkaline etch (commercial formulation), ■ solvent degrease, and ● phosphoric acid anodize

**Fig. 6** Cross section through “AC DC” engineered oxide layer showing “crumpet” structure with (a) open structure at the surface for wetting and bonding and (b) dense structure at metal interface for corrosion protection (After Mubashar et al. (2009a))

anodizing stage which produces a thick compact film for corrosion protection, as shown in Fig. 6b. The complete cross section of the oxide layer somewhat resembles that of a crumpet. The complete process takes approximately 15 min, compared with approximately 95 min for the commercial CAA process and has been shown to result in comparable performance under a range of conditions, as illustrated by Fig. 7.

### 31.2.3 Natural and Accelerated Aging

A comparison of aging joints in natural and laboratory conditions has been undertaken by Ashcroft et al. (2001); they commented that their data are probably unique. The aluminum adherends were etched in chromic acid and bonded with a total of eight

**Fig. 7** Comparison of wedge test results for CAA and AC DC pretreated aluminum/epoxy joints conditioned at 50 °C in deionized water. Legend refers to different parameters used in the AC DC process

**Table 2** Natural weathers used by Ashcroft et al. (2001)

	Climate	Location	Average conditions		
			Temperature	r.h.	Monthly rainfall
	Hot/wet	Australia	23 °C	85%	297 mm
	Hot/dry	Australia	25 °C	55%	39 mm
	Temperate	UK	10 °C	78%	49 mm

epoxide or phenolic adhesives, which were exposed to the natural weathers shown in Table 2. Laboratory aging was at 20 °C and 60% r.h. or at 35 °C and 85% r.h.

The mode of failure was predominantly cohesive, but the amount of interfacial failure increased with both natural and laboratory aging. This was often accompanied by metallic corrosion, particularly in hot/wet conditions.

A conclusion was that there is no simple method of determining the long-term durability from accelerated tests and that excessive temperatures and humidities will trigger degradation mechanisms which are not representative. In general, accelerated tests tend to overestimate the reduction of joint strength.

### 31.2.4 Stress

Joints tend to weaken more rapidly if they are stressed during exposure. Davis and Fay (1993) reported the time to failure for joints, both stressed and unstressed, with mild steel and zinc-coated steel adherends. Results for zinc-nickel-coated steels are

shown in Fig. 8 showing that all unstressed joints survived for 2.5 years and that survival of the others decreases with increasing stress.

Fay and Maddison (1990) measured times to failure at 100% r.h. and 42–48 °C for joints in steel with a number of surface treatments and bonded with a toughened epoxide adhesive. Their results showed that failure was hastened by increasing stress and that time to failure can be much increased by selection of an appropriate surface treatment.

Parker (1988) described durability of stressed and unstressed joints in clad aluminum alloy BS 2L73 exposed to hot/wet, hot/dry, and temperate climates for up to 8 years. A variety of surface treatments were used. Joints were stressed to either 10% or 20% of their dry strength. Failure was hastened by increasing stress. At 20% stress the order of effectiveness of surface treatments was phosphoric acid anodize > chromic acid anodize > chromic acid etch.

The effect of cyclic stresses on the durability of aluminum-epoxide joints has been observed by Briskham and Smith (2000), using a range of surface treatments. Joints were immersed in water at 55 °C with average stress levels of approximately 0.15 or 1.2 MPa and a frequency of 2 Hz. The best-performing treatment was phosphoric acid anodization and treatment with an aminosilane coupling agent was the poorest, which perhaps was not expected as this performed better than all the other methods with unstressed joints. Joints with phosphoric acid anodization consistently failed in a cohesive manner, while all the other methods showed some interfacial failure.

Reference has been made above to work by Ashcroft et al. (2001) on aging joints in natural and laboratory conditions. Their program included exposing stressed joints, and their results for joints in a natural hot/wet climate after 6 years are shown in Fig. 9 (see Table 1 for further description of the adhesives used in this study). It can be seen that all stressed joints with the epoxy polyamide (E-P) and one of the modified epoxy (ME120k) adhesives are reduced to zero strength, while most of the others maintain a significant fraction of their strength.

The effect of moisture under various types of loading is another area that has been explored. Fernandes et al. (2016) experimentally observed the effect of moisture under mode I and mode II loading of composite-bonded double cantilever and

**Fig. 8** Average failure times of the zinc-nickel coated steel joints

**Fig. 9** Effect of stress on double lap joints exposed to hot/wet climate for 6 years (After Ashcroft et al. (2001). Crown copyright)

end-notched flexure adhesive joints. The joints were conditioned at 55%, 75% r.h., and in water, and fracture energies for the two modes, i.e., mode I and II, were determined. A reduction in fracture energy under both modes of fracture was observed. However, a sharp decrease in fracture energy was observed between 75% r.h. and water than between 55% and 75% r.h. Krishnan et al. (2016) conditioned glass fiber composite pipes by placing them in water at 80 °C for 1,500 h. The pipes were then tested by applying cyclic loads. Five stress conditions were applied ranging from completely axial stress to fully hoop stress. By using the first ply failure as the failure criterion of the pipes, failure envelopes were developed under the selected loading conditions. It was observed that the failure mode of the composite pipes changed as the stress loading conditions were changed. The three types of failure observed included matrix cracking, local leakage failure, and weepage failure.

### 31.3 Water and Adhesives

#### 31.3.1 Water Diffusion into Adhesive Bondline

All adhesives absorb water, and water uptake data for a number of structural adhesives are collected in Table 3. Such data are obtained by measuring the weight of water absorbed by an immersed film and include the diffusion coefficient  $D$  and the weight absorbed at equilibrium  $M_E$ . This means that adhesive layers in joints will absorb water and its vapor and transmit it to the interface. This cannot be prevented by sealing the edges with a paint or lacquer, as these also absorb water. The data can

283 be used to calculate the rate at which water will enter joints and water concentration  
284 profiles within them (Comyn 1983). This is discussed in more detail in Sect. 4.2.

285 The rate of the initial fall in strength of exposed joints is controlled by the rate of  
286 water diffusion in the bondline. This is demonstrated in Fig. 10 where joint strengths  
287 are compared with the amount of water to have entered a joint. Although the scales  
288 of the two ordinates have been adjusted to give a best fit, there is nevertheless an  
289 excellent comparison between the points, which are for measured joint strengths, and  
290 the line which is the calculated water level.

291 Parker (1988) has shown a linear relationship between joint strength and the  
292 square root of exposure time to humid conditions, for some titanium alloy joints  
293 bonded with a modified epoxide adhesive, demonstrating that the decline in strength  
294 is controlled by the diffusion of water. Some joints had been exposed for 11 years.

**Fig. 10** Comparison of joint strength (*experimental points*) with calculated water uptake (*line*) by joints bonded with DGEBA-DAPEE epoxide adhesive (After Brewis et al. (1980b))

**Table 4** Values of work of adhesion for various interfaces in dry air and in water

Interface	Work of adhesion ( $\text{mJm}^{-2}$ )		Interfacial debonding in water
	Air	Water	
Epoxide/steel	291	−255	Yes
Epoxide/aluminum	232	−137	Yes
Epoxide/silica	178	−57	Yes
Epoxide/CFRP	88–90	22–44	No

The diffusion of water in structural adhesives obeys the Arrhenius equation, which means that the rate of diffusion increases strongly with temperature. The expected consequence of this is that joints will weaken more rapidly as the temperature rises. This was shown to be the case by Gledhill and Kinloch (1974) and Gledhill et al. (1980). Here butt joints in mild steel, prepared by degreasing and grit blasting, were bonded with an epoxide adhesive and immersed in water.

### 31.3.2 Water and Adhesive Interfaces

Water in a joint may attack the adhesive by causing it to swell, craze, crack, or hydrolyze, but it is its role in attacking the interface which is potentially the most important in bringing about weakening (Comyn 1983).

Thermodynamic work of adhesion is the minimum amount of work that must be done to separate an adhesive-substrate interface (see ► Chap. 6, “Thermodynamics of Adhesion”). If this has a positive value, the interface is stable. A negative value indicates an unstable bond, and this is the case for adhesive-metal interfaces in water. Some data are shown in Table 4. This is because metal oxides have very high surface free energies, water has extreme properties, and in particular is the high value of the polar component of surface free energy, which is approximately  $51 \text{ mJ m}^{-2}$ .

Kinloch (1983) has compared work of adhesion of adhesive interfaces in air and in water with their tendency to debond interfacially in an unstressed condition. Some data are shown in Table 4. The fact that interfacial debonding only occurs when the

thermodynamic work of adhesion is negative is evidence of the validity of thermodynamics in predicting the durability of adhesive bonds. Because metals have high-energy oxide surfaces, the work of adhesion in the presence of water will be negative, i.e., water may displace the adhesive from the substrate. However, it should be remembered that thermodynamic work of adhesion is only of relevance when the mechanism of bonding is entirely by physical adsorption. Further, work of adhesion can only be related to joint strengths when failure is at the interface and, as discussed in Sect. 2.1 in a joint with an effective surface pretreatment apparent interfacial on closer inspection which may in fact be in the adhesive or primer close to the interface. This is significant as the effect of water where this type of failure has been seen has been shown to be largely reversible, whereas thermodynamic displacement of the adhesive by water is irreversible.

Chemical bonds across the interface would confer strength and resist the thermodynamic displacement of the adhesive by water. These may be ionic attractions for adhesives on metals and covalent bonds with silane coupling agents. Mechanisms of adhesion have been reviewed by Comyn (2005).

## **31.4 Modeling the Effects of Moisture and Stress on Bonded Joints**

### **31.4.1 Introduction**

It is generally agreed that the most common cause of environmental degradation in bonded joints involves the absorption of moisture into the joint. This has a number of effects that must be incorporated into any mechanistically based mechanical model of the joint to be used for modeling the effects of environmental aging. The most important of these are:

- (i) Plasticization of the adhesive (and adherend in some cases), which will affect mechanical properties, the internal stress distribution, and potentially the failure criterion
- (ii) Hygroscopic expansion of the adhesive, which will affect residual stresses in the joint
- (iii) Weakening of the interface (or interphase) by various mechanisms, which will potentially affect the failure criterion

In order to be able to predict the effects cited above, it is first necessary to be able to quantify moisture transport through the joint. The absorbed moisture will cause swelling as well as degradation of the constituent parts and the interface region.

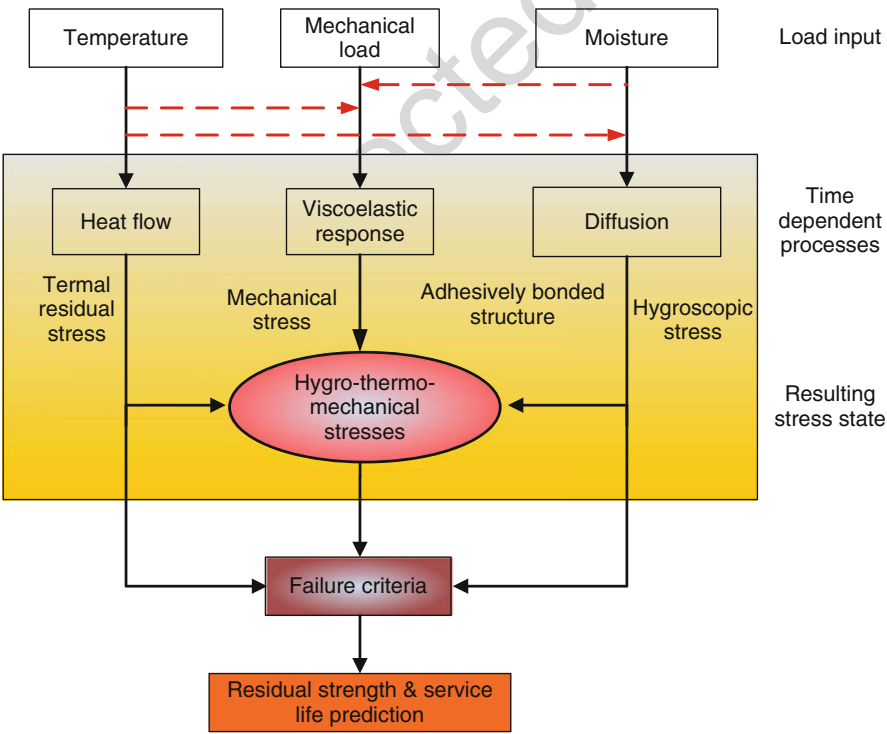

This will affect the stresses in the joint and the residual strength. Once both moisture transport and the subsequent degradation processes have been successfully modeled, there is still the critical issue of predicting the residual strength. Traditionally, strength of materials or fracture mechanics methods have been used to predict the failure of bonded joints. However, both of these approaches have limitations, and neither approach can model the evolving initiation and propagation of damage that is

a characteristic of failure in many environmentally degraded joints. Owing to these limitations, progressive damage models are being increasingly used to model the behavior of advanced materials such as structural adhesives.

This section discusses the steps involved in current state-of-the-art environmental degradation modeling of bonded joints. Essentially, this involves three main steps.

The first step is modeling moisture transport through the joint in order to determine the moisture concentration distribution through the joint as a function of time. The second step involves evaluation of the transient mechanical-hygrothermal stress-strain state resulting from the combined effects of hygrothermal effects and applied loads. The final step involves incorporation of damage processes in order to model the progressive failure of the joint and hence enable the residual strength or lifetime of a joint to be predicted. These steps are illustrated in Fig. 11 which shows a general framework for explicitly modeling the effects of environment on the mechanical performance of bonded joints.

There are two main challenges to developing an accurate predictive method along these lines: firstly, accurate modeling of the various effects of aging on the mechanical model, and secondly, incorporating a failure model that accurately represents not just the final failure load but the complete cycle of damage initiation and propagation leading to failure. These issues will be discussed in the following sections.

**Fig. 11** Framework for modeling the environmental aging of adhesively bonded joint

### 31.4.2 Diffusion of Moisture in Bonded Joints

In order to understand and model the effect of absorbed moisture on adhesives, we need to investigate moisture transport mechanisms and how they can be represented mathematically. Mass (or molecular) diffusion describes the transport of molecules from a region of higher concentration to one of lower concentration. This is a stochastic process, driven by the random motion of the molecules. This results in a time-dependent mixing of material, with eventual complete mixing as equilibrium is reached. Mass diffusion is analogous to other types of diffusion, such as heat diffusion, which describes conduction of heat in a solid material, and hence similar mathematical representations can be made.

#### Modeling Diffusion

It has been suggested by Crank (1975) that the kinetics of sorption of moisture in polymers is governed by two limiting cases. Case I (Fickian or diffusion controlled), in which moisture transport is a stochastic process driven by the presence of a concentration gradient, predominates in systems where the penetrant has little hygroelastic effect on the polymer or the rate of diffusion is much less than that of relaxation. In Case I diffusion, the weight uptake is initially linear with respect to the square root of time, i.e., if the amount sorbed at time  $t$  is  $Kt^n$ , then  $n$  is equal to 0.5.

In Case II (relaxation controlled) diffusion is more rapid than relaxation, consequently, there is a discontinuity in concentration between the swollen and unswollen polymer. Initially the discontinuity advances into the polymer with a constant velocity resulting in linear initial uptake of penetrant with respect to time, i.e., if the amount absorbed at time  $t$  is  $Kt^n$ , then  $n$  is equal to 1. In many cases, both the mechanisms described above are present to varying degrees, resulting in anomalous uptake, i.e.,  $n$  is between 0.5 and 1. Various different forms of anomalous uptake have been identified, as described by Crank (1975).

#### Fickian Diffusion

In this case diffusion can be presented in a quantitative manner by adapting the mathematical equations of heat conduction derived by Fourier in 1822, as shown by Fick in 1855. The mathematical theory of diffusion is based on the hypothesis that the rate of transfer of a diffusing substance through a unit area of a section is proportional to the concentration gradient measured normal to the section. This hypothesis is presented mathematically by Eq. 1, which is usually referred to as Fick's first law (Crank 1975):

$$F = -D \frac{\partial c}{\partial x} \quad (1)$$

where  $F$  is the flux or rate of transfer per unit area,  $c$  is the concentration of diffusing substance,  $x$  is the space coordinate measured normal to the section, and  $D$  is the diffusion coefficient. The negative sign in Eq. 1 is due to the fact that diffusion occurs in the direction opposite to that of increasing concentration.

411 Considering the transport of moisture through an element in which concentration  
 412 increases, there must be a proportional decrease in flux across the distance of  
 413 the element in order to conserve mass. This is expressed mathematically by  
 414 Fick's second law, which is shown in Eq. 2 for one-dimensional diffusion:

$$\frac{\partial c}{\partial t} = -\frac{\partial F}{\partial x} = \frac{\partial}{\partial x} \left( D \frac{\partial c}{\partial x} \right) = D \frac{\partial^2 c}{\partial x^2} \quad (2)$$

415 Equation 2 can easily be extended to two or three dimensions. Many classes of  
 416 problem are governed by an equation of a similar form to Fick's second law, e.g., the  
 417 governing equation for heat transfer is given by

$$\frac{\partial}{\partial x} \left( k_x \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial y} \left( k_y \frac{\partial T}{\partial y} \right) + \frac{\partial}{\partial z} \left( k_z \frac{\partial T}{\partial z} \right) + Q = \rho c \frac{\partial T}{\partial t} \quad (3)$$

418 where  $T$  is temperature,  $k_i$  is conductivity in the  $i$  direction,  $Q$  is rate of internal  
 419 heat generation,  $c$  is specific capacity, and  $\rho$  is density. This form of equation is  
 420 sometimes called the quasi-harmonic equation; other classes of problem  
 421 governed by this equation include electrical conduction and magnetostatics. All  
 422 problems governed by the quasi-harmonic equation can be solved by finite  
 423 element analysis programs with general field solvers. These solvers are often  
 424 presented in terms of thermal analysis in commercial finite element software;  
 425 however, they can also be used for other classes of problem by using the analogy  
 426 of the controlling equation.

427 Equation 2 can be solved using standard techniques for solving differential  
 428 equations for cases with simple boundary conditions, e.g., where  $D$  is assumed to  
 429 be constant or has a defined variation with concentration. For example, the solution  
 430 to Eq. 2, for the case of a plane, semi-infinite sheet (i.e., 1D diffusion) where the  
 431 region  $x$  ( $-l < x < l$ ) is initially at uniform concentration  $C_o$ , the surfaces are  
 432 maintained at a constant concentration  $C_1$  and temperature, and  $D$  is constant, is  
 433 given by Eq. 4:

$$\frac{C - C_o}{C_1 - C_o} = 1 - \frac{4}{\pi} \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} e^{\left[ \frac{-D(2n+1)^2 \pi^2 t}{4l^2} \right]} \cos \frac{(2n+1)\pi x}{2l} \quad (4)$$

434 Similar solutions can be found for two- or three-dimensional diffusion; however,  
 435 these require the summation of the terms of multiple infinite series to obtain  
 436 convergence. A simpler method is to solve as the product of the 1D solutions. For  
 437 example, in two dimensions, the total concentration can be calculation from the  
 438 concentration in the  $x$  and  $y$  directions using Eq. 5:

$$1 - \frac{c}{c_0} = \left( 1 - \frac{c_x}{c_0} \right) \left( 1 - \frac{c_y}{c_0} \right) \quad (5)$$

Equation 4 can be integrated with respect to  $x$  to determine the total mass of water absorbed at time  $t$ . If  $M_t$  indicates the mass of the total amount of penetrant absorbed at time  $t$  and  $M_\infty$  is the mass at saturation, then

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2 \pi^2} e^{\left[ \frac{-D(2n+1)^2 \pi^2 t}{4l^2} \right]} \quad (6)$$

At low concentrations, Eq. 6 can be simplified to Eq. 7:

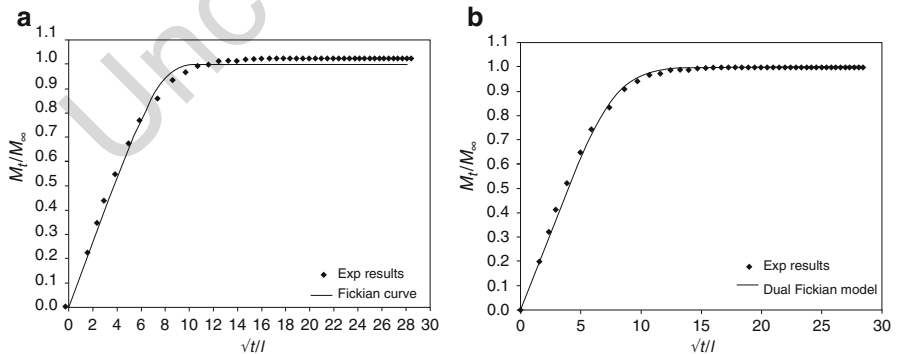

$$\frac{M_t}{M_\infty} = \frac{4}{l} \left[ \frac{Dt}{\pi} \right]^{1/2} \quad (7)$$

Equations 6 and 7 are used with experimental mass uptake data to determine  $D$ . This can then be used in Eq. 4 to predict concentration variation through a joint as a function of time.

### Non-Fickian Diffusion

In some cases, the Fickian model does not accurately represent moisture uptake in adhesives. This is illustrated in Fig. 12a which shows the uptake plot for an epoxide immersed in water at 50 °C. The experimental data appears to indicate Fickian diffusion; however, the best fit of the Fickian diffusion equation to the data indicates equilibrium is reached more slowly than predicted by Fickian diffusion. This type of behavior is sometimes termed pseudo-Fickian behavior. In general, anomalous behavior is seen at high temperatures and humidity.

Many models have been suggested to describe anomalous (non-Fickian) uptake, and a number of the more relevant to structural adhesives will be discussed. Diffusion-relaxation models are concerned with moisture transport when both Case I and Case II mechanisms are present. Berens and Hopfenberg (1978) assumed

**Fig. 12** Moisture uptake in an epoxide demonstrating (a) non-Fickian uptake and (b) improved curve fitting with dual-Fickian model

that the net penetrant uptake could be empirically separated into two parts, a Fickian diffusion-controlled uptake and a polymer relaxation-controlled uptake. The equation for mass uptake using Berens and Hopfenberg's model is shown below:

$$M_t = M_{D\infty} \left[ 1 - \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2 \pi^2} e^{\left[ \frac{-D(2n+1)^2 \pi^2 t}{4l^2} \right]} \right] + \sum_i M_{R\infty,i} [1 - e^{-\Omega_i t}] \quad (8)$$

where  $M_t$  is the total mass at time  $t$  and  $M_{D\infty}$  is the equilibrium amount of sorption in the unrelaxed polymer.  $M_{R\infty,i}$  and  $\Omega_i$  are the equilibrium sorption owing to the relaxation process and the relaxation rate constant, respectively, for the  $i$ th relaxation process. Berens and Hopfenberg (1978) showed that in general, only one or two relaxation terms are required to provide a good fit to the experimental data.

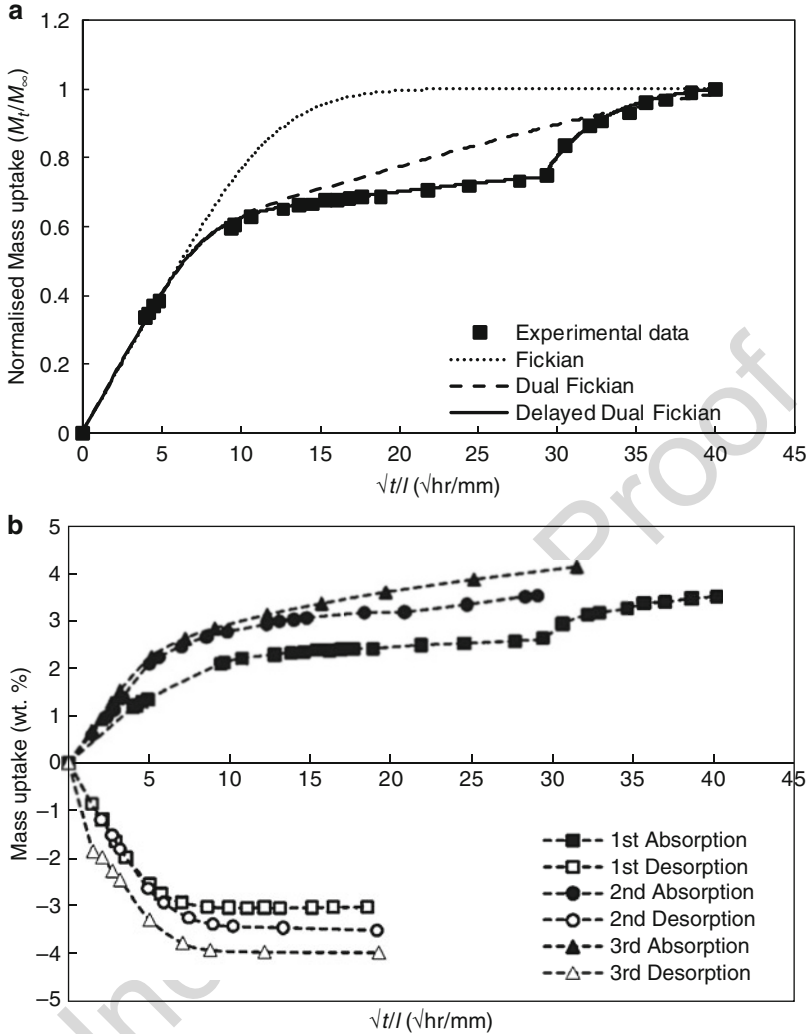

Dual-sorption models are based on the premise that while some penetrant molecules diffuse normally in the polymer matrix, others will be affected by polymer-penetrant interactions or micro-void filling. Carter and Kibler (1978) addressed this problem in terms of the probability that a water molecule may react with a polymer molecule. Their model is based on the theory that moisture in a polymer network can be either bound or free. The probability that a free water molecule becomes bound is  $\gamma$ , and the probability that a bound water molecule is emitted from the bound site and becomes mobile is  $\beta$ . When  $\gamma$  and  $\beta$  are small

$$\frac{M_t}{M_{\infty}} = 1 - \frac{\gamma}{\gamma + \beta} e^{-\beta t} - \frac{8\beta}{\pi^2(\gamma + \beta)} \sum_0^{\infty} \frac{1}{(2n+1)^2} e^{-K(2n+1)^2 t} \quad (9)$$

where  $K = \pi^2 D/l^2$ .

Loh et al. (2005) proposed a dual-uptake model based on the summation of two Fickian diffusion models. Physically this can be interpreted as two different uptake processes operating in parallel, both of which are adequately described by Fickian diffusion. This model was seen to accurately represent anomalous moisture transport in an epoxy-based material exposed to different levels of humidity. Both of the Fickian diffusion models are based on Eq. 4, with separate diffusion coefficients ( $D_1$  and  $D_2$ ) and saturation levels ( $M_{1\infty}$  and  $M_{2\infty}$ ), respectively. It can be seen in Fig. 12b that these models provide similar, good fits to the anomalous moisture uptake of the epoxy. It also has the advantage of the other anomalous models that it can be easily incorporated into a finite element analysis.

In some cases, a pseudo-equilibrium stage is reached in the moisture uptake, which is then followed by a secondary uptake process. This is illustrated in Fig. 13a. This type of behavior indicates that the absorbed moisture has triggered an additional moisture uptake mechanism. For example, differential hygroscopic expansion may lead to cracking and moisture uptake by capillary action. In order to model the moisture uptake shown in Fig. 13a, Mubashar et al. (2009a) proposed a dual Fickian model with a Heaviside step function. This model was termed the "delayed" dual Fickian model, where the secondary uptake is modeled by a power law. The mass uptake by a delayed dual Fickian model is, hence, given by

**Fig. 13** Moisture uptake in FM73 at 50 °C in deionized water showing (a) secondary uptake and (b) effects of cyclic uptake (After Mubashar et al. (2009b))

$$\begin{aligned}
 M_t = & \left( 1 - \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} e^{\frac{-D_1(2n+1)^2 \pi^2 t}{4l^2}} \right) \times M_{1\infty} \\
 & + \left( 1 - \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} e^{\frac{-D_2(2n+1)^2 \pi^2 t}{4l^2}} \right) \times M_{2\infty} + \Phi(t - t_1)(at^b + c)
 \end{aligned} \quad (10)$$

where  $\Phi$  is the Heaviside step function,  $t_1$  is the start time of secondary uptake as determined experimentally, and  $a$  and  $b$  are the power law constants determined by

curve fitting. It can be seen in Fig. 13a that this provides an excellent fit to data with a secondary uptake curve.

Another consideration in modeling the uptake of moisture by adhesives is that the uptake behavior can be different in absorption and desorption and can change with number of sorption cycles. This is illustrated in Fig. 13b. It can be seen that the rate of moisture absorption and the equilibrium moisture content increase from the first to second absorption cycle, although there is little difference between the second and third absorption cycles. Desorption is faster than absorption and more closely resembles Fickian diffusion. Mubashar et al. (2009a) proposed a method of incorporating the moisture history effects illustrated in Fig. 13b in a finite element-based predictive methodology.

The equilibrium moisture content in an adhesive is dependent on the relative humidity. Henry's law states that at constant temperature, the amount of a given gas dissolved in a given type and volume of liquid is directly proportional to the partial pressure of that gas in equilibrium with that liquid. This can be extended to molecular diffusion of a fluid in a polymer as the equilibrium quantity of a diluent within a polymer,  $c_d$ , is proportional to the environmental activity of the diluent,  $a_d$ :

$$c_d = ka_d \quad (11)$$

where  $k$  is Henry's law constant and, in the case of moisture absorption, the activity that relates to relative humidity as activity is  $p/p_0$  and relative humidity is  $(p/p_0) \times 100$ . The symbols  $p$  and  $p_0$  represent the vapor pressure and saturated vapor pressure of water, respectively. Henry's law does not allow for polymer-penetrant chemical interaction and is generally only applicable at low concentrations or in systems in which the penetrant and polymer have little affinity for each other.

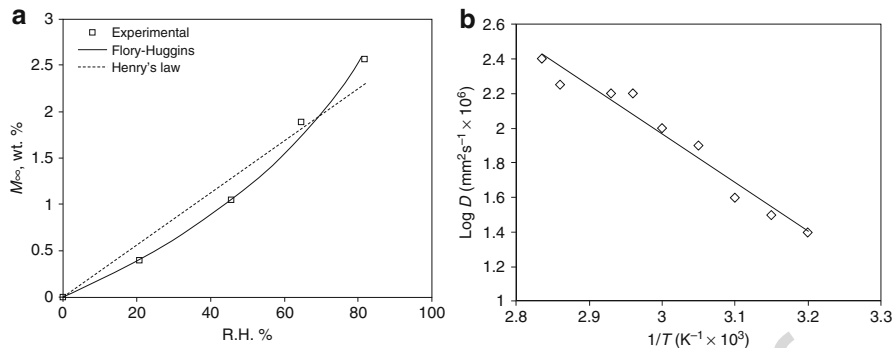

An improvement on Henry's law is the Flory-Huggins model, which takes into account the large difference in size between the polymer and penetrant molecules and interactions between the two:

$$\ln a_d = \ln V_d + \left(1 - \frac{v_d}{v_p}\right)V_p + \chi_d V_p^2 \quad (12)$$

where the subscripts "d" and "p" refer to the diluent and polymer, respectively,  $V$  is volume fraction,  $v$  is molar volume, and  $\chi_d$  is a polymer-penetrant interaction term. As the molar volume of the polymer is generally much greater than that of the penetrant, Eq. 12 can be simplified to

$$\ln a_d = \ln V_d + V_p + \chi_d V_p^2 \quad (13)$$

Figure 14a shows the relationship between relative humidity and equilibrium moisture concentration for an epoxide. It can be seen for this material that the relationship between equilibrium moisture content and relative humidity is poorly described by Henry's law but is described satisfactorily by the Flory-Huggins equation.

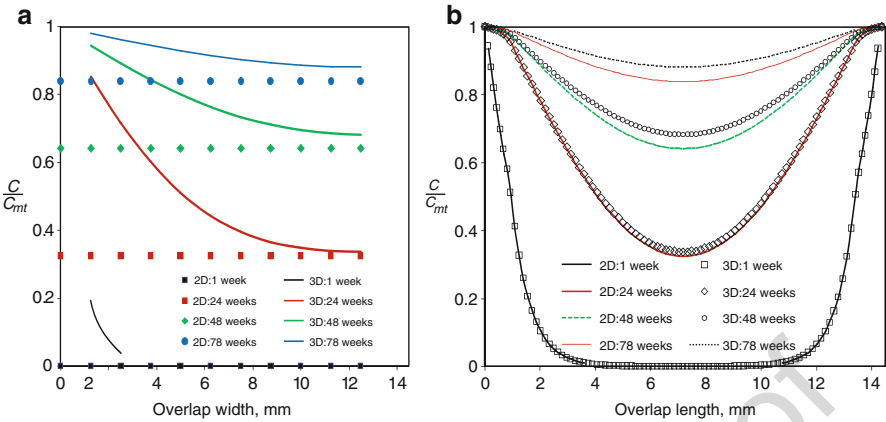

**Fig. 14** Moisture uptake in epoxide demonstrating (a) effect of relative humidity on equilibrium moisture content and (b) effect of temperature on diffusion coefficient

As noted in Sect. 3.1, the rate of diffusion increases with temperature, and it has been proposed that the diffusion coefficient of water in adhesives is related to temperature by the Arrhenius relationship in Eq. 14:

$$D = D_0 \exp\left(-\frac{E}{RT}\right) \quad (14)$$

where  $D$  is the diffusion constant at temperature,  $T$ ,  $D_0$  is a constant,  $E$  is the activation energy for diffusion, and  $R$  is the gas constant. Figure 14b shows that this relationship can be used to satisfactorily model the effect of temperature on the diffusion coefficient of an epoxy adhesive. It has also been seen experimentally that applied stress also increases the diffusion rate as the intermolecular distance increases; however, this is usually regarded as a secondary effect.

Once an appropriate diffusion model has been identified and the model parameters determined through experimentation, the moisture concentration within the adhesive on exposure to a particular environment can be predicted. For simple geometries and boundary conditions, analytical models can be used, whereas for more complex cases, the finite element method can be used. This is discussed in more detail by Abdel Wahab et al. (2001). An example of the predicted moisture concentration in an aluminum-epoxy single-lap joint conditioned at 50 °C/95% r.h. can be seen in Fig. 15. In this case, the moisture concentration was predicted using the finite element method and a dual Fickian model. The results from 2D plane strain and 3D finite element models were compared in order to evaluate the errors associated with a 2D simplification of the joint. In the 3D model, moisture can diffuse into the joint from the ends of the overlap and the sides of the joints, whereas in the 2D model, the latter diffusion path is not modeled and, hence, can be related to a joint with a very long diffusion path in the out-of-plane direction compared with the in-plane diffusion path. Figure 15a shows the variation in the moisture concentration across the width of the overlap and the center of the overlap. The 2D model underpredicts the moisture concentration at the edges; however, a reasonable

**Fig. 15** Predicted moisture concentration in an aluminum-epoxy single lap joint conditioned at 50 °C/95% r.h. Moisture distribution across (a) the joint width at the center of the overlap and (b) the overlap at the middle of the joint width (Jumbo 2007)

prediction of the moisture concentration at the center of the width is obtained. This is because the overlap length of the single-lap joint was 12.5 mm compared with a joint width 25 mm. The variation in concentration along the overlap in the middle of the joint width is shown in Fig. 15b. It can be seen that the difference between the 2D and 3D models increases at longer conditioning times as the moisture diffusing from the sides of the samples begins to make a more significant contribution to the total moisture concentration in the middle of the joint width. It can also be seen in this figure that even at 50 °C and a joint with a shortest diffusion distance of only 6.25 mm, the joint has still not reached saturation after 78 weeks of conditioning. This gives some indication of the time scales involved in reaching equilibrium in industrial joints under temperate service conditions.

### Modeling Stress and Strain

The first step in mechanical modeling is to determine the mechanical properties, which in a polymeric adhesive will be dependent on the temperature and the moisture concentration. Figure 16 shows the effect of absorbed moisture on stress-strain plots obtained from tensile testing bulk samples of a modified epoxy adhesive. It can be seen in Fig. 16a that at 22 °C, absorbed moisture has a relatively small effect on the modulus but a larger effect on the ultimate tensile strength (UTS) and failure strain. Comparing the dry plot with the plot with 1.8 weight % of absorbed moisture, it can be seen that the absorbed moisture has resulted in a slightly lower modulus, a reduction in UTS of approximately 20%, and an increase in strain to failure of over 100%. The plastic strain energy density at failure has also increased significantly. Whether the absorbed moisture is detrimental to performance will, hence, depend on the failure criterion used. Increasing the moisture to 2.3% sees a further extension of the trends seen with 1.8% absorbed moisture, whereas increasing the moisture to 4.1% results in a strain to failure of a similar value to the dry tested samples. Hence,

**Fig. 16** Effect of absorbed moisture on the bulk mechanical properties of a modified epoxy adhesive at (a) 22 °C (b) 90 °C

at high levels of moisture uptake, it can be seen that mechanical performance is reduced according to stress-, strain-, or energy-based failure criteria.

The effect of moisture on stress-strain plots for samples tested at 90 °C can be seen in Fig. 16b. Firstly, it is worth comparing the dry stress-strain plots at the two temperatures in Fig. 16a, b where it can be seen that increasing temperature has a similar effect to the absorbed moisture, i.e., reduction in modulus and UTS and an increase in strain to failure and plastic strain energy density at failure. However, comparing Fig. 16a, b for the samples with absorbed moisture shows that the effect of moisture is far more drastic. This can be explained by looking at the effect of moisture on the glass transition temperature ( $T_g$ ). Figure 17a shows the results from differential thermomechanical analysis (DTMA) of the modified epoxy adhesive used to generate the stress-strain plots shown in Fig. 16. It can be seen that as

**Fig. 17** (a) Results from DTMA testing of a modified epoxy adhesive, (b) relationship between  $\tan \delta$  peak and moisture concentration

moisture is absorbed, the  $\tan \delta$  peak broadens, eventually resolving to two distinct peaks. This can be attributed to the fact that as temperature increases in the DTMA test, moisture desorbs from the sample, resulting in a variation in moisture concentration through the sample. The first peak therefore represents the saturated material and the higher temperature peaks the partially dried material. The temperature of the first  $\tan \delta$  peak is assumed to represent the  $T_g$  of the saturated material and is plotted against the saturated moisture concentration in Fig. 17b. This figure shows that there is an approximately linear relationship between the temperature of the first  $\tan \delta$  peak (and hence  $T_g$ ) and the moisture concentration, with the slope indicating a decrease

in  $T_g$  of approximately 15 °C with each weight % of moisture absorbed. It can be seen from the figure that the dry  $T_g$  of the adhesive is approximately 130 °C but that with 3% absorbed moisture, this will have reduced to approximately 85 °C. This explains the drastic effect of moisture on the mechanical properties of the adhesive at 90 °C shown in Fig. 16b.

The results discussed above illustrate that the mechanical properties of an adhesive are highly dependent on moisture concentration, and similar trends have been observed by others investigating different adhesive systems, e.g., Viana et al. (2016a). This relationship, together with an appropriate diffusion model, can be used to predict the distribution of mechanical properties within an adhesive layer as moisture is absorbed. The next step is to model the effect of the absorbed moisture on the mechanical performance of the joint, normally through an examination of the stress distribution in the adhesive layer. Stresses can be broadly categorized as either mechanical stresses or residual stresses.

In a bonded joint, three main sources of residual stresses can be identified. These are changes in temperature, leading to thermal stresses; changes in moisture content, leading to hygroscopic stresses; and changes due to chemical reactions, leading to curing stresses. The curing stresses in typical adhesively bonded joints are small compared with the thermal and hygroscopic stresses and in any case can be incorporated into analysis of the thermal stresses once the stress-free temperature has been determined. In bonded joints there may be significant residual thermal stresses from the curing operation followed by modification of these stresses as moisture is absorbed. The combined stresses are termed hygrothermal stresses. These residual stresses are generally modeled in a similar way. In fact, it is more accurate to refer to this effect as residual strains as this is what is induced by the temperature and the moisture. The stresses are only generated when these strains are not allowed to develop fully by applied constraints. Residual thermal,  $\varepsilon_{th}$ , and hygroscopic,  $\varepsilon_{hy}$ , strains are determined from

$$\varepsilon_{th} = \alpha_{th}(\Delta T) \quad (15)$$

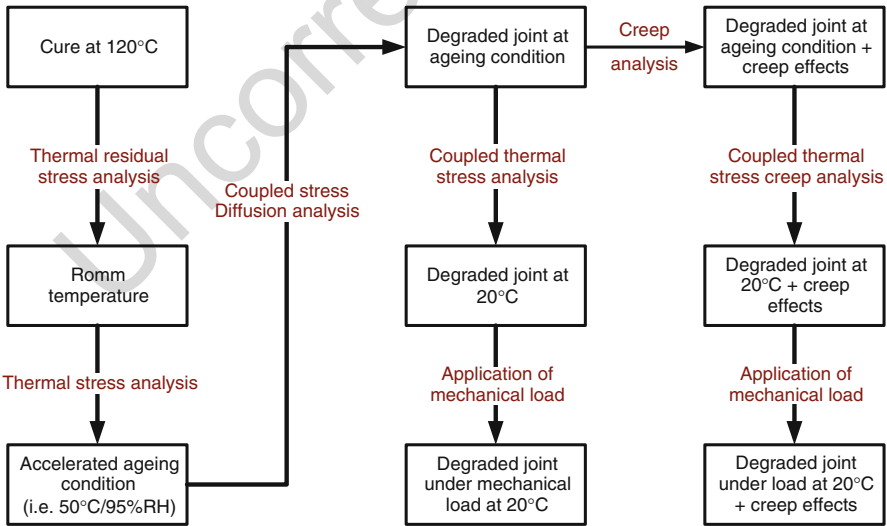

and

$$\varepsilon_{hy} = \alpha_{hy}(\Delta c) \quad (16)$$

where  $\alpha_{th}$  and  $\alpha_{hy}$  are experimentally determined coefficients of linear expansion. If only one form of residual strain is being modeled, then it is possible to use the thermal strain capability that almost all FE codes have. If both forms are to be modeled, then some FE codes (such as Abaqus) have user routines where coefficients of expansion can be defined or strains from a previous analysis can be used as initial conditions for a subsequent analysis. In both cases it will be necessary to run coupled analyses, where the output from one analysis (thermal or moisture) forms the input to another (stress). In addition to these forms of residual stress, it will also be necessary to model the change in adhesive material response (plasticization) caused by the absorbed moisture and any changes in temperature, as discussed

above. This is most easily achieved by utilizing the field-dependent material property facility that many FE codes have. In these, adhesive material properties such as modulus and yield stress or the constants relating to a viscoelastic constitutive model can be defined as a function of a field variable, such as temperature or moisture.

The steps in modeling the combined effects of thermal residual stresses on cooling from the cure temperature, hygrothermal stresses from conditioning in a high-humidity environment, and hygro-thermo-mechanical stresses from mechanically loading the environmentally aged joint are shown in Fig. 18. The option of allowing for relaxation of stresses through creep of the adhesive is also indicated in the figure. Figure 19 illustrates the hygro-thermo-mechanical evolution of von Mises equivalent stress in an aluminum-epoxy single-lap joint conditioned at 50 °C/95% r.h. The line plots indicate the levels of stress at each stage after cure, as illustrated in the hygro-thermo-mechanical analysis framework (Fig. 18). At 20 °C (dry) a fairly uniform thermal stress of approximately 25 MPa is seen, which increases slightly at the edges of the overlap. An increase in temperature to 50 °C reduces the stress to approximately 13 MPa in most areas along the overlap length. The stresses are further reduced to about 7 MPa after saturation with moisture, with the distribution retaining a similar shape after saturation. On cooling down to 20 °C after saturation, the stress level increases to about 10 MPa. The application of a 5 kN tensile load on the joint increases the stress in every area along the profile and results in a more nonuniform distribution, owing to the differential straining of the adherends and rotation of the overlap area under the applied load. It should be noted that the failure load for this joint is approximately 20 kN, as will be discussed in the next section.

**Fig. 18** Overall methodology for predicting the effect of environment on bonded joints including residual stress effects (Jumbo 2007)

**Fig. 19** Equivalent von Mises stress along the middle of the joint overlap in an aluminum-epoxy single lap joint conditioned at 50 °C/95% r.h (Jumbo 2007)

Han et al. (2014) developed a finite element model with full-field coupling of moisture, temperature, and stress fields where a stress-dependent diffusion coefficient was used. The effects of creep were introduced into the model via a time-hardening power law creep model, and the effects of thermal and hygroscopic expansion were also incorporated. The moisture, temperature, and stress fields were related using field variables and providing experimental data in a tabular form. Results of the finite element model showed good correlation with the experimental results obtained for a single-lap joint. Such finite element models are an attempt to improve the fidelity of the adhesive joint modeling and incorporate the synergetic effects of various factors by using multi-physics-based finite element formulations.

**Modeling Damage and Failure**

In order to predict failure, a suitable failure criterion needs to be applied to the mechanical model of the joint. The simplest form of failure analysis is to define failure when a suitable failure criterion has exceeded a permissible limit, e.g., when the equivalent von Mises stress has exceeded the yield stress of the material. However, this type of analysis is problematic when one has theoretical stress singularities, such as in adhesive joints, as the definition of failure becomes mesh dependent. Also, there is no indication of how the part eventually fails or what is the maximum load sustained. In order to predict this, progressive damage modeling is

required. Two different forms of progressive damage modeling have generally been used with adhesive joints: cohesive zone modeling (CZM), where the failure is localized along a plane (Loh et al. 2003; Liljedahl et al. 2007; Mubashar et al. 2011), and continuum damage modeling (CDM), where the failure can occur throughout the material (Hua et al. 2007). Potential sites for damage modeling include the adhesive, the interface, and the adherend. The CZM approach is more directly applicable to interfacial failure and certain forms of adherend failure, while the CDM is more relevant to failure in the adhesive. This subject is discussed in detail in ► Chap. 25, “Numerical Approach: Finite Element Analysis.”

Jumbo (2007) used both CZM and CDM, together with the procedure illustrated by Fig. 18, to predict the effect of environmental aging on the mechanical performance of a number of different types of bonded joint including the double-lap joint (DLJ) shown in Fig. 20a. A typical finite element mesh used in his analysis is shown in Fig. 20b. In the cohesive zone modeling, a bilinear cohesive material model was used, as illustrated in Fig. 21. The bilinear traction-separation law is given by

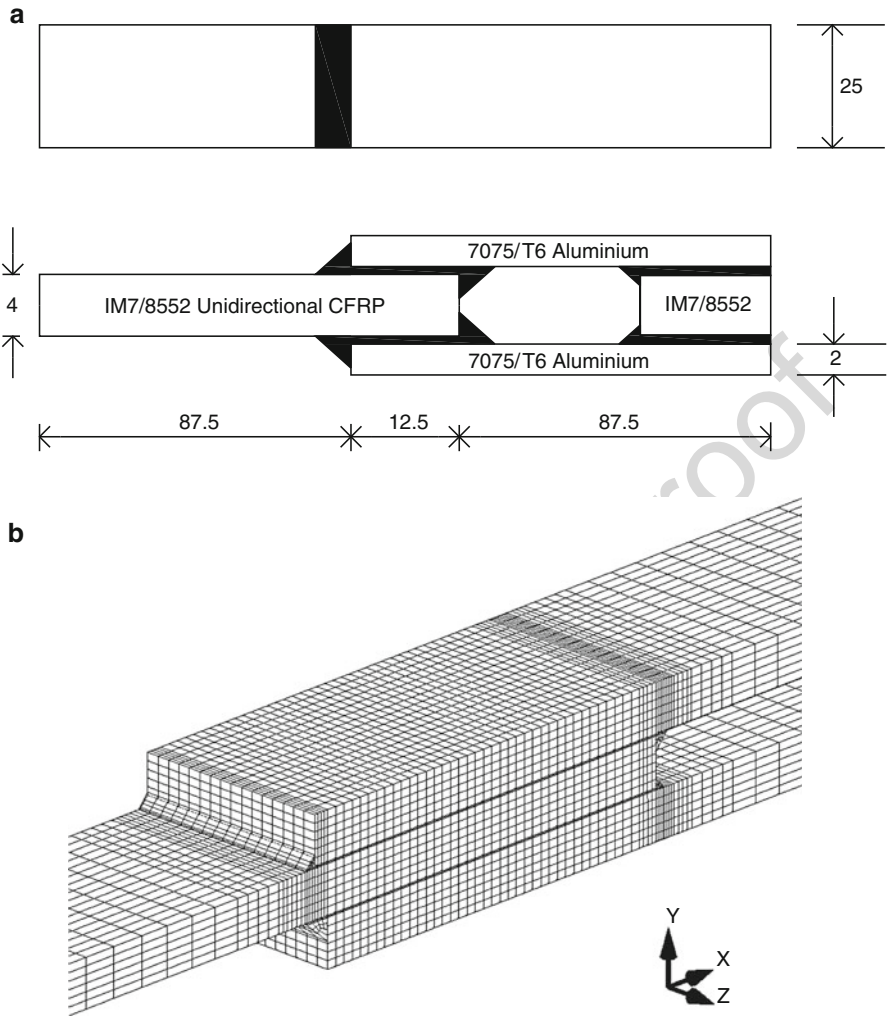

$$t_e = \frac{2G_c v_e}{v_m v_c} \quad \text{if } 0 \leq v_e \leq v_c \quad (17)$$

$$t_e = \frac{2G_c}{v_m} \left( \frac{v_m - v_e}{v_m - v_c} \right) \quad \text{if } v_c \leq v_e \leq v_m; \quad (18)$$

$$t_e = 0 \quad \text{if } v_e > v_m \quad (19)$$

It can be seen that the effective traction ( $t_e$ ) is a function of the effective opening displacement ( $v_e$ ) and is reversible until the critical effective opening displacement ( $v_c$ ) has been reached. The other parameters that define the failure behavior are the area under the traction-separation curve, which corresponds to the strain energy release rate ( $G_c$ ) and the maximum effective opening displacement ( $v_m$ ). The values for the moisture-dependent cohesive zone law parameters were derived from experimental work done by Liljedahl et al. (2005, 2007) using mixed mode flexure (MMF) tests, the moisture-dependent mechanical properties of the adhesive, and calibrated values using the load displacement plots from aluminum/adhesive FM73 (Cytac Engineered Materials Ltd.) single-lap joints. Moisture-dependent mechanical properties were also used for the carbon fiber-reinforced polymer (CFRP) adherend, together with a moisture-dependent Tsai-Wu failure criterion, although failure in the CFRP did not occur in the models, in agreement with the experiments.

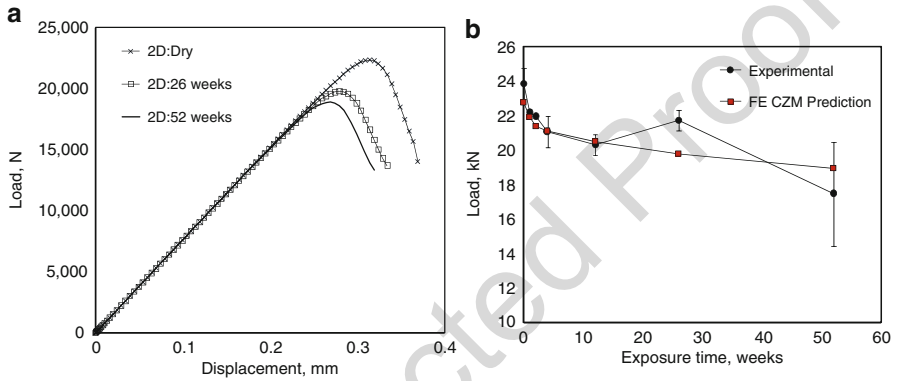

The predicted effect of 50 °C, 95% r.h. conditioning of the joint shown in Fig. 20 using the CZM discussed above is illustrated in Fig. 22. In Fig. 22a it can be seen that the failure load is predicted to decrease with conditioning time. A comparison of the predicted failure load with that measured experimentally can be seen in Fig. 22b. For exposure times up to 12 weeks, the CZM predictions show good agreement with the experimental failure loads. At 26 weeks, the failure load is underestimated and is within the large experimental error at 52 weeks. It is unknown whether the

**Fig. 20** (a) Dimensions of CFRP/Al double lap joint (b) typical FE mesh (Jumbo 2007)

experimental increase in strength at 26 weeks and subsequent decrease at 52 weeks are “real” effects or experimental scatter. The latter is more likely; in which case the predictions are probably as good as can be expected. Liu et al. (2016) used a similar approach for modeling the adhesive joint strength degradation in double-lap shear joints with carbon/epoxy composite adherends. The bilinear traction-separation law was degraded for the moisture-conditioned adhesive joints. Different degradation factors were used for the adhesive layer and the adhesive-adherend interface, where the interfacial layer was degraded using an extra factor. The degradation factors were determined using Eq. 20.:

**Fig. 21** Bilinear cohesive zone model

**Fig. 22** Effect of aging at 50 °C, 95% r.h. on (a) the load-displacement and (b) the failure load of a CFRP/Al/epoxy DLJ using CZM (Jumbo 2007)

$$T_H = T_0 \sqrt{\frac{\sigma_H}{\sigma}} f \quad (20)$$

where  $T_H$  and  $T_0$  are critical tractions with and without moisture absorption and  $\sigma_H$  and  $\sigma$  are ultimate tensile strengths of the adhesive with and without moisture absorption.  $f$  is the degrading factor used for the interface.

Jumbo (2007) also used the Gurson-Tvergaard-Needleman (GTN) CDM to predict failure in the same joints (see ► Chap. 23, “Constitutive Adhesive and Sealant Models”). This model was proposed by Gurson (1977) to model damage in elastic-plastic materials incorporating void formation, growth, and coalescence, leading to crack formation and failure, and was later extended by Needleman and Tvergaard (1984). This model is potentially applicable to damage prediction in rubber-toughened polymers, as the rubber particles are sites for cavity nucleation. The yield condition is defined as

$$F = \left( \frac{\bar{\sigma}}{\sigma_y} \right)^2 + 2q_1 f^* \cosh \left( \frac{q_2 \sigma_{kk}}{2\sigma_y} \right) - \left[ 1 + (q_1 f^*)^2 \right] = 0 \quad (21)$$

where  $\bar{\sigma}$  is the equivalent stress,  $\sigma_y$  is the yield stress of the matrix material, and  $\sigma_{kk}$  is the hydrostatic stress. The parameters  $q_1$  and  $q_2$  were introduced by Tvergaard to account for the effect of void interactions on the stress distribution between cavities but are usually derived from finite element calibration of experimental curves. Damage evolution is measured by the void volume fraction  $f$  which increases due to void nucleation and growth. Void nucleation is controlled by a normal distribution of stress or plastic strain, and the modified model replaces the void volume fraction  $f$  with the modified void volume fraction  $f^*$ . A rapid decrease in the load-carrying capacity of the material if void coalescence occurs is linked to  $f^*$ , such that

$$f^* = f \quad \text{if } f \leq f_c \quad (22)$$

where

$$f^* = f_c + \left( \frac{f_u^* - f_c}{f_F - f_c} \right) (f - f_c) \quad (23)$$

where  $f_c$  is the critical void volume fraction and  $f_F$  is the void volume at failure, and for most metals,  $f_u^* = 1/q_1$ . The existing value of the void volume fraction changes due to the growth of existing voids and the nucleation of new voids and is characterized by

$$\dot{f} = \dot{f}_{\text{growth}} + \dot{f}_{\text{nucleation}} \quad (24)$$

The growth of voids is given by

$$\dot{f}_{\text{growth}} = (1 - f) \dot{\varepsilon}_{kk}^p \quad (25)$$

For modeling purposes, plastic strain-controlled nucleation of void has been used and is given by

$$\dot{f}_{\text{nucleation}} = \frac{f_N}{S\sqrt{2\pi}} \exp \left[ -\frac{1}{2} \left( \frac{\varepsilon_m^p - \varepsilon_n}{S} \right)^2 \right] \dot{\varepsilon}_m^p \quad (26)$$

where  $f_N$  is the void volume fraction of forming particles,  $\varepsilon_n$  is the mean strain at which void nucleation occurs,  $S$  is the standard deviation,  $\sigma_n$  is the mean stress for void nucleation, and  $\sum = \bar{\sigma} + \frac{1}{3}\sigma_{kk}$ . When the material reaches 90% of the void volume fraction at failure,  $f_F$ , the material is considered to have failed, with the stiffness and of the failed element reduced to zero.

The property requirements for the model are

- Young's modulus and Poisson's ratio
- Moisture-dependent effective shear-hardening curves  $\sigma_o(\varepsilon_o^p)$ . The initial, critical, and failure volume fractions ( $f$ ,  $f_c$ , and  $f_F$ )

- The void interaction parameters,  $q_1$  and  $q_2$
- The volume fraction of nucleating particles  $f_N$
- The standard deviation and mean strain for void nucleation ( $S$  and  $\epsilon_n$ )

The direct experimental determination of some of these constants is difficult, leading to their determination by an iterative process using FE analysis. Hence, in Jumbo (2007), some of the model parameters were determined from experimental data and others by calibrations from FE analysis of a representative joint. The results are shown in Fig. 23. It can be seen that the 2D model slightly overpredicts the failure load but that a good agreement is seen with the experimental data with the 3D model. Comparing Figs. 22b and 23, it can be seen that the 3D Gurson model agrees well with the CZM.

### 31.5 Summary and Conclusions

It is often seen that the strength of adhesive joints decreases on aging in natural environments. This is usually because of the effect of environmental moisture, which is absorbed by polymeric adhesives and affects both the mechanical behavior of the adhesive and the interface between the adhesive and adherend. These effects are usually increased by increasing temperature or the application of stress. The effect on the interface is potentially the most damaging; however, this can usually be mitigated by the application of a suitable surface treatment prior to bonding. In this case it is often seen that the effects of absorbed moisture are largely reversible.

The effect of environment on adhesive joints is commonly investigated experimentally through accelerated aging tests in which joints are exposed to high temperature and humidity. This can provide a useful comparison of different systems but cannot be used to predict the performance of joints under actual service conditions. Currently, the best method of predicting the effect of environmental aging on the strength of bonded joints is through coupled hygro-mechanical finite element

**Fig. 23** Effect of aging at 50 °C, 95% r.h. on the failure load of a CFRP/Al/epoxy DLJ predicted using the Gurson CDM (Jumbo 2007)

analysis. The first stage in this method is to determine the moisture distribution in the joint as a function of time from a diffusion analysis. This is used to determine the spatial distribution of mechanical properties and the applied hygroscopic strain. A mechanical analysis is then used to determine the stresses in the joint as a function of aging time, and an appropriate failure criterion can be used to predict the residual strength of the joint as a function of aging time. This method is now well developed and has been validated for simple joints; however, further development and validation are required. It would also be useful to develop a software tool based on this method for the nonspecialist designer.

---

## 31.6 Further Information

The most comprehensive treatment of wet durability is Kinloch (1983). In this, Minford (1983) has compared wet durabilities of joints with phenolic and epoxide-based adhesives. Joints in aluminum have been reviewed by Brewis (1983), and Mahoon (1983) has dealt with titanium and Brockmann (1983) with steel. Reviews which have provided updates are those by Critchlow and Brewis (1995, 1996) which, respectively, deal with the surface treatment of titanium and aluminum and that by Armstrong (1997). A comprehensive comparison of accelerated aging and natural aging has been made by Ashcroft et al. (2001). Modeling the environmentally induced degradation of adhesively bonded joints has been reviewed by Crocombe et al. (2008). The effects of temperature and moisture on adhesives and adhesive joints have recently been reviewed by Viana et al. (2016b).

## Abstract

Adhesives are widely used on a spacecraft for several reasons. They allow a significant mass reduction and, using an adhesive allows. The combination of several properties (as the mechanical fixation and some electrical function). One of their main drawbacks is that they are organics and thus they react with space environment.

Among all the components of the space environment which could lead to material degradations, the three most important are the energetic charged particles (protons and electrons particles with different fluxes and energies), the electromagnetic radiation from the direct solar flux (and most specifically in the Ultra Violet wave length) and the Atomic Oxygen (ATOX) coming from the photo-dissociation of the oxygen molecules of the atmosphere by the solar

[denis.lavielle@airbus.com](mailto:denis.lavielle@airbus.com)

electromagnetic radiation. These factors lead to physicochemical degradation of the adhesives, which can affect their functional properties.

All the adhesives used in spacecraft have to be validated on ground before launch and their behavior in space environment must be evaluated. Test facilities are developed to simulate charged particles, UV, and ATOX constraints. Even if it is not possible to be 100% representative of the in-orbit conditions, tests, methodologies and specifications exist to correctly evaluate the degradation and to take into account the adhesives end of life properties, in the spacecraft design.

Atoms and molecules along the charged particles trajectory can be either excited or ionized. The primary effects are generally deformation, embrittlement, and discoloration, which impact the mechanical integrity of the adhesive. The modification of mechanical properties is generally the result of the competition between chain scissions and crosslinking in the macromolecular chains.

The main UV effect on adhesives is generally a degradation of their optical properties (e.g., solar cell cover glass). Indeed, during the interaction of a photon with an atom or a molecule of the material, the photon can either be absorbed or diffused with possible loss of energy. These photochemical effects may result in a change of color of the material, leading to an increase of solar absorptance.

Atomic Oxygen might also have detrimental effects on adhesives, mainly erosion of surfaces and oxidation.

---

## 32.1 Introduction

Spacecrafts and space systems in general significantly evolved till the first systems launch into orbit in the years 1960. The missions evolved and it is now required to have more and more power and function accessible for the telecommunication spacecraft as for the earth observation or scientific missions.

These missions' new developments and needs lead to a significant increase of the spacecraft sizes and masses. Due to launchers constraints, it is now required to optimize as much as possible the satellites design and all the parts and equipments are reduced and accommodated to limit their mass. Taking into account these constraints, it is not possible any more to have spacecraft mainly composed of metallic materials which strongly behave in the specific space environment. Polymers and composite materials used in space systems were thus more and more developed and current satellites hold various organic materials for various applications. Among all these organic materials, the adhesives are widely used including for external applications on the satellites and can thus be fully exposed to space environment.

In parallel of this mass reduction objective, space missions' durations are extended and satellites shall now withstand more than 15 years in orbit without degradation of their functionality. The reliability of all the satellites parts have to be demonstrated on ground before launch. Among all the parameters to be evaluated, the behavior of organic materials (including adhesives) to space environment is a driver in the spacecraft design. Indeed, the materials in orbit are submitted to various

**Fig. 1** Illustration of the satellites evolution. First spacecraft in orbit, Sputnik (*left*) and a recent telecommunication spacecraft (*right*)

constraints such as radiations of charged particles, ultraviolet, Atomic Oxygen... (Fig. 1).

The following chapter address the behavior of adhesives in space environment and is thus composed as follows.

In the first part of this chapter, a description of the typical uses and needs related to adhesives on spacecraft is given. Then, the specificities of the space environment are explained. Once in orbit, the adhesives have to withstand constraints as particles radiations, UV, and Atomic Oxygen (ATOX) that are not present on Earth.

Depending on the mission, the location and the adhesive use on the spacecraft, these constraints can vary a lot.

Before spacecraft launch, the adhesives have to be validated and tested on ground with conditions as representative as possible of the space environment. In this chapter, the testing methodologies are detailed.

Finally, the impact of this space environment on adhesives and the associated degradations are developed. The degradation mechanisms and the effects of the irradiation on the adhesive macroscopic properties are presented.

---

## 32.2 Adhesives Used in Space Programs

Adhesives are widely used in space applications for many different applications. This material family combines several properties which are really important for space programs:

- They allow durable bonding of dissimilar materials (e.g., polymer/metal, composite/metal, etc.)
- They allow significant mass reduction for mechanical fixation compared to traditional screws or rivets. This mass reduction is generally a driver for a domain where each gram avoided is important.
- Some adhesive families allow a use in an extended temperature range, which can be of high interest for external areas of the spacecraft. On spacecraft solar

**Fig. 2** Adhesives used for space applications should have low-outgassing levels. They shall withstand space environment harsh constraints: extreme temperatures, high vacuum, UV and radiation environment, and/or Atomic Oxygen

arrays, temperature excursions can reach  $-180\text{ }^{\circ}\text{C}/+180\text{ }^{\circ}\text{C}$  as illustrated in Fig. 2.

- The combination of several properties (mechanical fixation and electrical grounding as an example) is finally an advantage for spacecraft's design optimization.

The main use of adhesives on a space instrument or a spacecraft is the mechanical fixation. Adhesives shall withstand important loads due to the spacecraft launch (vibration and acoustics constraints). Once in-orbit, the most significant mechanical loads are shocks due to deployment of subassemblies (e.g., solar arrays, antennas). Another critical parameter is the large variation of materials thermal expansions which can be observed due to the important temperature ranges (typically between  $-180\text{ }^{\circ}\text{C}/+180\text{ }^{\circ}\text{C}$  for external appendices). This might induce thermomechanical deformations.

Therefore, impact of space environment on mechanical properties is mandatory to assess the acceptability for the use of adhesives on spacecraft structures. The mechanical design of structural adhesive joints is driven by mechanical loads during on-ground tests and launch. The ageing during operational in-orbit lifetime is driven by thermomechanical loads, as no vibration loads comparable to the launch loads exist.

In addition to its mechanical function, an adhesive could also be used for its electrical or thermal properties. Indeed, adhesives loaded with conductive fillers allow the grounding of most of the spacecraft parts. On the contrary, adhesives could

**Fig. 3** Examples of adhesive use on spacecrafts: bonded stand-off for MLI (multilayers insulation) blankets mechanical installation on spacecraft structure (*left*), optical surface reflectors bonded on spacecraft structure for thermal control purpose (*middle*), electronic PCB proceeds through “touch up” after completing frame bonding, which uses a new automated adhesive dispensing process (NASA.gov image) (*right*)

be also be used as varnish or conformal coating for electrical insulation purposes (see Fig. 3). When applied for the bonding of thermal active parts, as heatpipes, thermal conductivity of the adhesive is a driver to guarantee the thermal efficiency of the component onto the structure. The same advantage is foreseen in electronic assembly, as the ability of thermally conductive adhesives helps dissipating heat as more and more power dissipating components are mounted on PCB.

Finally, the optical properties of some adhesives are used on space systems. The most relevant example consists in transparent adhesives used for the bonding of the solar cells cover glasses. The evolution of the transmission properties of the adhesive (yellowing due to interaction between adhesive and radiations and UV) is a driver in the solar arrays design and sizing.

Even if adhesives are advantageous for some applications, they also present drawbacks for space applications. As they are organic products, their properties are modified during the spacecraft in-orbit life, due to exposure to space environment (and more specifically radiation and UV). Moreover, the adhesives are submitted to vacuum once in orbit and their volatile components outgas. This can be a major constraint for missions where the outgassed components could lead to the molecular contamination of the instruments optics, degrade their optical properties, and reduce the instruments performance.

Therefore, the validation on ground of adhesive behavior to such constraints is performed through dedicated and specific test campaigns.

Several adhesive chemical families are used in spaces programs. Among all of them, the most used are the epoxies for their mechanical properties, silicones for their good behavior to thermal environment, acrylics (generally used as tapes), and polyurethanes.

As space industry represents a relatively reduced commercial amount compared to other industrial sectors, it is not possible to develop specific adhesives for each application. Most of the adhesives used on a spacecraft are therefore commercial products nevertheless, for some really specific applications, developments are performed to cover a dedicated mission and the adhesive formulation can be adapted to be more resistant to space environment.

### 32.3 Environment Specification

The space environment represents a harsh medium for all spacecraft. Proper assessment of the potential effects is an essential part of the engineering process leading to the qualification of any element of the spacecraft (Space weather effect catalogue). As defined in ECSS Standard (ECSS-Q-ST-10-04C), the natural space environment of a given item corresponds of environmental conditions defined by the external physical world for the given mission.

The main components of the space environment that can lead to material degradations are:

- Meteoroids and debris
- Galactic cosmic rays (GCR)
- Solar energetic particles (SEP)
- Photons, from the  $\gamma$  rays to the radio frequency
- The solar wind
- Atomic Oxygen

Whereas debris and micrometeorites can induce instantaneously damages in the materials, the remaining constraints can be assimilated as ageing factors. In that latter cases, the cumulative effect of these constraints lead to progressive degradation of the materials all along the mission duration. In this chapter, we will focus on the effects of UV, particle radiations, and Atomic Oxygen (ATOX).

A spacecraft receives electromagnetic radiation originating from the direct solar flux. The solar spectrum can be divided as follows in several parts depending on the wavelength range considered:

- Soft X-rays or XUV (0.1 nm–10 nm)
- Extreme ultraviolet or EUV (10 nm–121 nm)
- Ultraviolet or UV (100 nm–400 nm)
- Visible or VIS (380 nm–760 nm)
- Infrared or IR (0.70  $\mu$ m–1 mm)

In general, for material testing, the spectrum used for solar simulation is limited to the UV region because, although this band is responsible for only 1% of the total solar irradiance, it is assumed that the major degradation of the materials is due to these photons.

The second type of radiation leading to potential degradation of the materials is particle radiation. Energetic charged particles are encountered in interplanetary space and in the magnetospheres of moons or planets. There are different types of particles, coming from different origins. The main ones are:

- The cosmic rays, entering the solar system from the interstellar medium and composed of protons, electrons, and fully ionized nuclei. Their energy remains in the GeV to TeV range.

- 187 – The solar energetic particles, originating from Sun flaring or from shock waves  
188 associated with coronal mass ejections, consist of protons, electrons, and heavy  
189 ions with energies from a few tens of keV to GeV ranges.
- 190 – The solar wind, which is part of the Sun's outer atmosphere expanding outwards  
191 and composed mainly of protons, electrons, alphas with an energy range between  
192 few eV and few keV.

193 Although the energy of the cosmic rays and the solar energetic particles are much  
194 higher than the ones of the solar wind or of the particles within the radiation belts,  
195 their flux are relatively low and thus their contribution to the material degradation is  
196 negligible. Conversely, this type of radiation (cosmic rays and solar energetic  
197 particles) are a major concern for electrical components as it can induce so called  
198 single event that could lead to their dysfunction or their destruction.

199 Geomagnetic fields of the planets or the moons influence the energetic particles  
200 and can also induce specific radiation environments. The particles coming from the  
201 interplanetary medium are trapped in the magnetic field and then accelerated along  
202 the field lines depending on their polarization. Thus, radiations belts are created  
203 around the planets or moons.

204 Around the Earth, these radiation belts are also called Van Allen belts. They are  
205 composed of an inner and an outer belt and extend from typically 100 up to  
206 65,000 km. These belts are mainly constituted of protons (with energies up to  
207 hundreds of MeV) and electrons (energies up to few MeV) coming from the  
208 solar wind.

209 As illustrated in Figs. 4 and 5, depending on its orbit (Low-Earth Orbit, Medium-  
210 Earth Orbit, Geostationary-Earth Orbit), the satellite will be submitted to different  
211 particles flux and energies with the Van Allen belts.

**Fig. 4** Radiation belts  
illustration (<https://www.britannica.com/science/Van-Allen-radiation-belt>)

**Fig. 5** Space radiations belts for the satellites different orbits ([https://www.nasa.gov/mission\\_pages/sunearth/news/gallery/20130228-radiationbelts.html](https://www.nasa.gov/mission_pages/sunearth/news/gallery/20130228-radiationbelts.html))

Whereas the LEO missions, characterized by a spacecraft altitude below typically 1000 km, are located below the inner belt and are submitted to relatively low particle radiations, GPS or GEO missions are inside the outer belt and submitted to higher particle fluxes, leading to significant dose levels compared to LEO ones. Additionally, in the outer belt, the fluxes of low-energy particles are higher than in the inner belt, leading to an increase of the deposited dose within the external materials, directly exposed to space environment.

In the case of interplanetary missions, specific radiation environments shall also be considered. As an example, in the case of Jovian missions, during the cruising phase between the planets, the spacecraft will be mostly submitted to solar wind but also to radiations belts of Jupiter or its moons (Ganymede, Europa, etc.), characterized by important fluxes of highly energetic electrons.

Missions towards the Sun are also exposed to very specific environments. The probes are exposed to very high flux of solar wind particles together with high temperatures, leading to potential synergistic effects.

Another component of the space environment able to induce degradation of the materials is Atomic Oxygen. These atoms are generated during the photo-dissociation of the oxygen molecules of the atmosphere by the solar electromagnetic radiation (mainly short wavelengths,  $\lambda < 243$  nm), leading to the breaking of the diatomic bonds (NASA-HDBK-6024). These atoms are very reactive and can interact with the spacecraft materials through oxidation mechanisms.

Atomic Oxygen is present around Earth but can also be produced in other planetary environments, such as the Mars orbital environment, where oxygen is present.

## 32.4 Testing

### 32.4.1 Adhesives Testing Methodology

As a general rule, any technology used on a spacecraft has to be qualified with regards to functional and environmental constraints.

For adhesives, this rule is also applicable. Therefore, for each adhesive application, a test plan is set up to finalize the different functional and environmental stresses that need to be verified on ground to validate further space application.

The main applications for adhesives in space are either structural (up to a certain extent for general purpose adhesives) or electrical for grounding adhesives or optical (to bond glasses or transparent materials) as already mentioned in ► Chap. 4, “Wetting of Solids.”

Due to the stringent space environment, many environmental stresses are to be considered both before launch (long-term storage) and after launch for the mission (vacuum, radiation, temperature cycling, etc.). All these stresses are mission dependent and are analyzed on a case by case basis even if general guidelines are driven by ECSS standards (ECSS-Q-ST-70-06C).

The adhesives qualifications generally consist in two levels:

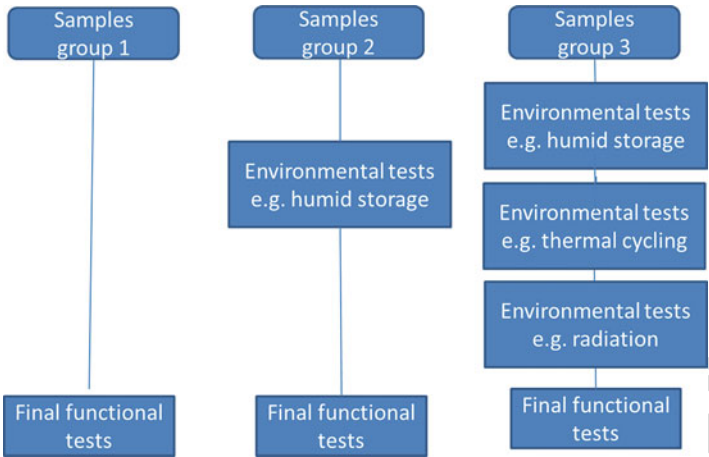

- A test campaign on samples. Samples are processed in order to evaluate the adhesive properties evolution before and after accelerated ageing.
- An overall validation at equipment and system level. Specific tests campaign could be performed on new development on spacecraft to qualify the bonding against vibrations and mechanical constraints representative of the launch campaign. (e.g., vibration, shock, etc.). This addition of some other stresses can reveal any potential weak points in adhesive use.

In all cases, functional studies (mechanical, thermal, electrical, etc.) are performed to determine the limits of the tests to be performed on test samples to validate the mission profile.

However, in terms of risk mitigation, the major part of the qualification is performed at sample level.

The general principle of the test campaign on adhesive samples is described in Fig. 6. The test flow-chart is composed of different branches:

- One set of reference samples (not experiencing any stress)
- Several sets of stressed samples that combine conditions to simulate the mission profile

**Fig. 6** Test campaign typical flow chart at adhesive samples level

A typical example of such a test program is represented in Fig. 6 where the central branch simulates storage conditions and the right branch cumulated storage and mission profile.

At the end of the program, both reference samples and stressed samples are functionally tested and final values are compared to reference ones.

The characterization tests are defined to be representative of the relevant properties. Mechanical tests as shear test or peeling can be performed if the adhesive is used for parts fixation. Electrical or optical measurements could also be done.

In function of the need, functional tests could be performed which aim to validate the macroscopic use of the adhesive. More detailed characterizations tests could be performed to understand the degradation phenomena which occurred in the material (DSC, RMN, etc.).

Generally, the test plan includes a success criteria based on an acceptable functional change before and after submission to environmental tests (typically 20% decrease for a mechanical strength decrease).

Among all the constraints seen by an adhesive on a spacecraft, the specific behavior to radiations, ATOX and UV has to be analyzed and validated by tests on ground.

**32.4.2 Test Facilities**

**Radiations**

For the specific radiation validation, as mentioned in Sect. 5, the best approach is to simulate as close as possible on ground the expected radiation mission constraint.

For particle radiation, particle accelerators (protons, electrons) are generally used to irradiate the samples. Parameters like particles, flux, vacuum conditions (to remove potential oxygen related bleaching) are key parameters to consider.

**Fig. 7** Example of calculated real total ionizing dose (TID) depth curve and ground irradiation dose profiles

Also, when characterizing materials in space, it is important to simulate the total ionizing dose profile expected in the material.

This dose is expressed in Grays or in rads (1 Gray = 100 rads): 1 Gray corresponds to the absorption of 1 Joule per kg of matter.

As explained in Sect. 5, in space, the resulting dose profile is due to a combination of different particles (nature, energy, and flux). It is not possible to reproduce on ground the exact combination but an appropriate choice of several particles with dedicated energies allows approaching the flight conditions as illustrated in Fig. 7.

In low-earth orbit missions, the spacecraft external dose is generally quite low, in the range of  $5 \times 10^5$  Gy on surface materials (typical order of magnitude). However, for geostationary missions, surface dose as high as  $1 \times 10^9$  Gy can be obtained and dose in the range of a few MGy can be achieved below a small shielding.

In adhesives directly exposed to external environment, the dose level decreases quickly when penetrating within the materials.

The use of Co60 (Cobalt 60 – gamma rays) exposure leads (due to gamma photons/matter interaction) to flat dose profile energy deposition. In that case, as the dose deposited within the material thickness is homogeneous, it is not possible to reproduce a dose profile and a dose level is applied, leading to an under/overexposure of the tested sample depending on the set parameters.

For bulk materials (and low radiation levels), Co60 exposure might be used provided it is representative of the expected in orbit conditions (heavily shielded material with typical aluminum shielding thickness higher than 5 mm, and dose contribution mainly related to Bremsstrahlung effect).

To simulate the dose profile on ground, particles accelerators like Van de Graaff are generally used with energies lying from a few tens of keV to a few MeV for

protons and few hundreds of keV to a few MeV (typically 3 to 5) for electrons. Ion implanters can also be used for low energy protons (up to a few hundred keV).

Generally, homogeneous irradiation surfaces are of the order of 50 mm × 50 mm up to 200 mm × 200 mm.

Fluxes used in the radiation tests are limited to a typical range of  $1 \times 10^{12}$  particles/cm<sup>2</sup>/s. When the flux is too high, a temperature increase can occur on the samples and change drastically the radiation behavior with regards to future mission conditions. This phenomenon is particularly true for organic materials as this temperature increase lead to the overrun of the glass transition. Generally, fluxes in orbit are a few orders of magnitude lower and radiation exposure last up to 15 years instead of a few hours or days for on-ground simulation.

Therefore, fluxes shall be a compromise between representativeness and test duration.

On some accelerators, secondary vacuum conditions are achievable or use of flowing Nitrogen gas is also acceptable (leading to absence of oxygen). For low energy protons (up to a few hundred keV), irradiations under secondary vacuum conditions are mandatory to avoid any interaction of particles with air molecules.

## UV

In general, the spectrum used for solar simulation is limited to the UV region, because it is assumed that the major degradation is due to these photons (ECSS-Q-ST-70-06C)].

For UV irradiation, one constraint is to simulate as close as possible the external atmosphere solar spectrum. Indeed, for organic materials like adhesives, specific wavelength, specific to extra-atmospheric solar spectrum could have a specific effect on materials degradation (low wavelength and high energy).

Xe-based lamp can generally be used in this case. The xenon lamp spectrum differs from all solar spectra because of the intense line output in the 800–1100 nm region. The use of specific filters allows the reduction of the mismatch and provides the closest spectral match to solar spectra.

Another constraint is to limit the acceleration factor. If not controlled, temperature as high as 200 °C can be reached quickly (especially under vacuum) at samples level and lead to thermal degradation not representative of real in orbit degradation.

Finally, vacuum conditions during exposure are important to make sure that no specific gas absorption will occur (decreasing the spectrum part at low end) and allowing oxygen residues interaction with material surface.

To do a space simulation in a reasonable time, it is required to accelerate the irradiations as fast as possible without modifying the degradation mechanisms which could induce wrong results. This problem is that of the reciprocity principle of equivalent sun hours (ESH). When using a nonfiltered Xenon light source, an acceleration factor limitation to 3 is recommended (ASTM E512) in order to limit the thermal charge on the materials.

In order to apply a higher acceleration factor, Xenon sources with specific filters can be used. These filters allow the removal of the visible and infrared part of the spectrum (see Fig. 8). Thus samples are only exposed to UV radiations leading to a thermal charge reduction by a factor of 10 (see Fig. 9).

**Fig. 8** Example of one UV simulation compared to Thekaekara spectrum

**Fig. 9** Typical output spectral distribution of AM 0 Simulators normalized to the ASTM E490 standard spectrum by matching total power density from 250–2500 nm (<https://www.newport.com/n/solar-simulator-spectral-irradiance-data>)

### Degradation Estimation

The solar constant is defined in (ECSS-Q-ST-10-04C) as the radiation that falls on a unit area of surface normal to the line from the Sun, per unit time, outside the atmosphere, at one astronomical unit (1 AU = average Earth-Sun distance).

In the case of ultraviolet radiations, it is estimated that the degradation is a function of the solar illumination in the UV (wavelengths typically between 200 and 400 nm), expressed in  $\text{W.m}^{-2}$ . This illumination is also usually expressed in space technology by the number of equivalent sun hours (ESH), which, for GEO environment, is equal to the UV part of the solar spectrum integrated over 1 h:

$$1 \text{ ESH} = 108 \times 3600 = 3.888.10^5 \text{ J.m}^{-2} \quad (1)$$

where  $108 \text{ W.m}^{-2}$  represent the integrated flux on the UV range of the solar spectrum.

### Equation 1: Definition of an ESH (Equivalent Sun Hours)

As an example, over 1 year (8760 h), GEO satellite materials, depending on their location on the spacecraft, can be exposed up to 2500 ESH per year.

Note that simulation tests in laboratory specify that the tested material will have to be irradiated with the same number of UV ESH and the same spectral distribution as the material in the specified mission conditions. It has to be noticed that the solar spectral distribution is very difficult to completely reproduce in laboratory. The difference can conduct to bad interpretation of the importance and/or nature of the degradation.

### ATOX

The Atomic Oxygen Simulators that are used around the world, depending on the energy of the Atomic Oxygen fluxes, can be divided into thermal and hyperthermal. The basic physical processes used for those sources are supersonic expansion, laser detonation, ion neutralization, electron-simulated desorption, and photo-dissociation (Kleiman et al. 2003).

One of the most representative technologies for materials testing applications was shown to be the laser-sustained discharge sources, where lasers are used to produce a high-temperature plasma that is subsequently expanded in a free jet or supersonic nozzle to produce a high-velocity neutral beam. Such sources have been demonstrated to produce beams of the desired velocity of  $8 \text{ km.s}^{-1}$  at flux levels of  $1017\text{--}1018 \text{ cm.s}^{-2}$ , i.e., exhibited both the appropriate energy for LEO simulation and high flux required for accelerated testing.

The cost and limited availability of materials test time in these high-quality LEO environment simulators has generated considerable interest in the use of thermal energy oxygen atoms produced by plasma asher for materials testing (Banks et al. 2013). This type of facility can be operated easily at low cost. However, the main drawback is the lack of representativeness with major differences in terms of variations in species, energies, thermal and radiation exposures, all of which may result in different reactions and erosion rates.

However, due to the variety and complexity of the differences between the LEO Atomic Oxygen environment and ground laboratory simulations, differences exist which have not allowed the development of a simple relationship or proportionality between the LEO and ground laboratory erosion yields. Two of the most significant differences between most ground laboratory and LEO environments are the energy and directionality of the Atomic Oxygen.

### Specific Test Facilities

Some laboratories have developed for decades a specific test facility that combines particle irradiation (electrons/protons) and UV irradiation under secondary vacuum. In addition, in-situ measurements like thermo-optical measurements can be performed before re-exposure of the samples to ambient atmosphere.

Typical exposure areas are here again around 50 mm × 50 mm up to 200 mm × 200 mm. Cooling systems (coupled to sample back surface to limit temperature increase) are used for sample temperature regulation.

Acceleration factors in the range of 10–50 are generally proposed and exposure of a few years in orbit can be simulated in a few days or weeks.

In terms of acceleration, it is important to note that the acceleration factors for UV and particle irradiation, even if tested in the same facility, are about different values. However, the same rule applies to not overstress the samples by a too high acceleration factor leading to too high temperature increase of the samples that would generate appearance of nonrepresentative ageing mechanisms.

---

## 32.5 Impact of Space Environment on Adhesives

### 32.5.1 Degradation Mechanisms

In the case of polymers, radiation effects have been extensively studied (Makhliis 1975; Paillous 1993). The difference must be done between charged particles (electrons, protons, heavy ions), which energy (from 1 keV to several MeV) is sufficient to excite and ionize molecules and UV photons but is insufficient to ionize them (excepted for far UV).

Indeed, ionization occurs when the incident energy of the particle is sufficient to overcome the binding energy of electrons in atoms or molecules, thus creating ions. On another hand, excitation occurs when the incident energy is not sufficient to ionize molecules but can create excited intermediate electronic states (triplets, singulets, color centers), by the excitation of the molecule and the transfer of an electron from a fundamental state to an excited state.

This can be summarized for a molecule AB by:

– Excitation  $AB \rightarrow AB^*$

– Ionization  $AB \rightarrow AB^+ + e^-$

We present here both effects of ultraviolet and charged particles, as these components of space environment contribute to the degradation of adhesives.

The effect of Atomic Oxygen (ATOX) are also presented.

An important point to be considered is the thickness of the degraded zone for each parameter.

In the case of ultraviolet radiations, the effect depends on the absorption of the material:

- For low absorbent materials in the considered wavelengths, the degradation can apply at high thickness,
- For high absorbent materials, the damage will be limited to more superficial effects.

The difficulty to evaluate the degraded zone is that the degradation generally appears as a change of the absorption properties of the material, the material becoming more absorbent. The consequence is a limitation of the degraded thickness as the irradiation persists.

In the case of charged particles, electrons and protons have to be distinguished, as their stopping power in matter is different. Depth penetration in matter, and thus degraded thickness, is far more important for electrons than for protons: a few microns for protons to compare with several hundred of microns to millimeters for electrons.

In this section, the degradation of the polymer matrices due to radiations is mainly considered. Nevertheless, as a function of the specific use of the adhesive, the degradation of the loads can also be important.

## Ultraviolet

During the interaction of a photon with an atom or a molecule of the material, the photon can either be absorbed or diffused with possible loss of energy. In space environment, the solar electromagnetic spectrum covers wavelengths from  $10^{-4}$  to  $10^4$   $\mu\text{m}$ , with a spectral distribution close to a black body at 5762 K. The total energetic flux (called the solar constant) is  $1366 \text{ W.m}^{-2}$  (ASTM E490). However, the degradation of materials is mainly due to the ultraviolet radiation, with wavelengths lower than 0.4  $\mu\text{m}$ . The energetic flux in this range is  $118 \text{ W.m}^{-2}$ .

Two phenomena can be distinguished, depending on the wavelength:

- $0.2 < \lambda < 0.4 \text{ } \mu\text{m}$ : the energy of ultraviolet photons is between 3.1 eV at 0.4  $\mu\text{m}$  and 6.2 eV at 0.2  $\mu\text{m}$ . This energy is not sufficient to ionize molecules but can generate excitation.
- $\lambda < 0.2 \text{ } \mu\text{m}$ : the energy of the photons is sufficient to ionize molecules, leading for example to scissions or crosslinking in polymer chains.

These photochemical effects may result in a change of color of the material, increase of solar absorptance and/or loss of mechanical properties.

**Charged Particles**

The energy of charged particles in space environment is usually between 1 keV and several MeV. Atoms and molecules along their trajectory can be either excited or ionized.

In the case of an ionization, the secondary electron, liberated during the primary interaction between the charged particle and the matter, can have sufficient energy to leave the site of the primary interaction and produce new excitations and ionizations along its trajectory, before being thermalized and absorbed at a few hundred angstroms from the primary interaction site (see Fig. 10). The reactions held on the track of the secondary electron are often grouped and form clusters, responsible for the chemical modification of the material.

If the secondary electron is not sufficiently energetic, it can be recaptured by the parent ion to form an excited molecule or a free radical. A free radical can recombine with the material to form the initial material or can diffuse around the interaction site, leading to the formation of new chemical products. This can be particularly important for contamination aspects. Indeed, the materials outgassing is controlled on space programs as it can degrade the nearest instruments (such as telescope) properties.

Consequently, if we consider that the nature of the created species only depends on the interaction with secondary electrons, then, it is independent of the nature of the radiation. On the contrary, the spatial distribution of the created species will depend on the radiation. In the case of protons, the primary track is linear and the defects are distributed in dense clusters very close to the track. In the case of

**Fig. 10** Distribution of ions and excited molecules along the trajectory of a rapid electron (Clegg and Collyer 1991)

electrons, the effects will be more dispersed because of the scattering of the particles in matter. Moreover, the difference of mass between electrons and protons induces different stopping powers and penetration depths in matter.

In the case of charged particles, it is generally estimated in a first approximation that the degradation is a function of the quantity of reactional intermediates (excited molecules, free radicals, etc.), then a function of the dose of energy which is absorbed in the material.

## ATOX

Atomic Oxygen can react with polymers, carbon, and many metals to form oxygen bonds with atoms on the exposed surface. For most polymers, hydrogen abstraction, oxygen addition, or oxygen insertion can occur. With continued Atomic Oxygen exposure, all oxygen interaction pathways eventually lead to volatile oxidation products. This results in gradual erosion of hydrocarbon or halocarbon material. Silicone materials, a family of commonly used spacecraft materials, are an exception to polymeric materials that erode away with Atomic Oxygen exposure. With Atomic Oxygen exposure, oxidation reactions cause the surface of silicones to oxidize and volatilize their hydrocarbon content and convert to a hardened silica-based surface layer, which is resistant to Atomic Oxygen erosion.

ATOX effects can be important on space materials and it is thus important to know it. However, this will not be discussed in details as adhesives are generally shielded from direct exposure to Atomic Oxygen, and they are not affected by this space environment factor.

## 32.5.2 Irradiation Effects

### Mechanical Properties

Change in mechanical properties is particularly critical in the case of polymers. Both UV and particles can damage polymers.

The primary effects are generally deformation, embrittlement, and discoloration, which impact the mechanical integrity and the thermal equilibrium of the material. These effects are determined by measurement of changes in lap shear strength, tensile strength, peel test or fatigue tests following irradiation.

The modification of mechanical properties is the result of the competition between chain scissions and crosslinking in the macromolecular chains. Scissions are ruptures in the macromolecular chain and lead to a diminution of the elastic and the resistance limits and an increase of the elongation capability. On another hand, crosslinking consists in the formation of new transversal bonds in the macromolecular chain: the polymer becomes two- or three-dimensional. This contributes to an increase of the resistance limit but a diminution of flexibility, the polymer becoming more fragile. The crosslinking is illustrated on silicone rubbers through several studies (Zhang et al. 2006; Jochem et al. 2013). After 200 keV proton irradiation up to a fluence of  $10^{15}$  p<sup>+</sup>/cm<sup>2</sup> or 400 keV electron irradiation up to a fluence of  $3.10^{15}$  e<sup>-</sup>/cm<sup>2</sup>, the network densifies, which leads to an increase of the glass

**Fig. 11** Cracks in an epoxy adhesive foil after irradiation

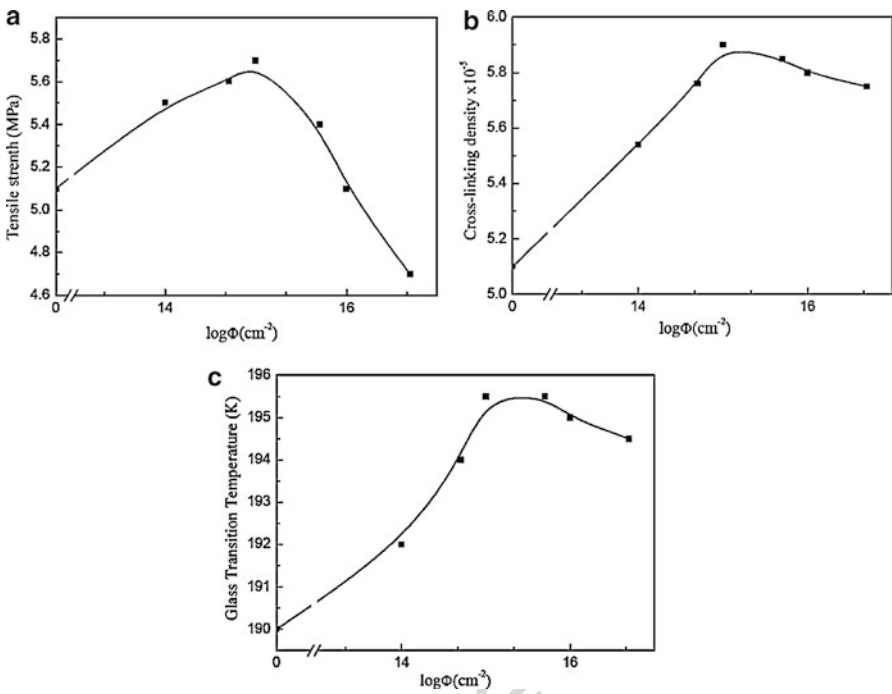

**Fig. 12** Illustration of the mechanical properties degradation (shear strength) on an acrylic adhesive before and after electrons irradiation

transition temperature of a few degrees, an increase in tensile strength and an increase of the modulus. All these changes reflect the increase of the macromolecular chain rigidity after irradiation. Even if protons penetrate less than electrons, the effects of the irradiation are similar and can be detected on the bulk material properties (see Figs. 11 and 12).

At higher doses, the competition between crosslinking and chain scission is in favor of the second one, resulting in a degradation of the polymer. As the crosslinks density decreases, the tensile strength also decreases and surface cracks are initiated as a result of the backbone chain length reduction (Fig. 13).

Few studies are available on epoxies used as adhesives, as they are generally protected from direct environment exposure and they are known to be very resistant to radiation from a mechanical point of view. When epoxies are used as a matrix for

**Fig. 13** Evolution of properties of a silicone rubber versus proton irradiation fluence: tensile strength (*left*), crosslinking density (*middle*), glass transition temperature (*right*) (Zhang et al. 2006)

composites in structural applications, plasticization of the polymers at elevated temperatures increases residual deformations in the material structure, while at low temperatures, embrittlement of the polymer, repeated from cycle to cycle, multiplies the effect of microcracking and changes of the composite's properties. Depending on the delta-CTE between the matrix and the fiber, the additional microcracking due to radiation degradation may be of second order compared to the effect of thermal cycling only as described in Fig. 14 (Paillous and Pailler 1994).

**Optical and Thermo-Optical Properties**

The macroscopic effect of the degradation of polymers is a change of color of the material, which is coming from the chemical reactions in organic molecules (bond breakage or crosslinking).

It is known that UV radiation can darken optical adhesives and coatings. In this regard, silicones are superior to epoxies. An example is given in Fig. 15 (Fisher et al. 2013). The UV irradiation of several silicone adhesives used for bonding solar cells on panels show a coloration of the glue, which is favored by the creation of crosslinks.

Charged particles may also lead to discoloration of adhesives. Depending on the particles energy, the effect can be observed in the bulk material (Fig. 16).

**Fig. 14** Example of typical microcracking evolution: effect of thermal cycling (*left*) and effect of a combined thermal cycling and GEO-simulated environment (*right*) on two different epoxy adhesives. In this example, the Epoxy A is affected by thermal cycling and radiations while the Epoxy B is only affected by radiative environment

**Fig. 15** Silicone glues used for the assembly of solar cells: Picture of sandwiched samples (coverglass/glue/coverglass) after UV exposure under vacuum using the ESTEC SUV facility, (a) Elastasil S 690, (b) Elastosil S 695, (c) Dow Coming DC 93-500 (Fisher et al. 2013)

An increase of the solar absorptivity can also be observed for polymer adhesive tapes, which can be critical if they are used for satellite thermal control purposes where specific optical properties are needed. Generally, this change is mainly attributed to the polymer substrate, with a slight contribution of the adhesive. As for example, the comparison between 3 M™ 92 (kapton®/silicone) and Permaccel P-224 (kapton®/acrylic) after combined UV and charged particles irradiation shows a slightly higher degradation of the silicone tape, due to the difference in the absorption properties of the adhesive (Marco et al. 2009) (see Fig. 17).

**Fig. 16** Silicone bulk adhesive evidence of color change before and after charged particles irradiation (strong darkening)

**Electrical Properties**

Changes in the electric conductivity have already been observed on materials after irradiation. This phenomenon results from the interaction of the charged particles of the space environment with materials and is very complex. It depends on the initial electrical conductivity (in surface and in volume), the secondary emission, and the photoemission of the material. In some cases, the accumulation of charges at the surface of the material can be followed by electric discharges and electromagnetic emission, which alters the material locally and can affect the good functioning of electronic equipments.

Epoxy adhesives have generally a good behavior with respect to radiation environment. The irradiation at high-radiation doses has however an effect on the bulk conductivity of epoxies. On Scotch-Weld™ DP490, a decrease of the bulk conductivity can be observed from  $10^{-14} \Omega^{-1} \cdot m^{-1}$  for epoxy pristine samples to  $2 \cdot 10^{-15} \Omega^{-1} \cdot m^{-1}$  after 400 keV electrons irradiation (up to  $10^6$  Gray) (Siegel and Stewart 1969). Indeed, at such dose level, high energy radiation can induce physicochemical ageing which tends to lower ionic transport and therefore the overall bulk conductivity.

**Fig. 18** Arrhenius plot of  $\sigma_{DC}$  as measured by surface potential decay method on irradiated silicone samples: without fillers (open symbols  $\circ, \square, \Delta$ ) and with fillers (filled symbols  $\bullet, \blacksquare, \blacktriangle$ ). Corresponding values of temperature and  $\sigma_{DC}$  are displayed on the upper x-axis and right-hand y-axis, respectively. Arrhenius fits of data are represented by dashed lines (Lewandowski et al. 2016)

Silicone adhesives irradiated in similar conditions (400 keV electrons, up to  $1.4 \cdot 10^6$  Gray) also reveals a decrease in the electrical conductivity (Lewandowski et al. 2016). The behavior of the adhesive is affected by the presence of the inorganic fillers in the formulation, which contribute to enhance the degradation (Fig. 18). A suggested mechanism is the crosslinking in the silicone network and at filler-matrix interfaces. The densification of  $\text{SiO}_3$  crosslinks in the polymer network after irradiation leads to an increase in resistivity. On another hand, if the polymer is charged with inorganic fillers, the  $\text{SiO}_4$  crosslinks generated at filler-matrix interface become the most restrictive barrier to the charge transport, so that the increase of resistivity is higher for charged adhesive than for the neat one.

**Outgassing**

Once in space environment, adhesives are under vacuum, so they exhibit outgassing of volatile and sometimes condensable components, which can become contaminants for critical surfaces. Irradiation can affect the outgassing, as the degradation of the polymer leads to gas generation. Indeed, gas yields are good indicators of radiation resistance and can help in understanding degradation mechanisms.

VUV radiation and protons can increase the outgassing rate of adhesive materials. A study dedicated to the vacuum UV photolysis of a polydimethylsiloxane (PDMS) polymer has indicated the breakdown of the  $\text{Si-CH}_3$  bond as the most probable reaction occurring and resulting in the formation of methane and hydrogen as volatile split-off compounds (Roggero 2015).

Another problem is the liberation of contaminant species when scissions of chains occur. These sources of contamination can affect all the spacecraft and have to be taken into account in contamination studies.

**Fig. 19** Bubbles creation on an acrylic transfer tape due to irradiation (before irradiation on *left*/ after irradiation on *right*).

In the case of very high dose rates, volatile species created during irradiation might not have time to diffuse out of the material. The internal constraints generated by the gas accumulation can then lead to unexpected phenomena.

Figure 19 presents an example of acrylic adhesive degradation after exposure to particles irradiation with a high flux. Outgassing phenomena is highlighted as bubbles are visible below the tape.

## 32.6 Conclusion

Various properties of the adhesives are used on satellites. Indeed, they can be used for optical, thermal, electrical reasons in addition to their more common fixation use. To fulfill all these functions, several materials families are applied as silicones, epoxies, acrylics, or polyurethanes.

In function of their location on a spacecraft and depending on the mission, they can be submitted to different constraints and, among all of them, the specific space environment constraints (charged particles, UV, or Atomic Oxygen). It is important to know and to understand the physicochemical degradations in the adhesive materials due to this environment to evaluate the EOL (end of life) properties and to be able to correctly design the satellites parts.

It is not possible to reproduce the exact space environment on ground; nevertheless, specific test facilities were developed to be able to test as representatively as possible the different materials (including adhesives) and to characterize their degradation. As an example, some of the facilities enable to cumulate UV and different charged particles irradiation under vacuum.

Various effects of space environment can be observed on adhesives in function of the constraint type. The reaction of a material to charged particles, UV and Atomic Oxygen are different and several properties can be affected.

The photochemical effect induced by the interaction of a photon with the material while submitted to UV irradiation may result in a change of color of the adhesive and/or loss of mechanical properties.

While submitted to charged particles irradiation (protons or electrons), the adhesives atoms and molecules can be either excited or ionized. The result consists generally in a first step in a cross linking of the macromolecules and finally in a chain scission while submitted to an increasing ionization dose level. The overall mechanical properties of the adhesives are generally impacted with an increase of the adhesive stiffness associated to an additional brittleness.

Atomic Oxygen can also react with polymers and, for the sensitive materials, a surface erosion is generally the main effect.

Adhesives are used on spacecraft for various applications. Depending on the satellite mission, the use and location of the adhesive, the undergone environment can be very different, leading to various material degradations mechanisms.

In the future, two different ways forward for adhesives on the space industry could be considered:

- Specific developments and formulation of adhesives used on scientific programs for dedicated applications (functionalization of the adhesives). These specific developments would take into account the behavior of the organic compound with regards to space constraints.
- Using more commercial adhesives not specifically developed to withstand the space constraints (charged particles, Atomic Oxygen, or UV). In this case, there will not have specific developments but an adaptation of the spacecraft design to take into account the adhesive limitations and its degradation due to the environment.

In both cases, it is important to know and to understand the behavior of adhesives in space environment and the physicochemical phenomenon associated. The tests performed on ground in dedicated facilities and the R&D studies on this really specific domain are thus a major point in the future of space programs.

## Abstract

Fatigue involves the failure of materials under cyclic loading, where the maximum load can be significantly lower than that required to cause static failure. Polymeric adhesives, as with most materials, are susceptible to fatigue failure, and hence, fatigue should be accounted for when designing bonded structures subjected to cyclic loading. Adhesive joints have potentially good fatigue resistance compared with other joining methods; however, they are also susceptible to accelerated fatigue failure due to the combined actions of fatigue with

environmental ageing and/or viscoelastic creep. In this chapter, the effect of the environment and various fatigue loading parameters on the fatigue behavior of adhesively bonded joints is discussed before describing the main methods of characterizing and predicting fatigue. Traditionally, fatigue behavior has been characterized through the use of experimentally derived stress–life plots, and fracture mechanics-based progressive crack growth methods have also been widely discussed. In more recent years, damage mechanics-based progressive modeling methods have been proposed that have the advantage of predicting both initiation and crack progression phases of fatigue and have also been shown to be readily adapted to the prediction of variable amplitude fatigue and combined fatigue–environmental ageing. The chapter finishes with descriptions of two special cases of fatigue: creep-fatigue and impact fatigue, which have been shown to be extremely detrimental to the fatigue life of bonded joints under certain conditions.

---

### 33.1 Introduction

In engineering, fatigue relates to the failure of a structure under cyclic loading, generally, at a significantly lower load than that required for quasistatic failure. Some form of fatigue loading is present in most engineering structures, for example, aircraft, ships, cars, buildings, and bridges, and is also seen in many nonengineering applications, such as sports equipment, furniture, and even human parts, such as knees and elbows. Fatigue is a particularly dangerous phenomenon as it can result in sudden, catastrophic failure after many years, or decades, of safe service. This is because a long period can be spent in the initiation phase of fatigue damage, in which there are little or no outward signs of damage. Damage can accelerate unstably once a critical degree of damage has been attained, leading to rapid failure of the structure. Fatigue damage can be initiated or accelerated by many factors, such as accidental impact, overloading, corrosion, surface damage, and abrasion.

The ubiquitous nature and potentially disastrous effect of fatigue in engineering structures means that in applications where cyclic loading is significant, the designer must attempt to design against fatigue failure. Unfortunately, the stochastic nature of fatigue damage means it is difficult to predict accurately. This difficulty is compounded by the fact that the in-service loading and environment of many engineering components, which can significantly affect the fatigue process, are seldom known to a great degree of accuracy. Hence, it is generally difficult to design against fatigue failure without resorting to large safety factors, and hence incurring the large structural inefficiencies associated with overdesign, with subsequent cost and performance consequences. An alternative to designing against fatigue failure is to monitor parts for fatigue damage at prescribed intervals and remove them from service before damage reaches a critical point. This is a useful and efficient method of preventing fatigue failure where crack growth is stable and can be easily monitored. However, in some cases, such as is often the case with adhesive joints, monitoring fatigue damage is difficult, for example, if the damage initiation is in an

inaccessible location or the critical crack size before rapid fracture is small. In this case, an alternative strategy is required to combat fatigue, such as automatic replacement of parts after the design life or a “safe fail” design.

One of the benefits of bonded joints is that stresses are more uniformly distributed than in riveted or bolted joints. However, stress concentrations will, of course, still exist in bonded joints, as discussed in detail in ► Chaps. 24, “Analytical Approach,” and ► 25, “Numerical Approach: Finite Element Analysis.” Another potential advantage is that the bonding process does not explicitly weaken the adherends as the high temperatures and phase transformations involved in welding and the hole drilling required for rivets and bolts can. Although, it should be noted that there are likely to be stress concentrations in the adherend in the joint area which may initiate adherend fatigue failure, such as is seen in aluminum adherend single-lap joints at high cycles and in the delamination of composite adherends. In general, adhesively bonded joints perform well in fatigue compared with bolted and welded joints; however, a number of potential problems for adhesive joints subjected to fatigue should also be recognized. Both the adhesive and the interfacial region between adhesive and adherend are potentially sensitive to the environment and this will affect the fatigue resistance of the joint. Adhesives can also be susceptible to creep under certain conditions, and combined with fatigue this can lead to accelerated failure. In a bonded joint, failure can occur in the adhesive, in the adherend, or in the interfacial region between the two, and the relative fatigue resistance of the various components is dependent on many factors, such as geometry, environment, and loading, and may vary as damage progresses. This complex failure process means that it can be difficult to accurately predict fatigue failure in adhesively bonded joints under real service conditions.

Section 2 discusses some of the main factors when considering fatigue, with particular reference to issues applicable to bonded joint. Section 3 discusses how various loading parameters and environmental conditions affect the fatigue behavior of bonded joints. Section 4 presents the main methods of characterizing and predicting the response of bonded joints to fatigue loading. Finally, there are sections on the special cases of creep-fatigue and impact fatigue (Sects. 5 and 6), before the final summary and conclusion.

---

## 33.2 General Considerations

### 33.2.1 Fatigue Loading

In fatigue, the load varies with time, and the load spectrum is usually characterized in terms of peaks and troughs in the varying load. A fatigue cycle is defined as the time between adjacent peaks, and the fatigue frequency is the number of cycles in a unit time, for example, Hz (cycles per second). A fatigue spectrum can be characterized in terms of the applied load or displacement for simple samples, but in more complex structures, it is often more useful to consider the cyclic stress (or some other

**Fig. 1** Constant amplitude, constant frequency, stress-controlled, sinusoidal waveform

parameter that can be related to failure, such as strain or strain energy release rate) in areas of possible fatigue failure.

It is common in laboratory experiments to represent fatigue as a constant amplitude, sinusoidal waveform, as illustrated in Fig. 1. This is termed constant amplitude fatigue (CAF) and the waveform may be defined by the frequency and two stress parameters, such as the maximum stress ( $\sigma_{\max}$ ) and the stress amplitude ( $\sigma_a$ ). Other parameters defined in Fig. 1 are the mean stress ( $\sigma_m$ ), the minimum stress ( $\sigma_{\min}$ ), and the stress range ( $\Delta\sigma$ ). In most engineering applications, however, it is likely that frequency, amplitude, mean, and waveform will vary with time. This is called variable amplitude fatigue (VAF). The first step in analyzing components subjected to VAF is the characterization of fatigue spectra experienced by the component in service. It is possible to characterize the in-service load spectra through simulation or experimentation. In some cases, a typical spectrum may be repeated throughout the structure's life and will be similar for each structure manufactured, for example, the takeoff and landing sequences of a commercial passenger aircraft or the run-up sequence of power generation equipment. However, for many applications, e.g., private cars, the spectra can vary considerably from unit to unit. In this case, a "worst-case scenario" or statistical approach may have to be taken.

Once the in-service load spectrum has been generated, it can be used in simulations and/or testing. In order to accelerate a fatigue test program, it is generally preferable to reduce the spectrum. In metals, where the materials may be rate insensitive over a large range, an easy method of accelerating tests is to compress the spectrum by testing at high frequency, although any time-dependent effects, such as corrosion or creep, will not be accurately represented in such a test. Hence, when devising accelerated service simulation tests for adhesive joints, care must be taken

**Fig. 2** Example of a load-controlled, variable amplitude waveform

when introducing acceleration techniques that any influential time-dependent or load sequencing effects are retained in the spectrum. Another way of reducing the spectrum is to remove cycles from the spectrum that do not contribute to the fatigue damage. Figure 2 shows a reduced fatigue spectrum used to represent the fatigue loading on an aircraft wing. It can be seen that this is a load-controlled fatigue spectrum that includes changes in the load amplitude and mean, but maintains a constant frequency.

### 33.2.2 Fatigue Initiation and Propagation

The fatigue life of a structure is often divided into initiation and propagation phases. In adhesively bonded joints, the differentiation between these two phases, and even if there really are two such phases, remains a contentious issue. At the predictive modeling level, a distinction can be made between how a propagating crack is analyzed and how the number of cycles before a macrocrack has formed can be predicted, and this can pragmatically be used to differentiate between the initiation and propagation phases.

Fatigue initiation in adhesives is a complex and little-understood process. Commercial adhesives are multicomponent materials, with filler particles, carrier mats, and toughening particles typically added, and failure may involve many mechanisms, including matrix microcracking (initiation, growth, and coalescence), filler particle fracture or debonding, cavitation of rubber toughening particles, and debonding of carrier mat fibers. An additional difficulty in characterizing the fatigue initiation process in bonded joints is that initial damage tends to be internal. This makes nondestructive characterization difficult, whereas with destructive characterization methods, it is difficult to avoid sectioning artifacts. In most cases, a purely mechanistic definition of the initiation and propagation phases is not achievable, and a more pragmatic approach must be taken. In terms of in-service inspection,

initiation may be linked to the detectability of flaws, the end of the initiation life being indicated by the first detection of a crack using whatever technique is being deployed. For the stress analyst, a useful differentiation is to treat the fatigue damage as an initiation phase until a sufficient crack has formed that further growth can be predicted using fracture mechanics. In finite element-based damage mechanics, the initiation phase can be defined as the period before complete damage of an element.

Mechanistically, there is also a blurring between the definitions of “damage” and “cracking” in a bonded joint. For example, a region considered as damaged rather than cracked will often contain microcracking, and in a cracked joint, only an idealized version of the main macrocrack is usually considered, whereas this will almost certainly be accompanied by other types of damage in a process zone ahead and around the main crack. In finite element modeling, damage is often represented by reducing the material properties (the continuum damage mechanics approach), usually stiffness, of an element. Cracking is usually modeled by detaching elements at nodes, after which fracture mechanics methods can be used to model crack propagation. In cohesive zone modeling, both damage and crack growth are represented by using specialized elements to join adjacent continuum elements. This is discussed in detail in ► [Chap. 25, “Numerical Approach: Finite Element Analysis.”](#)

### 33.2.3 Fatigue Testing

Mechanical testing of bonded joints can range from inexpensive coupon tests through the testing of structural elements to the testing of full prototypes, which may be extremely expensive. In all cases, however, fatigue testing will be considerably lengthier and more costly than quasistatic testing.

Coupon tests can fulfil a number of roles. Single material tests may be used to generate material property data, while joints can be tested to compare material systems or joint geometries, evaluate performance over a range of loading and environmental conditions, generate design data, or provide validation data for predictive models. Coupon samples used in the fatigue testing of bonded joints are similar to those used in quasistatic testing, as discussed in ► [Chaps. 19, “Failure Strength Tests,”](#) and ► [20, “Fracture Tests.”](#) Simple lap joints, such as single- and double-lap joints, are generally used to generate stress–life ( $S$ – $N$ ) curves, and standard fracture mechanics tests, such as the double cantilever beam, are used to generate fatigue crack growth curves. The fatigue testing of adhesive lap joints is covered by the standards BS EN ISO 9664:1995 and ASTM D3166-99. In the former, it recommends that at least four samples should be tested at three different stress amplitude values for a given stress mean, such that failure occurs between  $10^4$  and  $10^6$  cycles. This standard also advises on statistical analysis of the data. In general, fatigue data exhibits greater scatter than quasistatic data and this needs to be taken into account when using safety factors with fatigue data. Further advice on the application of statistics to fatigue data can be found in BS 3518-5:1966.

### 33.3 Factors Affecting Fatigue Behavior

#### 33.3.1 Load Factors

Load factors that will affect the fatigue behavior of adhesively bonded joints include the amplitude, mean, and minimum stresses and frequency. In common with most materials, fatigue life in a bonded joint will tend to decrease if the stress amplitude or the mean stress increases. The maximum stress is also important. If this is greater than the yield stress, then low cycle fatigue (LCF) will occur, greatly reducing the fatigue life. In some cases, a critical stress, called an endurance limit, may exist, below which fatigue failure will not occur. As adhesives tend to be viscoelastic or viscoplastic in nature, then a nonzero mean stress can lead to progressive creep of the joint over time. This is exacerbated at low frequencies, where time under load may become as significant as number of cycles in defining failure. At high frequencies, hysteretic heating may lead to premature failure or the high strain rates involved may induce brittle fracture. High strain rates are also seen in impact fatigue, in addition to dynamic effects, which, as discussed in Sect. 6, can be extremely detrimental to adhesives. Most bonded joints are designed for tensile loading, and if the joint is subjected to accidental compressive loading, then buckling may occur, from which high peel forces will arise, leading to rapid fracture.

In variable amplitude fatigue, load interaction effects have been observed to both accelerate and retard the rate of fatigue damage, in different materials. Fatigue crack growth rate retardation is probably the more commonly reported phenomenon. For example, it is generally reported that overloads retard fatigue crack propagation in ductile metals. Proposed mechanisms to account for this phenomenon include the effect of compressive residual stresses in the vicinity of the crack tip, crack tip closure effects, and crack tip blunting. Although neglecting such beneficial effects by using a noninteractive lifetime predictive methodology can remove the opportunity to achieve a lighter structure, at least, the design errs on the side of safety. However, if the load interactions cause crack growth acceleration, the structure under investigation can fail much earlier than predicted using CAF data and a noninteractive prediction methodology. Although most published work indicates retardation behavior after an overload, there is also work in the literature reporting crack growth acceleration for both metals and composites. These studies report several different mechanisms accounting for the acceleration behavior. For example, Nisitani and Nakamura (1982) studied the crack growth behavior of steel specimens tested under a spectrum composed of a very small number of overloads and a very large number of cycles below or near the fatigue limit. They observed that the application of a linear cumulative damage rule resulted in extremely nonconservative predictions of fatigue life. A possible explanation was that although understress cycles cannot initiate a crack, they can potentially contribute to the fatigue damage created by overloads. Farrow (1989) found that the fatigue life of composite laminates subjected to small block loading was shorter than that for laminates subjected to large block loadings when the blocks had different mean stress levels. He called this phenomenon the “cycle mix effect.” Schaff and

Davidson (1997a, b) reviewed the study made by Farrow and developed a strength-based wearout model. They suggested that the cycle mix effect occurred during the transition from one CAF stage to another having a higher mean stress value, although they did not discuss the mechanisms behind the strength degradation during this transition. Erpolat et al. (2004a) observed a similar crack acceleration effect when VAF testing bonded CFRP double-lap joints.

**33.3.2 Environmental Factors**

It is well known that adhesives and adhesion can be adversely affected by factors in the natural environment effects, and that this is a topic of considerable complexity (see ► Chap. 31, “Effect of Water and Mechanical Stress on Durability”). When environmental effects are combined with fatigue testing, we have an added complexity, owing to the introduction of coupled time-dependent effects. The main effects of environmental exposure can be classified as those affecting the adhesive, those affecting the adherend, and those affecting the interface (or interphase) between the two. In terms of the adhesive, an increase in temperature or the absorption of moisture generally results in plasticization of the adhesive, with an accompanying reduction in modulus and failure load. However, strain to failure and fracture toughness may increase. This can affect fatigue initiation and propagation in a number of ways. The plasticization will tend to reduce stress concentrations, although stresses may now be significant over a larger area; hence, the resistance to brittle fatigue failure may increase, but the resistance to creep-fatigue may decrease. These effects will become more significant close to the glass transition temperature ( $T_g$ ), and similarity can be seen between the effects of absorbed moisture, increased temperature, and decreased test rate (or frequency). Some of these issues are illustrated by the results shown in Table 1 (data from Ashcroft et al. 2001a, b). This table shows the fatigue limits for bonded CFRP lap-strap and double-lap joints. In the case of the lap-strap joints, it can be seen that temperature has little effect on

**Table 1** Effect of environment on the fatigue limit for bonded CFRP-epoxy lap-strap and double-lap joints (Data from Ashcroft et al. 2001a, b)

		90 °C/ambient	3.3

the fatigue threshold of those sample stored and tested in nominally dry conditions. However, samples tested in hot-wet conditions experience a significant reduction in the fatigue threshold. Samples were also conditioned under high humidity conditions until saturation. Samples subsequently tested wet at 22 °C had no change in the fatigue threshold compared to those tested dry, whereas samples tested at 90 °C, whether wet or dry, experienced a large reduction in the fatigue threshold. Interpretation of these results is complicated by the fact that complex mixed mode failure paths were observed. In order to explain these results, the effect of temperature and moisture on the mechanical behavior of the adhesive must be considered. The stress to failure and modulus of the adhesive decreases as the temperature increases, but the strain to failure and total strain energy density at failure increases. The competing effects of these different trends conspire to maintain the fatigue limit at a relatively constant value between 22 °C and 90 °C when stored and tested dry. Differential thermomechanical analysis (DTMA) was carried out on samples saturated to different moisture levels, and it was seen that for every 1% of moisture absorbed, the glass transition point of the adhesive decreased by approximately 15 °C. As the  $T_g$  of this adhesive is approximately 130 °C, the saturated adhesive tested at 22 °C would not be expected to behave markedly differently from those tested dry at 22 °C and 90 °C. However, the saturated sample tested at 90 °C is in the glass transition temperature range as the adhesive is capable of absorbing 3–4% of moisture. It is clearly less capable of resisting stress under these conditions, and hence the fatigue limit is greatly reduced. If the lap-strap results are now compared with the results from testing double-lap joint manufactured using the same materials, it can be seen in Table 1 that whereas the lap-strap joints are relatively temperature insensitive over the test range when dry, the double-lap joints experience a large decrease in fatigue resistance as temperature is increased from 22 °C to 90 °C. This can be attributed to creep-enhanced failure at the higher temperature in the double-lap joint, which experiences accumulated creep because the joint remains under a tensile load throughout the fatigue testing. This phenomenon is prevented in the case of the lap-strap joints because the CFRP strap adherend spanning the loading points remains elastic. The combined effects of fatigue and creep are discussed further in Sect. 5.

Moisture can also affect the interface between the adhesive and adherend, and this can significantly affect the fatigue behavior of a bonded joint. For example, Little (1999) carried out fatigue tests on aluminum single-lap joints bonded with the same adhesive as that in the experiments discussed above. He found that with chromic acid-etched (CAE) adherends, there was little difference in the fatigue threshold of those samples tested dry and those tested immersed in distilled water at 28 °C. However, samples with grit-blasted and degreased (GBD) adherends exhibited a significantly lower fatigue threshold when tested wet, and the locus of failure changed from cohesive failure in the adhesive to failure in the interfacial region. Datla et al. (2011a) also investigated the combined effects of temperature and humidity on the fatigue behavior of adhesive joints with pretreated aluminum adherends. In their case, an asymmetric double cantilever beam was used and it was found that for their system, the joint degradation was mainly influenced by

elevated temperature at high crack growth rates and elevated moisture at low crack growth rates. They also investigated the effect of a cyclic ageing environment for this joint, with intermittent salt spray on these joints (Datla et al. 2011b) and found superior fatigue performance compared with joints subjected to constant humidity ageing. They attributed this to salt water environment causing lower water concentrations in the adhesive. For further reading on this subject, Costa et al. (2017) have recently reviewed the published literature regarding the effect of environmental conditions and ageing on fatigue performance.

### 33.4 Prediction Methods

The ability to predict the fatigue behavior of bonded joints is potentially useful for a number of reasons. Firstly, it can be used to support the design of bonded structures, to ensure that fatigue failure is not likely to occur in service, and to aid in the design of efficient fatigue-resistant joints, resulting in safer, cheaper, and higher performance structures. Analytical or computational predictive modeling can help in these objectives; however, the current state of confidence in such modeling means that in most cases, it must be accompanied by a complementary testing program. Modeling can also be helpful in developing and understanding of the mechanisms involved in fatigue failure. This can be achieved through comparing the results from carefully designed experimental tests with the predicted results from progressive damage models. Finally, predictive modeling can be used to support the in-service monitoring and re-lifeing of structures.

The main goals in the modeling of fatigue are to predict the time (or number of cycles) for a certain event to occur (such as macrocrack formation, critical extent of damage, or complete failure) or to predict the rate of change of a fatigue-related parameter, such as crack length or “damage.” The various methods of doing this are presented in this section, and the approach used is to introduce and describe each of the main methods that have been used to date, together with one or two examples of their application to bonded joints.

#### 33.4.1 Total-Life Methods

In the total-life approach, the number of cycles to failure ( $N_f$ ) is plotted as a function of a load-related variable, such as stress or strain amplitude. Where the loading is low enough that the deformation is predominantly elastic, a stress variable ( $S$ ) is usually chosen and the resultant plot is termed an  $S$ – $N$  curve, or Wöhler plot, and this is known as the stress–life approach. Under these conditions, a long fatigue life is often seen, and hence this is sometimes termed “high cycle fatigue” (HCF). The  $S$ – $N$  data is either plotted as a log-linear or a log-log plot and a characteristic equation can be obtained by empirical curve fitting. The constants in the curve-fitted equations are dependent on many factors, including material, geometry, surface condition, environment, and mean stress. Caution should be exercised when trying to apply  $S$ – $N$

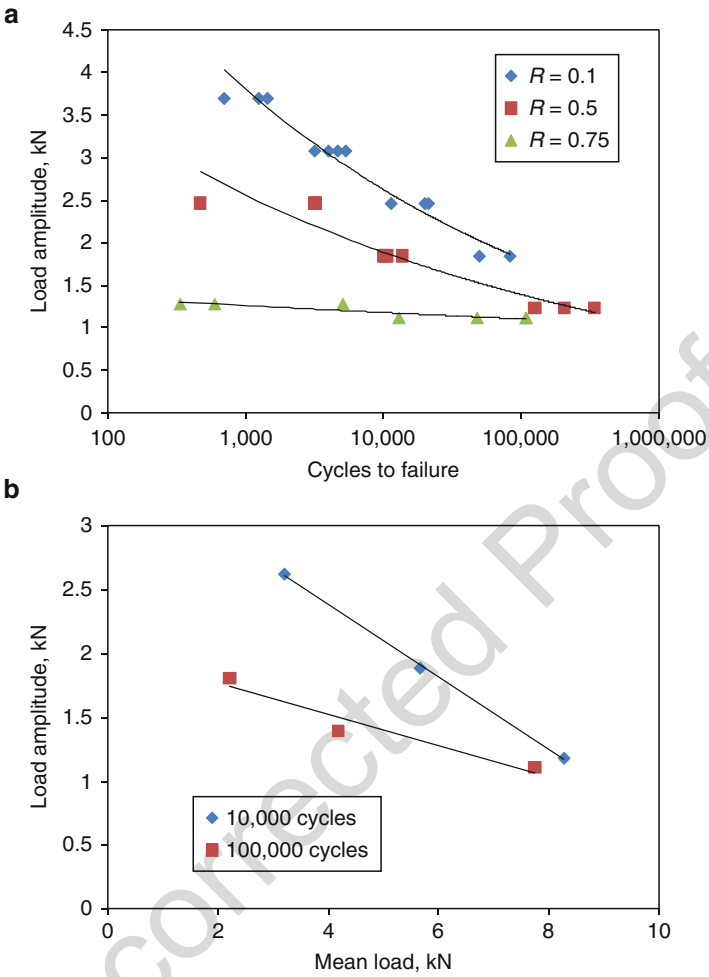

**Fig. 3** Load-life curve for CFRP-epoxy double-lap joints (Data from Ashcroft et al. 2001b)

data beyond the samples and conditions used to generate the data. The standard stress-life method gives no indication of the progression of damage, although in some cases, the onset of cracking is indicated on the plot in addition to the complete failure, hence allowing the initiation and propagation phases to be differentiated. The above factors mean that the  $S-N$  curve is of rather limited use in predicting fatigue behavior; however, it is still useful as a design tool and in fatigue modeling as a source of validation data. A further limitation in the application of  $S-N$  curves to fatigue prediction in bonded joints is that there is no unique relation between the easily determined average shear stress in the adhesive layer and the maximum stress. For this reason, load rather than stress is often used in total-life plots for bonded joints and these are known as  $L-N$  curves. A typical  $L-N$  curve for epoxy-bonded CFRP double-lap joints is shown in Fig. 3. It can be seen that the  $L-N$  curve can be divided into a number of different regions: a low cycle fatigue (LCF) region below approximately 1000 cycles, a high cycle fatigue (HCF) region between approximately 1000 and 100,000 cycles, and an endurance limit region above approximately 100,000 cycles.

Fatigue life depends not only on the load amplitude but also on the mean load as either increasing the mean or increasing the amplitude tends to result in a reduction of the fatigue life. This is illustrated in Fig. 4a, which shows results from fatigue testing steel-epoxy single-lap joints at different load amplitudes and  $R$ -ratios (maximum load/minimum load), where an increasing value of  $R$  indicates an increasing mean for a given load range. It can be seen that either increasing the mean or increasing the amplitude results in a reduction of the fatigue life. The relationship between amplitude and mean on the fatigue life can be illustrated in a constant-life diagram in which combinations of mean and amplitude are plotted for a given fatigue life. A constant-life diagram plotted from the data in Fig. 4a is shown in Fig. 4b. This

**Fig. 4** (a) Effect of  $R$ -ratio on fatigue life. (b) Constant-life diagram (Data from Crocombe and Richardson 1999)

relationship can be represented by the Goodman (linear) or Gerber (parabolic) relationships (Dowling 1999). It can be seen that in this case, a linear relationship provides a reasonable fit to the experimental data.

In some cases, efforts have been made to differentiate between the initiation and propagation phases in the  $S-N$  behavior of bonded joints. Shenoy et al. (2009a) used a combination of back-face strain measurements and sectioning of partially fatigued joints to measure damage and crack growth as a function of number of fatigue cycles.

It was seen from the sectioned joints that there could be extensive internal damage in the joint without external signs of cracking; therefore, determination of an initiation phase from external observations alone is likely to lead to an

**Fig. 5** Enhanced load–life curve for adhesively bonded single-lap joints, showing regions of crack initiation (CI), stable crack growth (SCG), and fast crack growth (FG). The broken lines show back-face strain as a function of number of cycles (Shenoy et al. 2009a)

overestimation of the percentage of the fatigue life sent in initiation. Shenoy et al. (2009a) identified three regions in the fatigue life of an aluminum/epoxy single-lap joint, as illustrated in Fig. 5. An initiation period (CI) in which damage starts to accumulate, but a macrocrack has not yet formed, a stable crack growth (SCG) region in which a macrocrack has formed and is growing slowly, and a fast crack growth region (FCG), which leads to rapid failure of the joint. It was seen that the percentage of life spent in each region varied with the fatigue load. At low loads, the fatigue life was dominated by crack initiation, whereas crack growth dominated at high loads. The broken lines in Fig. 5 show how the back-face strain signal varies as a function of fatigue cycles. This can be used to characterize the different phases of crack growth, in particular a rapid change in the back-face strain is seen when the fatigue failure enters the fast crack growth region.

The  $S$ – $N$  (or  $L$ – $N$ ) curve is only directly applicable to constant amplitude fatigue, whereas in most practical applications for structural joints a variable amplitude fatigue spectrum is more likely. A simple method of using  $S$ – $N$  data to predict variable amplitude fatigue is that proposed by Palmgren (1924) and further developed by Miner (1945). The Palmgren–Miner (P–M) rule can be represented by

$$\sum \frac{n_i}{N_{fi}} = C \quad (1)$$

where  $n_i$  is the number of cycles in a constant amplitude block,  $N_{fi}$  is the number of cycles to failure at the stress amplitude for that particular block and can be obtained from the  $S$ – $N$  curve, and  $C$  is the Miner's sum and is ideally assumed to equal 1. Using Eq. (1), the fatigue life of a sample in variable amplitude fatigue can be predicted from an  $S$ – $N$  curve obtained from constant amplitude fatigue testing of similar samples. However, there are a number of serious limitations to this method, primarily, the assumptions that damage accumulation is linear, that there is no damage below the fatigue threshold, and that there are no load history effects.

**Fig. 6** Comparison of P–M, extended P–M, and elementary P–M methods of predicting variable amplitude fatigue cycles to failure

Modifications to the P–M rule have been suggested to address some of the deficiencies; for instance, the extended and elementary P–M rules shown in Fig. 6 have been proposed to allow cycles below the fatigue threshold to contribute to the damage sum. Modifications to account for nonlinear damage accumulation and interaction effects have also been suggested; however, any improvements are at the expense of increased complexity and/or increased testing requirements, and the basic flaw in the method, i.e., that it bears no relation to the actual progression of damage in the sample, is still not addressed. Erpolat et al. (2004a) used the P–M law and the extended P–M law, in which cycles below the endurance limit also contribute to damage accumulation, to predict failure in an epoxy-CFRP double-lap joint subjected to a variable amplitude (VA) fatigue spectrum. The resulting Miner's sum was significantly less than 1, varying between 0.04 and 0.3, and decreased with increasing load. This indicates that load sequencing is causing damage acceleration, i.e., that the P–M rule is nonconservative in this case.

Some materials exhibit a stress level below which fatigue failure will not occur, known as the fatigue or fatigue limit. In this case, it may be possible to use the data from one sample to predict the fatigue limit for a different geometry or loading condition. A useful method is to experimentally determine the fatigue limit using a calibration sample and to then calculate the value of a suitable failure parameter at the fatigue limit. The fatigue limit can then be predicted for different geometries for failure in the same material by determining the load at which the fatigue limit value of the chosen failure parameter is reached in the new geometry. This is a potentially attractive method as the fatigue threshold value of the chosen failure criterion can be determined from an inexpensive test and then used to predict the fatigue limit for joints that would be expensive to test experimentally. However, in practice, there are the same difficulties as those in the prediction of the quasistatic failure load of adhesive joints, i.e., selection of an appropriate and robust failure criterion, dealing with the theoretical stress singularities, scaling issues and differences in the stress conditions in the simple test and application joints. Abdel Wahab et al. (2001a) predicted the fatigue threshold in CFRP-epoxy lap joints using a variety of stress- and strain-based failure criteria, taking the value of stress and strain at a distance of

0.04 mm from the singularity to avoid mesh sensitivity. They also used the plastic zone size as a failure criterion.

Under high stress amplitudes, plastic deformation occurs and the fatigue life is considerably shortened. This is known as “low cycle fatigue” (LCF). Coffin (1954) and Manson (1954) proposed that  $N_f$  could be related to the plastic strain amplitude,  $\Delta\epsilon_p/2$ , in the LCF region.

$$\frac{\Delta\epsilon_p}{2} = B(N_f)^\beta \quad (2)$$

where  $B$  and  $\beta$  are material constants. The strain–life approach is more difficult to implement than the stress–life method as plastic strain is difficult to measure, particularly for nonhomogenous material systems such as bonded joints. Also, structural joints tend to be used in HCF applications, and hence the strain–life method has seen little application to adhesively bonded joints. Abdel Wahab et al. (2010a, b) proposed a low cycle fatigue damage law based on continuum damage mechanics and applied this to bulk adhesive samples and single-lap joints.

### 33.4.2 Phenomenological Methods

In the phenomenological approach, fatigue damage is characterized as a function of a measurable parameter, most commonly the residual strength or stiffness after fatigue damage. The reduction in stiffness with fatigue damage, known as stiffness wearout, has the advantage that it can be measured nondestructively; however, it is not directly linked to a failure criterion and may not be very sensitive to the early stages of damage. The strength wearout method provides a useful characterization of the degradation of residual strength, but requires extensive destructive testing. In the strength wearout method, the joint’s strength is initially equal to the static strength,  $S_u$ , but decreases to  $S_R(n)$  as damage accumulates through the application of  $n$  fatigue cycles. This degradation can be represented by:

$$S_R(n) = S_u - f(S_u, S_{\max}, R)n^\kappa \quad (3)$$

where  $\kappa$  is a strength degradation parameter,  $S_{\max}$  is the maximum stress, and  $R$  is the ratio of minimum to maximum stress (i.e.,  $R = S_{\min}/S_{\max}$ ). Failure occurs when the residual strength equals the maximum stress of the spectrum, i.e., when  $S_R(N_f) = S_{\max}$ .

Shenoy et al. (2009b) proposed a modified version of this equation that they termed the normalized nonlinear strength wearout model (NNLSWM), which is given by:

$$L_n = 1 - \frac{(L_u - L_{\max})}{L_u} (N_n)^\eta \quad (4)$$

**Fig. 7** The normalized nonlinear strength wearout model applied to aluminum-epoxy single-lap joints tested at different loads (Shenoy et al. 2009b)

where  $\eta$  is a constant and the normalized residual failure load,  $L_n$ , is:

$$L_n = \frac{L_R(n)}{L_u}$$

and the normalized cycles to failure,  $N_n$ , is:

$$N_n = \frac{n}{N_f}$$

where  $L_R(n)$  is the quasistatic failure load after  $n$  fatigue cycles and  $L_u$  is the quasistatic failure load prior to fatigue loading. Figure 7 shows this model applied to aluminum alloy-epoxy single-lap joints tested at three different fatigue loads. It can be seen that the model fits all the data reasonable well, thus providing a simple method of predicting the residual strength in a joint under any combination of constant fatigue load and number of cycles. However, if the fatigue load varies, modifications to this approach may be required, as discussed in the next section.

Schaff and Davidson (1997a, b) used the strength wearout method to predict the residual strength degradation of a composite material subjected to a variable amplitude loading spectrum. However, they noted a crack acceleration effect in the transition from one constant amplitude (CA) block to another, the cycle mix effect, and proposed a cycle mix factor, CM, to account for this. Erpolat et al. (2004a) proposed a modified form of Schaff and Davidson's cycle mix equation to model the degradation of CFRP-epoxy double-lap joints subjected to a variable amplitude fatigue spectrum. They showed that this model represented the fatigue life of bonded joints under variable amplitude fatigue more accurately than Palmgren–Miner's law. Shenoy et al. (2009c) proposed various further modifications to this approach, which they applied to aluminum alloy-epoxy single-lap joints subjected to various forms of VAF. The application of the cycle mix factor to predict strength wearout and cycles

**Fig. 8** Illustration of the nonlinear strength wearout with cycle mix factor approach to predict variable amplitude fatigue

to failure for VAF is illustrated in Fig. 8. The figure shows two strength wearout curves, showing the reduction in the residual load for constant amplitude fatigue with maximum fatigue loads of  $L_{max1}$  and  $L_{max2}$ . Both of these curves can be represented by a nonlinear strength wearout equation, such as Eq. (4). If a variable amplitude fatigue spectrum commences with a maximum fatigue load of  $L_{max2}$ , then the decrease in the residual load with fatigue cycles initially follows path  $a-b$ . If at point  $b$  the maximum fatigue load increases to  $L_{max1}$ , there is a horizontal jump to the strength wearout curve for the higher load and the residual load starts to decrease more quickly, following curve  $c-d$ . At point  $d$ , the maximum load is decreased to  $L_{max2}$ , and we have another horizontal jump to the relevant strength wearout curve. However, at point  $e$ , the cycle mix factor is also applied, which has the effect of an immediate reduction in the residual load by an amount CM (or  $CM_m$ ). Shenoy et al. (2009c) proposed two cycle mix factors. The first was the cycle-independent cycle mix factor used by Erpolat et al. (2004a) given in Eq. (5).

$$CM = \alpha \left[ (\Delta L_{mn})^{\beta L_{max}} (\Delta L_{max,1} / \Delta L_{mn,1})^{\gamma} \right] \quad (5)$$

$\Delta L_{mn}$  and  $\Delta L_{max}$  are the mean and maximum load changes during the transition from one mean load to the other,  $\alpha$  and  $\beta$  are experimentally determined parameters, and  $\gamma$  was assumed to be unity in this case. The second was termed the modified cycle mix factor (MCM) approach. This was developed after observing that a better fit to the experimental data could be made if the cycle mix factor was greater in the

low cycle regime than in the high cycle regime. As it had already been noted that with these joints the fatigue life was propagation dominated in the low cycle regime and initiation dominated in the high cycle regime, the desired effect was achieved by making the cycle mix factor dependent on the extent of damage in the sample, as shown in Eq. (6).

$$CM_m = \left( \frac{\zeta}{OL} + \alpha \right) \left[ (\Delta L_{mn})^{\beta L_{max}} (\Delta L_{max} / \Delta L_{mn})^y \right] \quad (6)$$

where OL is the overlap length and  $\zeta$  is a damage parameter. In Shenoy et al. (2009c),  $\zeta$  was determined by fitting a power law curve to experimental plots of damage/crack growth against number of cycles. Hence,  $\zeta$  was defined as:

$$\zeta = m_1 (n)^{m_2} \quad (7)$$

where  $m_1$  and  $m_2$  are experimentally determined constants.

It can be seen in Fig. 9 that the cycle mix parameter was applied when the fatigue loading became less severe, i.e., after the jump from  $d$  to  $e$ , but not when the fatigue loading became more severe, i.e., following the jump from  $b$  to  $c$ . This is consistent with Gomatam and Sancaktar (2006) who observed damage acceleration when “moderate” loading conditions followed “severe” loading conditions, but not when the order was reversed. It is also consistent with the mechanistic argument put forward by Ashcroft (2004) who attributed crack growth accelerations seen in adhesives subjected to intermittent overloads to the damage caused by the overloads to the adhesive ahead of the crack tip. It was proposed that this damage reduced the fatigue resistance of the adhesive and resulted in accelerated crack growth for the cycles of lower amplitude following an overload.

**Fig. 9** Experimental fatigue crack growth curve for a CFRP-epoxy double cantilever beam (Data from Ashcroft and Shaw 2002)

As with strength degradation, stiffness degradation rate can be considered as a power function of the number of load cycles. Although stiffness degradation has the advantage that it can be measured nondestructively, it does not give a direct indication of the residual strength of a fatigued structure. However, if this link can be made, then stiffness degradation can be a useful method of in-service structural integrity monitoring.

### 33.4.3 Fracture Mechanics Methods

The fracture mechanics approach deals predominantly with the crack propagation phase; hence, it is assumed that crack initiation occurs during the early stages of the fatigue cycling or that there is a preexisting crack. The rate of fatigue crack growth,  $da/dN$ , is then correlated with an appropriate fracture mechanics parameter, such as Griffith's (1921) strain energy release rate,  $G$ , or Irwin's (1958) stress intensity factor,  $K$ . Paris et al. (1961) proposed that  $da/dN$  was a power function of the stress intensity factor range,  $\Delta K (=K_{\max} - K_{\min})$ , i.e.:

$$\frac{da}{dN} = C \Delta K^m \quad (8)$$

where  $C$  and  $m$  are empirical constants, dependent on factors such as the material, the fatigue frequency, the  $R$ -ratio, and environment. Although  $K$  is the most widely used fracture mechanics parameter in the fracture analysis of metals, it is more difficult to apply to bonded joints, where the constraint effects of the substrates on the adhesive layer complicates characterization of the stress field around the crack tip. Therefore,  $G$  is often used as the governing fracture parameter for adhesives if linear elastic fracture mechanics (LEFM) is applicable (i.e., localized plasticity). If an elastoplastic fracture mechanics (EPFM) parameter is required, owing to more widespread plasticity, then the J-integral ( $J$ ) is generally used (Rice 1968). If creep is significant, then a time-dependent fracture mechanics parameter, such as  $C^*$  or  $C_t$ , should be considered, as discussed in Sect. 5.

A plot of the experimentally measured crack growth rate against the calculated  $G_{\max}$  or  $\Delta G$  often exhibits three regions, as illustrated in Fig. 9, which shows the fatigue crack growth curve for a CFRP-epoxy double cantilever beam (DCB). Region I is defined by the threshold strain energy release rate,  $G_{th}$ , in which crack growth is slow enough to be deemed negligible. Region II is described by a power law equation similar to Eq. (6) and is, hence, sometimes referred to as the Paris Region. In Region III, there is unstable fast crack growth as  $G_{\max}$  approaches the critical strain energy release rate,  $G_c$ .

In a general form, the relationship between the fatigue crack propagation rate and a relevant fracture parameter,  $\Gamma$ , can be represented by:

$$\frac{da}{dN} = f(\Gamma) \quad (9)$$

The number of cycles to failure can be determined from:

$$N_f = \left( \int_{a_0}^{a_f} \frac{da}{f(F)} \right) \quad (10)$$

where  $a_0$  is the initial crack length and  $a_f$  is the final crack length. Equation (10) can be solved using numerical crack growth integration (NCGI). A simple method of predicting VA fatigue from a CA FCG curve is to perform numerical crack growth integration. In this method, the crack size,  $a$ , and corresponding fracture parameter, such as strain energy release rate range,  $\Delta G$ , is assumed to be constant throughout a CA stage. The crack growth rate per cycle,  $da/dN$ , for this stage can be obtained using an appropriate correlation, such as the Paris law. Multiplication of this rate by the number of cycles in the stage,  $n$ , gives the overall crack growth during the stage,  $\Delta a$ . This is used to find the crack size for the subsequent stage ( $a_{i+1} = a_i + \Delta a_i$ ) and the procedure is repeated until  $G_{\max}$  exceeds the fracture energy,  $G_c$ , or until  $\Delta G$  becomes equal to  $\Delta G_{th}$ . This algorithm is summarized below.

Repeat

$$a_{i+1} = a_i + n_i \cdot \frac{da}{dN}(\Delta G_i(R_i, a_i, \dots)) \quad (11)$$

Until  $G_{\max, i+1} \geq G_c$  { $G$  increasing with  $a$ } or

Until  $\Delta G_{\max, i+1} \leq \Delta G_{th}$  { $G$  decreasing with  $a$ }

Abdel Wahab et al. (2004) proposed a general method of predicting fatigue crack growth and failure in bonded lap joints incorporating NCGI and finite element analysis (FEA). The crack growth law was determined from tests using a DCB sample and this was used to predict the fatigue crack growth, and hence the fatigue life, of single- and double-lap joints manufactured from the same materials.

The numerical integration technique can easily be adapted to the prediction of fatigue crack growth in variable amplitude (VA) fatigue. Erpolat et al. (2004b) applied the NCGI technique for the prediction of crack growth in CFRP/epoxy DCB joints subjected to periodic overloads. This tended to underestimate the experimentally measured crack growth, indicating a crack growth acceleration mechanism, and an unstable, rapid crack growth period was also seen when high initial values of  $G_{\max}$  were applied. This behavior was attributed to the generation of increased damage in the process zone ahead of the crack tip when the overloads were applied, and Ashcroft (2004) proposed a fracture mechanics-based model that could predict this behavior. It was assumed that under constant amplitude conditions, FCG can be represented by  $\Delta G_{th}$ ,  $G_c$ , and the two Paris constants,  $C$  and  $m$ , as represented by CA in Fig. 10. It can be seen that if a CA fatigue load with a strain energy release rate range of  $\Delta G_A$  is applied, then the resulting crack growth rate will be  $(da/dN)_{CA}$ . In most cases,  $\Delta G_A$  will be calculated assuming undamaged material ahead of the crack tip, and this is likely to be adequate for predictive purposes. However, the crack resistance and hence  $(da/dN)_{CA}$  will be associated with the damage zone

**Fig. 10** The damage shift method of predicting fatigue crack growth under variable amplitude (Ashcroft 2004)

created by the CA fatigue loading. If an overload is superimposed onto the CA spectrum, then the damage ahead of the crack zone will increase and the resistance to crack propagation will decrease. It is proposed that this increased damage can be represented by a lateral shift in the FCG curve. The FCG curve associated with this increased damage is represented by curve OL in Fig. 10. It can be seen that the value of  $da/dN$  at  $\Delta G_A$  has increased to  $(da/dN)_{OL}$ , i.e., that there is a crack acceleration effect, which is represented by a “damage shift” parameter,  $\psi_E$ , which can be easily determined for a given spectrum through a simple experimental test program. Theoretically, all that is needed to determine  $\psi_E$  is the crack growth rates under CA and VA fatigue for a single value of  $\Delta G_A$ .

If  $\Delta G_A$  is increased, a critical point will eventually be reached at which  $G_{max}$  of the overloads is equal to the value of  $G_c$  for the shifted FCG curve, OL. This point is shown as  $\Delta G_{AC}$  in Fig. 10. Unstable or quasistatic fracture then occurs. If  $G$  increases with crack length, then this will lead to catastrophic failure of the joint. However, if  $G$  decreases with  $a$ , as when testing DCB samples in displacement control, then the crack will eventually stop if the  $G$  arrest ( $G_{arr}$ ) value is reached before the joint has completely fractured. The value of  $\Delta G_A$  associated with the crack arrest point ( $\Delta G_{arr}$ ) will now be much smaller, and hence crack growth will be greatly reduced. This is consistent with the experimental crack growth behavior shown in Fig. 11, where there is a rapid increase in crack length after approximately 5000 fatigue cycles, after which there is a period of lower crack growth rate than that predicted by NCGI. It can be seen in Fig. 11 that the damage shift model is capable of predicting both the initial crack jump and the subsequent reduction in the crack growth rate.

The fatigue crack growth approach will only predict the correct fatigue life if it is dominated by the fatigue propagation phase. However, if the initiation phase is significant, then this approach will underestimate the fatigue life and a method of predicting the number of cycles before the macrocrack forms is required. This can be done empirically in a similar fashion to the stress–life approach, with the number of

**Fig. 11** Fatigue crack growth for CFRP-epoxy DCB subjected to overloads

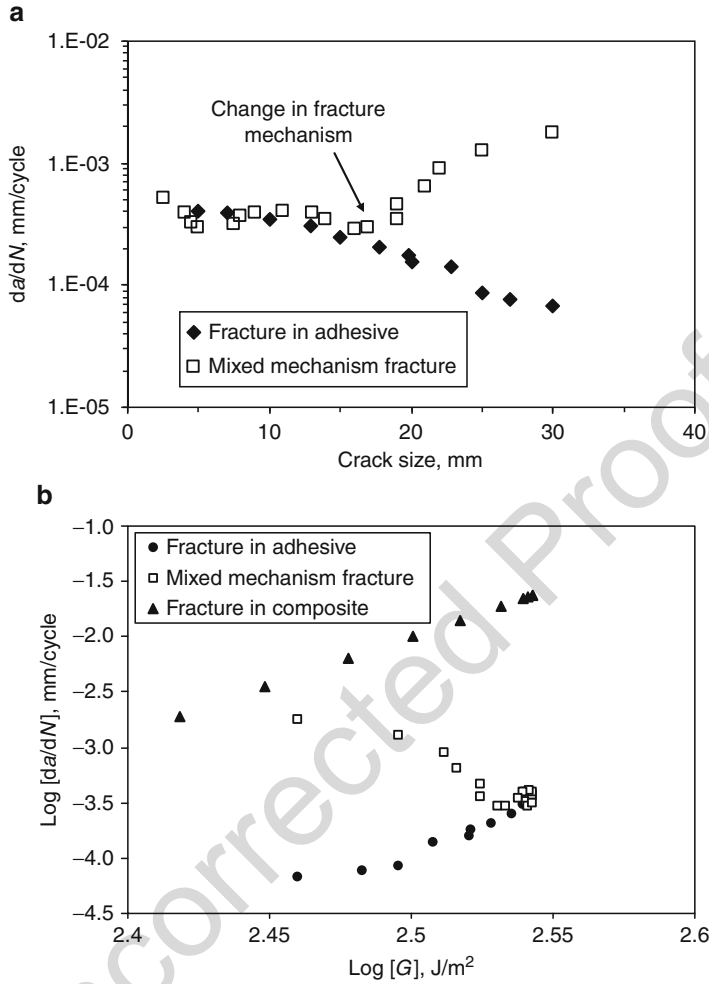

cycles to fatigue initiation,  $N_i$ , being plotted as a function of a suitable stress (or other) parameter rather than cycles to total failure,  $N_f$  (Shenoy et al. 2009a). An alternative approach, suggested by Levebvre and Dillard (1999), is to use a stress singularity parameter as the fatigue initiation criterion. They showed that under certain conditions, the singular stress,  $\sigma_{kl}$ , in an adhesive lap joint could be represented by:

$$\sigma_{kl} = \frac{Q_{kl}}{x^\lambda} \quad (12)$$

where  $Q_{kl}$  is a generalized stress intensity factor, dependent on load, and  $\lambda$  is an eigenvalue that can be related to the order of the singularity. It was proposed that  $N_i$  could be defined in terms of  $\Delta Q$  (or  $Q_{\max}$ ) and  $\lambda$  in a 3D failure map. This approach has been combined with a fracture mechanics approach by Quaresimin and Ricotta (2006) to obtain a predictive method explicitly modeling both the initiation and propagation phases. An alternative to this is to use one of the damage mechanics methods described in Sect. 4.4.

Adhesives and polymer composites tend to exhibit fast fracture, and hence it may be preferable to design for a service life with no crack growth, using  $G_{th}$  as the design criteria. Abdel Wahab et al. (2001a) investigated this approach for bonded lap-strap joints. Elastic ( $G$ ) and elastoplastic ( $J$ ) fracture parameters, crack placement, and initial crack size were investigated. This approach has also been extended to samples subjected to environmental ageing by incorporating the method with a semicoupled transient hygro-mechanical finite element analysis (Ashcroft et al. 2003). Ashcroft and Shaw (2002) used  $G_{th}$  from testing DCB joints to predict the  $10^6$  cycle endurance limit in lap-strap and double-lap joints at different temperatures. The predictions were reasonable, apart from the double-lap joint tested at  $90^\circ\text{C}$ , which failed at a far lower load than predicted. This was attributed to accumulative creep in the double-lap joint, which could be seen in plots of displacement against cycles at constant load amplitude.

**Fig. 12** (a) Fatigue crack growth rate as a function of crack length for fracture in the adhesive and a mixed mechanism fracture. (b) Fatigue crack growth plots for fracture in the adhesive layer in the composite and a mixed mechanism fracture

It is quite common in adhesively bonded joints to have more than one failure mechanism, for example, cohesive failure in the adhesive, failure at the interface, interlaminar failure, or matrix failure in composite substrates, occurring in the fatigue life of a joint. This will affect the fatigue crack growth, as illustrated in Fig. 12a. If the various mechanisms occur sequentially, then failure criteria for the joint can also be applied sequentially in a fatigue lifetime predictive methodology. However, if more than one mechanism is occurring at one time, anomalous fatigue crack growth can occur. This is illustrated in Fig. 12b for the case of a CFRP-epoxy lap-strap joint in which fracture is initially in the adhesive before developing into a

mixed mechanism failure with an increasing proportion of failure in the composite adherend. It can be seen that in the mechanism fracture, the fatigue crack growth exhibits anomalous behavior as the crack growth rate decreases as strain energy release rate increases, which is not represented by a Paris-type crack growth law. Ashcroft et al. (2010) proposed a mixed mechanism fracture model of the following form:

$$\left(\frac{da}{dn}\right)_m = f \left[ A_a, \left(\frac{da}{dn}\right)_a, A_c \left(\frac{da}{dn}\right)_c \right] \quad (13)$$

where  $A$  indicates area fraction of failure mode, as seen in the fracture surface, and the subscripts m, a, and c represent mixed, adhesive, and composite, respectively. The simplest form of this law is a simple additive one, i.e.:

$$\left(\frac{da}{dn}\right)_m = A_a \left(\frac{da}{dn}\right)_a + A_c \left(\frac{da}{dn}\right)_c \quad (14)$$

Equation (14) assumes there is a proportional relationship between the area fraction of a particular failure mode and its effect on the mixed FCG rate; however, this is not necessarily the case. It may be the case that one of the fracture mechanisms has a disproportionate effect on the mixed FCG rate. A simple way to accommodate this is to substitute the actual area fraction,  $A_i$ , in Eq. (14) with an effective area fraction,  $A'_i$ , as illustrated in Eq. (15)

$$\left(\frac{da}{dn}\right)_m = A'_a \left(\frac{da}{dn}\right)_a + A'_c \left(\frac{da}{dn}\right)_c \quad (15)$$

A method of mapping the actual area fraction to the effective area fraction is required, and Ashcroft et al. (2010) illustrated how power laws and polynomial relationships could be used for this purpose. It was shown that the proposed model was capable of predicting the anomalous fatigue crack growth behavior shown in Fig. 12.

### 33.4.4 Damage Mechanics Methods

The fracture mechanics methods have the limitation that the initiation phase is not accounted for and that damage is through a single planar crack propagating through undamaged material, which may not physically represent the real behavior very well. The damage mechanics approach addresses some of these problems by allowing progressive degradation and failure to be modeled, thus representing both initiation and propagation phases. Continuum damage mechanics (CDM) requires a damage variable,  $D$ , to be defined as a measure of the severity of the material damage, where  $D$  is equal to 0 for undamaged material and 1 for fully damaged material. Abdel Wahab et al. (2001b) developed the following fatigue damage equation:

$$D = 1 - \left[ 1 - A(\beta + m + 1) \Delta \sigma_{\text{eq}}^{\beta+m} R_v^{\beta/2} N \right]^{\frac{1}{\beta+m+1}} \quad (16)$$

where  $\Delta \sigma_{\text{eq}}$  is the von Mises stress range,  $R_v$  is the triaxiality function (which is the square of the ratio of the damage equivalent stress to the von Mises equivalent stress),  $m$  is the power constant in the Ramberg–Osgood equation, and  $A$  and  $\beta$  are experimentally determined damage parameters. The number of cycles to failure ( $N_f$ ) can be determined from Eq. (16) using the condition at the fully damaged state,  $D = 1$  at  $N = N_f$ , giving:

$$N_f = \frac{\Delta \sigma_{\text{eq}}^{-\beta-m} R_v^{-\frac{\beta}{2}}}{A(\beta + m + 1)} \quad (17)$$

Abdel Wahab et al. (2001b) found that the approach described above compared favorably with the fracture mechanics approach when applied to the constant amplitude fatigue of CFRP-epoxy double-lap joints. Abdel Wahab et al. (2010a) later extended this approach to the low cycle fatigue of bulk adhesive where damage evolution curves were derived assuming isotropic damage and a stress triaxiality function equal to one that agreed well with experimental measurements. In further work, Abdel Wahab et al. (2010b) applied the approach to single-lap joints which required determination of the triaxiality function to account for the multiaxial stress state in the joint, and it was seen that this value varied along the adhesive layer. The dependency of the triaxiality function on the joint type was further investigated by Abdel Wahab et al. (2011a, b).

Although the CDM approach described above enabled the progressive degradation of the adhesive layer to be characterized, it did not allow the initiation and propagation phases of fatigue to be explicitly modeled. Shenoy et al. (2010a) used a damage mechanics-based approach to progressively model the initiation and evolution of damage in an adhesive joint, leading to crack formation and growth. In this approach, the damage rate  $dD/dN$  was assumed to be a power law function of the localized equivalent plastic strain range,  $\Delta \epsilon_p$ , i.e.:

$$\frac{dD}{dN} = C_D (\Delta \epsilon_p)^{m_D} D \quad (18)$$

where  $C_D$  and  $m_D$  are experimentally derived constants. The fatigue damage law was implemented in a finite element model. In each element, the rate of damage was determined from the finite element analysis using Eq. (18), and the element properties degraded as:

$$E = E_0(1 - D)$$

$$\sigma_{yp} = \sigma_{yp0}(1 - D) \quad (19)$$

$$\beta = \beta_0(1 - D)$$

where  $E_0$ ,  $\sigma_{yp0}$ , and  $\beta_0$  are Young's modulus, yield stress, and plastic surface modifier constant for the Parabolic Mohr–Coulomb model, respectively, and  $D = 1$  represents a fully damaged element, which was used to define the macrocrack length. The fatigue life was broken into a number of steps with a specified number of cycles,  $\Delta N$ , and at each step, the increased damage determined using Shenoy et al. (2010a):

$$D_{i+1} = D_i + \frac{dD}{dN} dN \quad (20)$$

showed that this method could be used to predict total-life plots, the fatigue initiation life, fatigue crack growth curves, and strength and stiffness wearout plots and could also be extended to variable amplitude fatigue (Shenoy et al. 2010b). Walander et al. (2014) experimentally studied Mode-I fatigue crack growth in rubber and polyurethane-based adhesives using a double-cantilever beam specimen. A damage growth law of a similar form to Eq. (20) related damage evolution with three material parameters:  $\alpha$ ,  $\beta$ , and  $\sigma_{th}$ , which were determined from the experimental data. Good correlation between the experimental data and the proposed damage law for fatigue was reported.

A similar approach was proposed by Khoramishad et al. (2010a) in which the rate of damage was related to the maximum principal strain,  $\epsilon_{max}$ , rather than the equivalent strain and a threshold strain,  $\epsilon_{th}$ , was used rather than a plastic strain in order to define a strain below which fatigue damage does not occur.

$$\frac{dD}{dN} = \begin{cases} C \times (\epsilon_{max} - \epsilon_{th})^b, & \epsilon_{max} > \epsilon_{th} \\ 0, & \epsilon_{max} \leq \epsilon_{th} \end{cases} \quad (21)$$

where  $C$  and  $b$  are experimentally determined material damage constants. In this case, the damage initiation and fracture was modeled using a bilinear cohesive zone model (as described in ► Chap. 25, “Numerical Approach: Finite Element Analysis”) and the damage variable was used to degrade the parameters of the cohesive model as illustrated in Fig. 13. This method was later extended to incorporate the effect of varying load ratio (Khoramishad et al. 2010b), variable amplitude fatigue (Khoramishad et al. 2011), and the effect of moisture degradation (Katnam et al. 2011).

Pirondi and Moroni (2010) also proposed a method of predicting fatigue crack growth using cohesive zone elements within a finite element analysis. In this case, the damage rate was related to the strain energy release rate. Oinen and Marquis (2011) presented a damage model for the shear decohesion of combined clamped and adhesively bonded (i.e., hybrid) joints that incorporated a linear-exponential cohesive zone model and a frictional contact model to account for a combined slip and decohesion response to loading.

### 33.5 Creep-Fatigue

Evidence of creep in the fatigue testing of bonded lap joints has been observed by a number of authors. It was seen in Sect. 4.3 that application of a standard fracture mechanics method can significantly overpredict the fatigue life if there is

**Fig. 13** Degradation of cohesive zone model parameters with increasing fatigue damage (Khoramishad et al. 2010a)

significant accumulated creep. This is not surprising as polymeric adhesives will exhibit some degree of viscoelastic or viscoplastic behavior over a part of their operating range. The importance of the creep contribution to fatigue failure will depend on a number of factors such as the nature of the adhesive, the ambient temperature and humidity, the joint geometry, the mean fatigue load, and the frequency. Fatigue crack growth in such circumstances may still be adequately represented by LEFM or EPFM parameters; however, different fatigue crack growth curves will be required for different frequencies and temperatures, as shown in Fig. 14. However, if creep is significant, then fatigue crack growth may be better represented by a time-dependent fracture mechanics (TDFM)

**Fig. 14** The effect of test frequency on fatigue crack growth plots for steel-epoxy DCB samples (Al-Ghamdi et al. 2003)

parameter. Landes and Begley (1976) proposed a TDFM parameter analogous to Rice's J-integral that they called  $C^*$  and defined it as follows:

$$C^* = \int_{\Gamma} W^* dy - T_i \left\{ \partial \frac{\dot{u}}{\partial x} \right\} ds \quad (22)$$

where

$$W^* = \int_0^{\dot{\epsilon}_{ij}} \sigma_{ij} d\dot{\epsilon}_{ij} \quad (23)$$

$\Gamma$  is a line contour taken counter clockwise from the lower crack surface to the upper crack surface,  $W^*$  is the strain energy rate density associated with the stress  $\sigma_{ij}$  and strain rate  $\dot{\epsilon}_{ij}$ ,  $T_i$  is the traction vector defined by the outward normal  $n$  along  $\Gamma$ ,  $\dot{u}_i$  is the displacement rate vector, and  $s$  is the arc length along the contour.  $C^*$  is valid

only for extensive steady-state creep condition, and Saxena (1986) proposed an alternative parameter,  $C_t$ , that was suitable for characterizing creep crack growth from small scale to extensive creep conditions. This was defined as:

$$C_t = -\frac{1}{B} \partial U_t^* \left( \frac{a, t, \dot{V}_c}{\partial a} \right) \quad (24)$$

where  $B$  is sample width,  $a$  is crack length,  $t$  is time,  $U_t^*$  is an instantaneous stress–power parameter, and  $\dot{V}_c$  is the load line deflection rate.

In cyclic loading,  $C_t$  will vary with the applied load, and an average value of  $C_t$ ,  $C_{t(ave)}$ , may be used to characterize the fatigue-creep crack growth. Al-Ghamdi et al. (2004) proposed three methods of predicting creep-fatigue crack growth in bonded joints. In the first method, an appropriate fracture mechanics parameter is selected and plotted against the fatigue crack growth rate (FCGR =  $da/dN$ ) or the creep crack growth rate (CCGR =  $da/dt$ ). A suitable crack growth law is fitted to the experimental data and crack growth law constants are determined at different temperatures and frequencies. Empirical interpolation can then be used to determine crack growth law constants at unknown temperatures and frequencies. This method can also be used to predict crack growth under conditions of varying frequency, load, and temperature.

The second method was called the *dominant damage approach* and assumes that fatigue and creep are independent mechanisms and that crack growth is determined by whichever is dominant. In this case, crack growth should be predominantly either cycle or time dependent. For example, if creep is the dominant damage mechanism, then plots of  $da/dt$  against a suitable TDFM should be independent of frequency and can be used to predict the fatigue life in terms of time under load rather than number of cycles.

The third method was termed the *crack growth partitioning approach* in which it is assumed that crack growth can be partitioned into separate cycle-dependent (fatigue) and time-dependent (creep) components, both of which contribute the total crack, as represented by the following equation:

$$\frac{da}{dN} = \left( \frac{da}{dN} \right)_{\text{fatigue}} + \frac{1}{f} \left( \frac{da}{dt} \right)_{\text{creep}} \quad (26)$$

Al-Ghamdi et al. (2004) proposed the following form of Eq. (26):

$$\frac{da}{dN} = D(G_{\max})^n + \frac{mC_{t(ave)}^q}{f} \quad (27)$$

where the fatigue crack growth constants  $D$  and  $n$  are determined from high-frequency tests, and the creep crack growth constants  $m$  and  $q$  are determined from constant load crack growth tests. Under some conditions, this method still underpredicts the crack growth, in which case a creep-fatigue interaction term may be added:

$$\frac{da}{dN} = D(G_{\max})^n + \frac{mC_{t(ave)}^q}{f} + CF_{\text{int.}} \quad (28)$$

where  $CF_{\text{int.}} = R_f^p R_c^y C_{fc}$  and  $R_f$  and  $R_c$  are scaling factors for the cyclic and time-dependent components, respectively.

$$R_f = \frac{(da/dN)}{(da/dN) + (da/dt)/f}$$

$$R_c = \frac{(da/dt)/f}{(da/dN) + (da/dt)/f}$$

and  $p$ ,  $y$ , and  $C_{fc}$  are empirical constants.

### 33.6 Impact Fatigue

There is increasing interest in the effects of repetitive low-velocity impacts produced in components and structures by vibrating loads. This type of loading is known as impact fatigue. Typical plots of normalized force as a function of time from the impact fatigue testing of a bonded single-lap joint are shown in Fig. 15. It can be seen that the duration of the main peak is approximately 2 ms and that subsequent peaks are of significantly smaller magnitude. It can also be seen that the maximum force,  $F_{\max}$ , and the load time for the first peak,  $T_F$ , decrease with the number of cycles, which is indicative of progressive fatigue damage in the adhesive. As the force is not constant in an impact fatigue test, it is useful to define a mean maximum force  $\bar{F}_{\max}$  as:

**Fig. 15** Variation in force and strain with time in a typical impact in the impact fatigue testing of a bonded lap joint (Casas-Rodriguez et al. 2007)

**Fig. 16**  $F$ - $N$  diagrams for aluminum-epoxy single-lap joints in impact and standard fatigue (Casas-Rodriguez et al. 2007)

$$\bar{F}_{\max} = \frac{1}{N_f} \sum_{i=1}^{N_f} F_i^{\max} \quad (29)$$

In Fig. 16, the normalized mean maximum force is plotted against the logarithm of cycle to failure and it can be seen that an approximately linear relationship is observed, with cycles to failure increasing as the force decreases, as expected. A plot for similar single-lap joints, manufactured with the same materials and processes, tested in standard fatigue with a constant force amplitude, sinusoidal waveform can also be seen in Fig. 16. It can be seen from this that the impact fatigue appears to be significantly more damaging than the standard fatigue. Casas-Rodriguez et al. (2008) also compared damage and crack growth in CFRP-epoxy lap-strap joints in standard and impact fatigue and found that the accumulated energy associated with damage in impact fatigue was significantly lower than that associated with similar damage in standard fatigue. It was also seen that the fracture surfaces, and hence, the fracture mechanisms, were quite different for the two types of loading. Ashcroft et al. (2011) also investigated the impact fatigue of notched bulk adhesive samples, developing an impact fatigue growth law based on the dynamic strain energy release rate.

### 33.7 Conclusion

It can be seen that a number of techniques have been used to model fatigue in bonded joints. Although most methods have limitations, all are useful in understanding and/or characterizing the fatigue response of bonded joints, and it is expected that further

developments will continue in all the methods described. For instance, the traditional load–life approach is useful in characterizing global fatigue behavior, but is of little use in fatigue life prediction and provides no useful information on damage progression in the joint. However, combined with monitoring techniques, such as back-face strain or embedded sensors, and FEA, the method could potentially form the basis of an extremely powerful in-service damage monitoring technique for industry.

The fracture mechanics approach is potentially a more flexible tool than the stress–life approach as it allows the progression of cracking to failure to be modeled and can be transferred to different sample geometries. Problems with the traditional fracture mechanics approach include: selection of initial crack size and crack path, selection of appropriate failure criteria, load history, and creep effects. Also the fracture mechanics approach does not accurately represent the accumulation and progression of damage observed experimentally in many cases. However, recent modifications to the standard fracture mechanics method have seen many of these limitations tackled.

In future developments, it is expected that fatigue studies of bonded joints will continue to increase our knowledge of how fatigue damage forms and progresses in bonded joints and this will feed into the models being developed. In addition to further developments and extension to the approaches described above, it is expected that an area for huge potential advances is in the incorporation of increasingly sophisticated damage growth laws into finite element analysis models to develop a more mechanistically accurate representation of fatigue in bonded joint than is currently available. It is also hoped that many of the techniques described above will reach sufficient maturity to form the basis of useful tools for industry, both in the initial design and in-service monitoring of bonded joints in structural applications subjected to cyclic loading.

## Abstract

Polymer-based adhesives that have been especially designed to feature a high degree of toughness, flexibility, or even deliberately viscoelastic properties exhibit a pronounced time-dependent stress-strain behavior under static mechanical load conditions. Therefore, a suitable mechanical approach to describe and experimentally access phenomena related to creep in polymers and adhesives

P. L. Geiß (✉) · M. Schumann

needs to consider elastic as well as viscous material properties. Creep occurs at load levels below the yield strength, and particularly, creep of viscoelastic materials by definition is assigned to reversible deformation being able to recover after unloading. In technical practice, the term creep is often being used to describe arbitrary time-dependent strain including viscous and elastic-viscous behavior. The concept of generating mechanical substitute models dates back to the late eighteenth century. The Maxwell model, for example, represents a serial connection of a spring-(elastic) and a dashpot-(viscous) element. Other viscoelastic models are discussed in terms of their creep (retardation) strain and relaxation stress response to a corresponding stress or strain input in the generalized form of a step-unit function. The resulting constitutive laws for stress-strain-time relationship under static stress or strain conditions can be applied in the limits of linear elasticity where the Boltzmann superposition principle and the correspondence principle are valid. The options for experimentally accessing creep and relaxation phenomena range from standardized procedures to advanced test methods, which are discussed in the context of experimental data. Applying the theoretical background of the standard models for viscoelasticity to the experimental results can improve the reliability of predictive methods intending to extrapolate results from short-term experiments to a long-term timescale.

---

## 34.1 Introduction

In the seventeenth century, the British physicist Robert Hooke (Purrington 2009) defined the basic relation between stress and strain as “*Ut tensio, sic vis.*,” meaning extension is proportional to force. This so-called Hooke’s law is valid for many inorganic materials in the linear elastic region, where force-induced deformations are reversible and the material will completely return to its initial shape after removing the force without any delay or residual plastic deformations.

In the linear elastic region, constitutive material models are able to correlate strain to stress without the need to consider the history of stress and strain events a specific object or assembly has been subjected to previously. If an elastoplastic material is subjected to mechanical stress, it will also respond with instantaneous elastic deformation but above the yield strength deform plastically at a deformation rate governed by the process of deformation. Again, the behavior is not considered to be time dependent.

In most crystalline or amorphous inorganic materials, strong metallic bonds or ionic bonds are responsible for a dense structure and high level of rigidity. After exceeding the linear elastic stress-strain area, in metal alloys plastic deformation is related to the generation and movement of dislocations in the crystalline structure such as edge dislocations, screw dislocations, and sliding along grain boundaries. Amorphous inorganic glassy materials generally exhibit brittle fracture properties on a short-term timescale but are known to also deform plastically and time dependently under long-term static load conditions or at elevated temperatures. Metals and alloys also respond to elevated temperatures with a reduction of the linear elastic

deformation threshold generally referred to as the yield strength, especially once the temperature approaches or has exceeded the recrystallization temperature.

The mechanisms of plastic deformation and creep under static load conditions in organic polymer materials such as adhesives are somehow different from that and need to be considered when using structural adhesive bonds in the presence of so-called dead loads which frequently may occur due to the mere influence of gravity of the mass of a certain structure.

In 1921, Hermann Staudinger (Priesner 1983) postulated that polymers consist of chain-like macromolecules with typically carbon-carbon bonds as the repeating unit responsible for creating the backbone of a polymer chain. The average molecular weight, its statistical distribution, the presence of secondary bonds between adjacent chains, the degree of entanglement, and crosslinking by side chains are the dominant parameters influencing the mechanical properties of polymer materials.

Depending on the degree of geometric order, polymer materials may also develop crystallinity by self-organized alignment of chains or segments into stacks and on a superordinated level into spherulites. Examples of semicrystalline polymer materials include isotactic or syndiotactic polypropylene. Most adhesive polymer materials, however, show little or no macroscopic level of crystallinity. Plastic deformation in polymers can either take place by the creation of voids (crazing), by the rotation between chain segments, or by sliding between adjacent polymer chains. While crazing can be considered as a specific type of cracking on a micro- and nanoscopic size level, segment rotation and chain sliding are reversible physical phenomenon.

Micro-Brownian movement is related to a change in conformation without dislocating the center of gravity of the polymer chain, while strain by macro-Brownian is characterized by a local movement of the center of gravity of a polymer chain under the effect of, e.g., mechanical stress. As with the mechanisms of creep described above for inorganic crystalline or amorphous materials, the inelastic deformation of polymers is strongly related to the temperature, since in addition to mechanical stress, temperature serves as a source of activation energy to stimulate rotation and related Brownian movement on a nanoscopic level. In the range of the glass transition area, the ability of chain segments to rotate is strongly promoted with increasing temperature. Above the so-called glassy state of a polymer, the linear elastic properties diminish, and the relation between stress and strain can no longer be approximated by Hooke's law with adequate accuracy. This is the reason why several viscoelastic models have been subsequently developed, to provide means of describing, analyzing, and predicting the mechanical behavior of materials exhibiting an elastic and viscous time- and temperature-dependent stress-strain relationship.

---

## 34.2 Viscoelastic Models

The term viscoelasticity combines viscous and elastic stress-strain flow characteristics. If material behavior is dominated by viscous flow, it is generally referred to as a fluid, whereas if the elastic properties dominate the mechanical properties of a material, it is considered to be solid. Most adhesives are applied in a liquid or

112 pasty condition to allow wetting and promote spreading and then are required to  
 113 phase change into a solid. In the liquid state, rheology provides the methods to  
 114 differentiate between elastic and viscous flow characteristics, while dynamic  
 115 mechanical analysis of cured adhesive polymers uses similar principles to access  
 116 elastic and viscous parameters of the stress-strain response.

117 If no stress threshold is required to initiate viscous flow, the behavior is called  
 118 viscoelastic; if a certain stress threshold (yield strength) needs to be overcome before  
 119 the beginning of time-dependent viscous flow, the behavior is addressed as viscoplastic.

120 When subjected to constant stress for a certain period of time, three basic parts of  
 121 strain response may typically be observed. Immediately after applying a certain  
 122 amount of stress, instantaneous elastic strain takes place followed by delayed elastic  
 123 strain. Delayed elastic strain will completely recover after removing stress. It is often  
 124 referred to as primary creep. Following delayed elastic strain, viscous flow can often  
 125 be observed for polymer adhesive materials with low crosslinking density. Strain  
 126 caused by viscous flow leads to permanent deformation and is generally referred to  
 127 as non-recoverable strain or secondary creep. Figure 1 illustrates schematically the  
 128 strain response of such a material to a limited period of stress. The level of  
 129 instantaneous elastic strain upon loading corresponds to the instantaneous strain  
 130 recovery after removing the load.

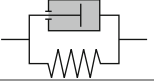

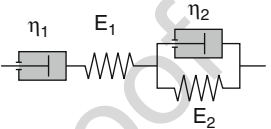

131 The aim of viscoelastic models is to use a combination of mechanical elastic and  
 132 viscous standard elements to generate a comprehensive mechanical substitute sys-  
 133 tem showing more or less simplified viscoelastic properties and thus to provide  
 134 parameters for building constitutive equations suitable for the prediction of visco-  
 135 elastic behavior and the characterization of viscoelastic materials.

136 James Clerk Maxwell (Niven 2003) proposed in 1867 a simplified mechanical  
 137 model consisting of a viscous dashpot in a serial connection to an elastic spring to  
 138 describe viscoelastic material properties.

**Fig. 1** Schematic strain response of viscoelastic materials to a period of stress

**Table 1** Comparison of various viscoelastic models and related differential equations,  $\sigma$ : stress parameter,  $\epsilon$ : strain parameter,  $E$ : elastic parameter,  $\eta$ : viscous parameter,  $\lambda$ : relaxation time

t.2	HOOKE-spring element (linear elasticity) $\sigma = E_0 \cdot \epsilon$	
t.3	NEWTON-fluid (linear viscosity) $\sigma = \eta_0 \cdot \dot{\epsilon}$	
t.4	KELVIN-VOIGT-solid $\sigma = E_0 \cdot \epsilon + \eta_0 \cdot \dot{\epsilon}$	
t.5	MAXWELL-fluid $\sigma + \lambda_0 \cdot \dot{\sigma} = \eta_0 \cdot \dot{\epsilon}$ ( $\lambda_0 = \eta_0/E_0$ )	
t.6	BURGERS-fluid (four parameter model) $\sigma + \left(\frac{\eta_1}{E_1} + \frac{\eta_2}{E_2} + \frac{\eta_2}{E_2}\right) \cdot \dot{\sigma} + \left(\frac{\eta_1 \cdot \eta_2}{E_1 \cdot E_2}\right) \cdot \ddot{\sigma} = \eta_1 \cdot \dot{\epsilon} + \left(\frac{\eta_1 \cdot \eta_2}{E_2}\right) \cdot \ddot{\epsilon}$	

The spring element is considered to behave according to Hooke's law in a linear elastic manner, while the mechanical behavior of the dashpot equates linear viscous flow of a Newtonian fluid. The following models of, e.g., Lord Kelvin and Woldemar Voigt (Thomson 1875) suggested a parallel connection of a dashpot and a spring element, while the Burgers model (Burgers 1935) named after the Dutch physicist Johannes Martinus Burgers consists of a Maxwell element and a Kelvin-Voigt element in series. Further generalized Maxwell or Kelvin-Voigt models connected an arbitrary or even infinite number of single elements to generate a spectral distribution of relaxation and retardation properties. Table 1 gives an overview of the most commonly used mechanical models for viscoelasticity and their corresponding differential equations.

**34.2.1 Creep Under Static Stress Conditions (Retardation)**

The time-dependent increase in strain of viscoelastic polymers under static stress conditions is generally referred to as creep or retardation. To describe creep behavior of adhesive joints under static stress conditions using viscoelastic models, it is assumed that a specimen be subjected at a certain time  $t = 0$  to a defined constant level of tensile stress  $\sigma = \sigma_0$  or shear stress  $\tau = \tau_0$ .

The stress-strain history then provides the boundary conditions for solving the differential equation in the following way:

$$\begin{aligned} \epsilon &= 0 \text{ for } t < 0 \\ \sigma &= 0 \text{ for } t < 0 \\ \sigma &= \sigma_0 = \text{constant for } t \geq 0 \end{aligned} \tag{1}$$

### Creep Response of the Maxwell Model

The single spring element of the Maxwell fluid (Niven 2003) does not exhibit any time-related strain behavior, and the response to stress  $\sigma_0$  at  $t = 0$  can be expressed as

$$\varepsilon(t)_{\text{spring}} = \frac{\sigma_0}{E} \quad (2)$$

The parameter  $E$  represents the elastic constant of the spring element.

The time-dependent strain of the dashpot element due to viscous flow under constant stress can be described as follows:

$$\varepsilon(t)_{\text{dashpot}} = \frac{\sigma_0}{\eta} \cdot t \quad (3)$$

with  $\eta$  being a parameter related to the Newtonian viscous flow behavior of the dashpot element and the stress response of this dashpot being proportional to the strain rate. The overall time-dependent strain of the Maxwell fluid thus can be calculated as

$$\varepsilon(t) = \frac{\sigma_0}{\eta} \cdot t + \frac{\sigma_0}{E} \quad (4)$$

Dividing the viscous parameter  $\eta$  with a dimension unit of Pa·s by  $E$  with a dimension unit of Pa provides the parameter  $\lambda$  generally referred to as the relaxation time. The time-dependent retardation strain response of the Maxwell model can then be expressed as

$$\varepsilon(t) = \frac{\sigma_0}{\eta} \cdot t + \frac{\sigma_0}{E} = \frac{\sigma_0}{E} \cdot \left(1 + \frac{t}{\lambda}\right) = \sigma_0 \cdot F(t) \quad \text{with } \lambda = \eta/E \quad (5)$$

The term  $F(t)$  generally is referred to as the creep function. After a certain time of creep corresponding to  $\lambda$  has passed, the ratio  $t/\lambda$  equals 1, and the viscous strain matches the initial elastic strain.

The right side of Fig. 2 illustrates the resulting strain response for the schematic stress history indicated on the left side of Fig. 2.

The Maxwell model allows the approximation of elastic and creep strain under static stress as a function of time by assigning elastic compliance leading to instant

**Fig. 2** Stress history and corresponding creep response for viscoelastic materials according to the Maxwell spring and dashpot model

elastic strain to the spring part of the model. The flow due to creep is represented by the linear slope related to the single dashpot element with linear viscous flow properties.

In practice, viscoelastic adhesive polymers do not show a discontinuous sharp bend but rather a smooth transition from the initial elastic strain to steady-state creep. A further refinement of the viscoelastic model is therefore needed to create a model converging with actually observed viscoelastic behavior.

### Creep Response of the Kelvin-Voigt Model

The Kelvin-Voigt model (Thomson 1875) addresses this issue by using a parallel connection of a spring and a dashpot. The boundary condition for solving the corresponding differential equation is that spring and dashpot at all times share the same level of strain:

$$\varepsilon_{(\text{Spring})} = \varepsilon_{(\text{Dashpot})} \quad (6)$$

The applied stress is shared by both the spring and the dashpot element:

$$\sigma_0 = \sigma_{(\text{Spring})} + \sigma_{(\text{Dashpot})} \quad (7)$$

The solution of the differential equation for the time-dependent creep response under these boundary conditions can be expressed as

$$\varepsilon(t) = \frac{\sigma_0}{E} \cdot \left(1 - e^{-t/\lambda}\right) = \sigma_0 \cdot F(t) \quad (8)$$

where again the ratio  $\lambda = \eta/E$  is the relaxation time and  $F(t)$  is the creep function of the Kelvin-Voigt model. When a period of time with a duration of  $\lambda$  has passed, the exponent  $t/\lambda$  equals 1 and the factor  $e^{-1}$  attains a value of  $\approx 0.37$ . Accordingly, creep strain at relaxation time has reached  $\approx 63\%$  of the infinite ultimate value for this specific viscoelastic model. Figure 3 illustrates the schematic time-dependent creep response of the Kelvin-Voigt model for a similar load history like in Fig. 2.

Compared to the previously discussed Maxwell model and actual experimental data, the advantage of the Kelvin-Voigt model is that the strain exponentially approaches an ultimate strain limit without any discontinuities. Steady-state long-term creep and initial elastic strain, however, are not represented in the overall strain response according to the Kelvin-Voigt model.

**Fig. 3** Schematic creep response to a stress step function for viscoelastic materials according to the Kelvin-Voigt model

### Creep Response of the Burgers Model

The combination of both the Kelvin-Voigt and the Maxwell model in the Burgers model (Burgers 1935) leads to an even more realistic approach. The solution of the corresponding differential equation can be obtained by simply adding the Kelvin-Voigt and Maxwell shares of the time-dependent strain response.

$$\begin{aligned}\varepsilon(t) &= \sigma_0 \cdot \left( \frac{1}{E_1} + \frac{1}{\eta_1} \cdot t + \frac{1}{E_2} \left( 1 - e^{-\frac{t E_2}{\eta_2}} \right) \right) \\ &= \sigma_0 \cdot \left( \frac{1}{E_1} + \frac{1}{E_1 \cdot \lambda_1} \cdot t + \frac{1}{E_2} \left( 1 - e^{-\frac{t}{\lambda_2}} \right) \right) = \sigma_0 \cdot F(t)\end{aligned}\quad (9)$$

with the relaxation times  $\lambda_1 = \eta_1/E_1$  and  $\lambda_2 = \eta_2/E_2$  and  $F(t)$  being the creep function of the Burgers model. The assignment of the individual spring and dashpot elements according to this model has been shown in Table 1.

The schematic strain retardation response of the Burgers model to a step-function stress input is illustrated in Fig. 4.

The creep response according to the Burgers model in Fig. 4 covers all elementary aspects of time-dependent viscoelastic behavior including instantaneous elastic strain, secondary steady-state creep in the long-term area, and a delayed elastic strain transition behavior that can be, e.g., fitted to experimental data according to the choice of the  $\eta_1$ ,  $E_1$ ,  $\eta_2$ , and  $E_2$  parameters.

Increasing the number of interconnected spring and dashpot elements in building viscoelastic models will increase the degrees of freedom in fitting the models to experimental data and for generalized models based on an infinite number of single elements will match the continuum mechanics approach of solid and fluid dynamics.

The challenge in selecting an appropriate viscoelastic model for a specific area of practical application is to obtain the simplest relation but still to achieve the desired level of accuracy.

### 34.2.2 Creep Under Static Strain Conditions (Relaxation)

If a bonded assembly is subjected to a defined strain condition like a joint in a confined construction, creep-related phenomena in the adhesive polymer would lead

**Fig. 4** Creep response for viscoelastic materials according to the Burgers model

to a time-dependent reduction of stress. This process is generally referred to as relaxation.

In describing relaxation behavior of adhesive joints using viscoelastic models, it is assumed that a specimen is subjected at a certain time  $t = 0$  to a defined constant level of strain  $\varepsilon = \varepsilon_0$  in tensile load conditions or  $\tan \gamma = \tan \gamma_0$  in the case of shear-loaded joints.

The strain-stress history again provides the boundary conditions for the differential equation as follows:

$$\begin{aligned} \varepsilon &= 0 \text{ for } t < 0 \\ \sigma &= 0 \text{ for } t < 0 \\ \varepsilon &= \varepsilon_0 = \text{constant for } t \geq 0 \end{aligned} \quad (10)$$

### Relaxation of the Maxwell Model

Relaxation of the simple Maxwell fluid model will decrease the initial level of stress caused by the elasticity of the spring element by viscous elongation of the dashpot until all stress has been completely relieved. The solution of the first-order linear differential equation in the case of  $\varepsilon = \varepsilon_0 = \text{const}$  describes the time-dependent relaxation of stress for the Maxwell model as follows:

$$\sigma(t) = E \cdot \varepsilon_0 \cdot \left( e^{-\frac{t}{\lambda}} \right) = \varepsilon_0 \cdot R(t) \quad (11)$$

with  $E$  being a parameter representing the elastic constant of the spring element,  $\lambda = \eta/E$  being the relaxation time, and  $R(t)$  being the relaxation function of the Maxwell model. The characteristic time-dependent stress relaxation response of the Maxwell model to a step-function strain input is illustrated in Fig. 5.

### Relaxation of the Kelvin-Voigt Model

Since the Kelvin-Voigt model consists of a parallel connection of spring and dashpot, the initial level of stress depends on the viscosity  $\eta$  assigned to the dashpot and the strain rate when applying initial strain at  $t = 0$ .

**Fig. 5** Relaxation of stress according to the simple Maxwell model

The stress response to a step-function type of strain signal as indicated on the left side of Fig. 5 would jump to an infinite level. Therefore, this model is not able to give a reasonable approximation of relaxation phenomenon under these preconditions.

### Relaxation of the Burgers Model

The extension to the four-parameter Burgers model provides again a more detailed description of relaxation in viscoelastic polymer materials. The initial differential equation and the assignments of parameters are as follows:

$$\sigma + \left( \frac{\eta_1}{E_1} + \frac{\eta_1}{E_2} + \frac{\eta_2}{E_2} \right) \cdot \dot{\sigma} + \left( \frac{\eta_1 \cdot \eta_2}{E_1 \cdot E_2} \right) \cdot \ddot{\sigma} = \eta_1 \cdot \dot{\varepsilon} + \left( \frac{\eta_1 \cdot \eta_2}{E_2} \right) \cdot \ddot{\varepsilon} \quad (12)$$

The initial stress upon application of a constant strain is governed by the Maxwell spring element  $E_1$ , and relaxation on a long-term timescale is dominated by the Maxwell dashpot  $\eta_1$ , while the Kelvin-Voigt section with  $E_2$  and  $\eta_2$  governs the delayed elastic relaxation. Solving the differential equation by Laplace transformation is, e.g., comprehensively described in Betten (2008).

Another possibility to work with the parameters if the viscoelastic Burgers models in evaluating and predicting relaxation phenomena is by using a recursive definition of the relaxation function  $\sigma(t)$ . Therefore, the total period of time to be considered is first divided into  $n_t$  incremental steps, and the calculation of strain for each consecutive step is based on the value of the preceding one.

Starting at  $t = 0$ , again assuming a strain-stress sequence according to a strain step function for relaxation experiments with

$$\begin{aligned} \varepsilon &= 0 \text{ for } t < 0 \\ \sigma &= 0 \text{ for } t < 0 \\ \varepsilon &= \varepsilon_0 = \text{constant for } t \geq 0 \end{aligned} \quad (13)$$

both dashpots  $\eta_1$  and  $\eta_2$  will give a rigid response to an instantaneous strain input  $\varepsilon_0$ . In consequence, the total initial strain of the Burgers model in the first incremental step is governed by the spring element  $E_1$  and can be calculated as

$$\sigma(n_t = 1) = E_1 \cdot \varepsilon_0 \quad (14)$$

During the next incremental step,  $\sigma(n_t = 1)$  will cause the dashpot  $\eta_1$  to expand to a strain of

$$\varepsilon_{\eta_1}(n_t = 2) = \frac{\sigma(n_t = 1)}{\eta_1} \cdot \Delta t \quad (15)$$

During this step, no load has been transferred to the second spring element  $E_2$ , and the increase of strain in dashpot  $\eta_2$  can be approximated in the same manner:

$$\varepsilon_{\eta_2}(n_t = 2) = \frac{\sigma(n_t = 1)}{\eta_2} \cdot \Delta t \quad (16)$$

278 The total viscous strain  $\varepsilon_{\eta 1}(n_t = 2) + \varepsilon_{\eta 2}(n_t = 2)$  will reduce the elongation of  
 279 the  $E_1$  spring element to a value of  $\varepsilon_0 - (\varepsilon_{\eta 1}(n_t = 2) + \varepsilon_{\eta 2}(n_t = 2))$  and reduce the  
 280 overall stress in the next step to

$$\sigma(n_t = 2) = E_1 \cdot (\varepsilon_0 - \varepsilon_{\eta 1}(n_t = 2) - \varepsilon_{\eta 2}(n_t = 2)) \quad (17)$$

281 The last incremental effect to be considered according to this recursive model is  
 282 that the strain in dashpot  $\eta_2$  has transferred a part of the load to the spring element  $E_2$ .  
 283 For the calculation of the next step, this spring element carries the load

$$\sigma_{E2}(n_t = 3) = E_2 \cdot \varepsilon_{\eta 2}(n_t = 2) \quad (18)$$

284 The stress causing dashpot  $\eta_2$  to further expand is reduced accordingly to

$$\sigma_{\eta 2}(n_t = 3) = \sigma(n_t = 2) - E_2 \cdot \varepsilon_{\eta 2}(n_t = 2) \quad (19)$$

285 The resulting increase in strain of dashpot  $\eta_2$  for the next step will then be

$$\varepsilon_{\eta 2}(n_t = 3) = \frac{\sigma(n_t = 2) - E_2 \cdot \varepsilon_{\eta 2}(n_t = 2)}{\eta_2} \cdot \Delta t \quad (20)$$

286 Following the third increment, the calculation is repetitive, and the accuracy  
 287 depends on the choice of the number of increments  $\Delta t$  in relation to the total time  
 288 span to be considered. The recursive definition can easily be implemented into  
 289 computer-based spreadsheet calculation tools and be extended to other spring-  
 290 dashpot combinations if desired.

### 291 34.2.3 Generalized Models

292 The greater the number of connected spring and dashpot elements in a viscoelastic  
 293 model, the better a fitting to the material behavior of a specific polymer can be  
 294 accomplished. In the generalized Maxwell model, a spring and dashpot are  
 295 connected to an arbitrary number of Maxwell elements in parallel. In the generalized  
 296 Kelvin-Voigt model, a Maxwell element is connected to an arbitrary number of  
 297 Kelvin-Voigt elements in series.

298 The notional transition from a finite number of elements to an infinite number  
 299 (i.e., a spectrum) of elements leads to models where  $\Gamma(\lambda)$  expresses the probability  
 300 density of relaxation times in the generalized Maxwell model. The relaxation  
 301 function of the generalized Maxwell spectrum then is

$$R(t) = \int_0^{\infty} \Gamma(\lambda) \cdot e^{(-t/\lambda)} d\lambda \quad (21)$$

In a similar way, for an infinite number of elements in the generalized Kelvin-Voigt model,  $f(\lambda)$  may be used to express the probability density of retardation times, and the creep function  $F(t)$  for the spectrum in the case of the generalized Kelvin-Voigt model can be written as

$$F(t) = \int_0^{\infty} f(\lambda) \cdot (1 - e^{(-t/\lambda)}) d\lambda \quad (22)$$

The functions  $\Gamma(\lambda)$  and  $f(\lambda)$  characterize the retardation and respectively the relaxation spectra and thus represent the distribution of retardation and relaxation time values in a specific material. Further details are given in Haddad (1995) and de With (2006).

### 34.3 Superposition Principles

Describing and predicting viscoelastic properties of polymer materials or adhesively bonded joints on the basis of analytical mathematical equations is only justified in the limits of linear viscoelasticity. Linear viscoelasticity is typically limited to strain levels below 0.5%. Furthermore, linear viscoelastic behavior is associated to the Boltzmann superposition principle, the correspondence principle, and the principle of time-temperature superposition.

#### 34.3.1 Boltzmann Superposition Principle

According to the Boltzmann superposition principle, the time-dependent strain caused by two individual stress incidents  $\sigma_1(t)$  and  $\sigma_2(t)$  can be calculated as  $\varepsilon_1(t) + \varepsilon_2(t)$  if  $\sigma_1(t)$  would cause  $\varepsilon_1(t)$  and  $\sigma_2(t)$  would cause  $\varepsilon_2(t)$ . In consequence, according to the Boltzmann superposition principle in the linear viscoelastic range, strain responses from subsequent stress histories may simply be summarized if according to the criterion of proportionality at any instant of time, the strain response behaves proportional to the stress level:

$$f[c \cdot \sigma(t)] = c \cdot f[\sigma(t)] (c = \text{constant}) \quad (23)$$

The criterion of superposition of input histories can be expressed accordingly as

$$f[\sigma_1(t_1), \sigma_2(t_2), \dots, \sigma_n(t_n)] = f[\sigma_1(t_1)] + f[\sigma_2(t_2)] + \dots + f[\sigma_n(t_n)] \quad (24)$$

Figure 6 illustrates how the Boltzmann superposition principle will affect the total creep strain in a step-loaded creep experiment.

When at a time  $t_1$  the initial stress  $\sigma_1$  is applied, then the time-dependent strain  $\varepsilon_1(t)$  is induced in

**Fig. 6** Effect of the Boltzmann superposition principle on creep strain in a step-loading creep experiment

$$\varepsilon_1(t) = \sigma_1 \cdot J(t) \quad (25)$$

According to linear viscoelasticity, the compliance  $J(t)$  is independent of stress, i.e.,  $J(t)$  is the same for different stress levels at a particular time. Once the following stress increment  $\sigma_2 - \sigma_1$  is applied at time  $t_2$ , the additional strain increase due to stress increment  $\sigma_2 - \sigma_1$  is

$$\varepsilon_2(t) = (\sigma_2 - \sigma_1) \cdot J(t - t_2) \quad (26)$$

In a similar way, the additional strain increase due to  $\sigma_3 - \sigma_2$  can be calculated as

$$\varepsilon_3(t) = (\sigma_3 - \sigma_2) \cdot (t - t_3) \quad (27)$$

### 34.3.2 Correspondence Principle

The correspondence principle following the Boltzmann superposition principle allows the conversion of the common mechanical relationships of linear elasticity theory into linear viscoelasticity simply by replacing  $\sigma$  by time-dependent  $\sigma(t)$  and  $\varepsilon$  by time-dependent  $\varepsilon(t)$ . Young's modulus  $E$  is accordingly transformed to the creep modulus  $E_C(t) = \sigma/\varepsilon(t)$  or the creep compliance  $J(t) = \varepsilon(t)/\sigma$ , respectively, and the relaxation modulus  $E_R(t) = \sigma(t)/\varepsilon$ . These time-dependent parameters can be determined from tensile creep and relaxation experiments. In compression or shear mode, the corresponding parameters of moduli are calculated in a similar manner.

In linear viscoelasticity, the creep function and the relaxation function are inter-related, and each would permit the derivation of the viscoelastic constitutive relation under the condition that the principle of time invariance can be applied, meaning that the material is influenced only by  $\sigma(t)$  and  $\varepsilon(t)$  and no other influencing variables are being effective. In summary, in the idealized case of the isothermal linear viscoelasticity under the conditions of static stress or strain, the linear viscoelastic behavior of a material may adequately be described by the creep function  $F(t)$ , the relaxation function  $R(t)$ , the retardation spectrum, or the relaxation spectrum.

### 34.3.3 Time-Temperature Superposition Principle

The time-temperature superposition principle is based on the assumption that in the linear viscoelastic region, the different mechanical parameters exhibit similar temperature dependence. Under this precondition, an increase in temperature will cause a similar change in mechanical properties as an increase in time for the time-dependent mechanical viscoelastic parameters. In the case of a cyclic mechanical stress or strain excitation of a viscoelastic material, an increase of temperature will have a similar effect as a reduction of frequency according to the principle of time-temperature superposition. The principle of time-temperature superposition therefore is commonly applied on, e.g., data obtained by dynamic mechanical thermal analysis. The dynamic mechanical thermal analysis (DMTA) provides an effective method for measuring transitions due to morphological or chemical changes, or both, in a polymer as it is heated/cooled through a specified temperature range. For the dynamic mechanical thermal analysis (e.g., according to ASTM D 4065), a specimen of known geometry is subjected to a mechanical oscillation either at fixed or natural resonant frequencies. Elastic (storage) and viscous (loss) moduli of the specimen are then measured at varying temperatures and frequencies. Plots of the elastic modulus ( $E'$ ,  $G'$ ) related to the spring properties in the viscoelastic behavior or the loss modulus ( $E''$ ,  $G''$ ) related to the viscous dashpot properties are indicative of the viscoelastic characteristics of the specimen. The ratio  $E''/E'$  or  $G''/G'$  is defined as the loss factor  $\tan \delta$  which provides a measure of the mechanical damping due to inner friction of a viscoelastic polymer material. Rapid changes in viscoelastic properties in a particular range of temperatures, times, or frequencies are generally referred to as transition regions. Dynamic mechanical testing provides a method for determining elastic and loss moduli as a function of temperature, frequency or time, or both. A plot of the elastic modulus and loss modulus of material versus temperature provides a fingerprint of elastic and viscous properties as a function of temperature or frequency.

Experimental data obtained during such a dynamic mechanical analysis at different temperatures and frequencies can be converted using a shift function  $a = f(T)$  with  $T$  being the temperature, to merge temperature-dependent data into a master curve. This master curve then, e.g., represents the mechanical properties for a chosen temperature  $T_0$  at time or frequency levels beyond the range that had been experimentally applied in collecting the underlying data. The shift function was originally published by Williams, Landel, and Ferry (Ferry 1970) and proved to be applicable for most elastic and amorphous polymers and in its general form is fitted to give best conformity of the master curve by two parameters  $C_1$  and  $C_2$ :

$$\log a_T = \frac{C_1 \cdot (T - T_0)}{C_2 + T - T_0} \quad (28)$$

If the glass transition temperature  $T_G$  is chosen as  $T_0$ , for many polymer material parameters,  $C_1 = 17.44$  and  $C_2 = 51.6$  K have provided a good approximation.

This method can also be applied to the extrapolation of time- and temperature-dependent creep behavior. Experimental creep curves first need to be obtained at a series of different temperatures over a specific time period, followed by the values of compliance plotted on a logarithmic timescale. After one creep curve at a chosen temperature is defined as reference, creep curves at other temperatures are then shifted one by one along the log timescale until they superimpose to a single curve in the ideal case. Curves above the reference temperature are shifted to the right, and those below are shifted to the left. This procedure can be applied to predict long-term creep compliance on the basis of short-term tests at different temperature levels in the range of linear viscoelasticity.

In practice, polymers and adhesive joints are often being used under service conditions exceeding the limitations of linear viscoelasticity. Indications for non-linear viscoelastic properties include the observation that creep compliance changes for different stress levels and that the mechanical behavior not only depends on the summarized history of previous mechanical incidents but also from the sequence in which they have been applied. In this case, the simplified constitutive equations of linear viscoelasticity will fail in describing time-dependent mechanical properties. Further reference to nonlinear viscoelasticity is given in Haddad (1995) and Brinson and Brinson (2008).

## 34.4 Experimental Testing

### 34.4.1 Accessing Creep Properties of Adhesives by Rheometric Test Procedures

The term “rheology” was first introduced by Bingham and Crawford in 1948 (Scott Blair 1969). Rheology today provides a large range of experimental procedures to study the flow of fluids and the plastic deformation of soft solids.

Most scientific rheometric instruments are designed to apply a constant or oscillating torque to a sample located in a precisely adjusted and thermally controlled gap between test plates which may carry a flat or conical surface. The parallel plate (or plate-plate) geometry has the advantage of being able to take preformed sample discs which can be especially useful when working with film or tape adhesives. The main disadvantage of parallel plates is due to the fact that the shear rate varies across the radius of the sample. In most cases, an average value for the shear rate is displayed in the test results. The cone to plate geometry is designed to maintain a uniform shear rate by narrowing the shear gap toward the center of the sample.

Rheological tests are especially useful to experimentally determine the limits of linear viscoelasticity of an adhesive bulk sample, to investigate its zero-shear viscosity as a measure for creep under long-term loading, and to obtain a data basis for the calculation of relaxation time spectra.

**Limits of Linear Viscoelasticity (LVE)**

In a strain sweep under dynamic oscillation, increasing levels of strain are applied at a certain frequency. According to ASTM D 7175, the departure of the linear viscoelastic region is defined as the point at which the elastic modulus  $G'$  deviates by more than 10% from a constant (plateau) value. It should be considered that the choice of test frequency has an impact on the limit of LVE with higher frequencies causing a shift of the LVE limit to lower strain values. Figure 7 illustrates the oscillatory strain-sweep results for a hot melt adhesive in plate-plate geometry with a diameter of 25 mm at 70 °C and a test frequency of 0.1 Hz obtained with a Bohlin Gemini 150 rheometer. Departure from linear behavior occurs in this case at about 30% of deformation.

Reference on creep in relation to the rheology of pressure-sensitive adhesives is given in ► Chap. 15, “Pressure-Sensitive Adhesives (PSAs)” by C.W. Paul.

**Zero-Shear Viscosity**

At sufficiently low shear rates, creep-sensitive adhesives exhibit a so-called zero-shear viscosity (ZSV). Creep-sensitive adhesives include non-crosslinked hot melt adhesives or non-crosslinked pressure-sensitive adhesives. This parameter is indicative for the bulk adhesive’s resistance to permanent deformation under long-term loading.

Zero-shear viscosity (ZSV) may be derived for such materials from rheological creep tests under constant shear stress. The zero-shear viscosity is determined as the “steady-state viscosity” at sufficiently low levels of shear stress in the linear

**Fig. 7** Identification of the limit of linear viscoelasticity from an oscillatory strain-sweep test

**Fig. 8** Identification of secondary creep in a rheometric creep test

viscoelastic region, where strain curves should be independent of the level of stress. The steady-state viscosity criterion relates to the change in strain as a function of time and may be included in the experimental parameters of most rheometric instruments to facilitate the selection of a sufficient timescale. As the adhesive acquires secondary creep, the slope of the strain vs time diagram represents the zero-shear viscosity, and the differential of the slope approaches 1.00. Most rheometer software gives readout of the slope as the test progresses and can be set to automatically accept the data when this steady-state criterion is attained. Using state-of-the-art software tools for non-linear regression analysis, the viscoelastic parameters and relaxation time corresponding to a preselected model according to Table 1 may be fitted to the experimental data of rheometric creep/creep recovery tests. Figure 8 illustrates the time-dependent strain of a hot melt adhesive in a rotation-mode experiment under a constant stress of 1000 Pa, in plate-plate geometry with a diameter of 25 mm and a temperature of 70 °C. In this specific case, the zero-shear viscosity in the region of secondary creep converges to a level of approximately 1 MPas.

### 34.4.2 Retardation Test Methods with Adhesively Bonded Joints

Due to the polymer nature of most structural engineering adhesives, their viscoelastic deformation behavior is strongly time and temperature dependent and associated to creep (retardation) under static or so-called “dead-load” condition.

There are several standards dealing with creep and long-term mechanical properties.

ISO 899 Part 1 “Plastics – Determination of creep behaviour” specifies a method for determining the tensile creep of plastics in the form of standard bulk test specimens like specified in ISO 527. The method is suitable for use with rigid and semirigid and filled plastic materials and can be applied to the testing of adhesive bulk specimen in the form of dumb-bell-shaped test specimens molded directly or machined from molded sheets. The method is intended to provide data for engineering design and research and development purposes. Acquiring data for engineering-design purposes requires the use of extensometers like video extensometers allowing a precise measuring of the gauge length of the specimen during the test. A multi-sample tensile creep tester with video extensometer is displayed in Fig. 9.

Tensile creep properties strongly depend on the preparation procedure, the dimensions of the specimen, and the test environment. The thermal history of the test specimen has also shown to have a significant effect on creep behavior. Consequently, when exact comparative results are required, these factors must be carefully controlled.

**Fig. 9** Multi-sample tensile creep tester with video extensometer

**Fig. 10** Conversion of creep data into isochronous stress-strain diagrams

**Fig. 11** Conversion of creep data into iso-strain diagrams

In determining creep properties, a series of specimens are subjected to static loads at different levels, and their increase in strain over time is measured. Data may be either presented directly as creep strain on a logarithmic timescale, as creep modulus  $E_C(t) = \sigma/\varepsilon(t)$ , or as isochronous stress-strain diagrams where the relation between stress on the axis of ordinates over strain on the axis of abscissa is presented for different time levels. The schematic approach to converting creep data into an isochronous stress-strain diagram is illustrated in Fig. 10.

Other ways to present creep data include compilation to stress-time diagrams with continuous lines indicating time-dependent strain limits. Therefore, this way of plotting creep data is frequently referred to as an iso-strain diagram. The schematic approach for converting creep data into an iso-strain diagram is illustrated in Fig. 11.

A third alternative way of presenting the time-dependent stress-strain relationship due to creep under static load conditions is to plot the creep modulus  $E_C(t)$  on a logarithmic timescale. Provided that the materials creep is linear viscoelastic, data at different stress levels should cause similar time-dependent values of creep modulus. The schematic approach for converting creep data into a creep modulus versus time diagram is illustrated in Fig. 12.

Since the long-term behavior of bonded joints is strongly influenced by the adhesive-surface interaction at the interface, a prediction of creep and relaxation

**Fig. 12** Conversion of creep data into creep modulus versus time diagrams

for adhesives cannot only be founded on data obtained from adhesive bulk specimen in tensile mode but should consider shear load conditions and geometric bond line size effects close to practice adhesive joint assemblies.

The standard ISO 15109 “Adhesives – Determination of the time to rupture of bonded joints under static load” is focused on time to rupture of bonded lap shear specimens under a specific static load. No time-dependent shear strain is recorded according to this standard. Initial stress levels are chosen as a percentage of the ultimate tensile lap shear strength in quasi-static experiments in accordance with ISO 4587. The results are expressed as a graph of stress versus time to failure including remarks on the type of failure pattern for each specimen.

A more sophisticated procedure is described in ASTM D 1780 “Standard Practice for Conducting Creep Tests of Metal-to-Metal Adhesives.” This standard covers the determination of the amount of creep of metal-to-metal adhesive bonds due to the combined effects of temperature, tensile shear stress, and time. The primary intention of this test procedure using single lap shear specimens is to provide basic data for the choice of safe working stresses for applications in which the allowable deformation within the service life of the structure is the criterion of failure. The standard is intended to be used with standard testing machines in combination with extensometers allowing to measure shear strain close to the bond line of the employed lap shear specimen.

For the purpose of conducting creep experiments with adhesively bonded joints under natural or accelerated aging conditions, several spring loaded creep test instruments have been suggested. Since constant-stress creep tests are desirable, the usual common practice would be using constant dead weight load tests with gravity causing the predefined level of load. Creep tests made by means of spring loading or fixtures, which involve deflection or strain measurements for the application of load, are generally considered to be unsatisfactory because the creep strain of the specimen will cause a reduction of stress due to, e.g., contraction of a tensile spring. However, if the total deformation or extension in the adhesive is large, corrections can be used to compensate for the decrease in stress because of the extension in the adhesive. Spring-loaded units have the advantage of reduced weight

compared to creep testers applying the required creep load directly by means of masses. Commercial creep test instruments overcome the problem of bulky load weights by using cantilevers to amplify the load to the desired stress level during the creep experiment. Special care needs to be taken to eliminate friction in the cantilever movement since this is likely to tamper the test results.

Spring-loaded instruments for conducting creep tests on single lap shear specimens in tensile or compressive mode are described, e.g., in ASTM D 2294 “Standard Test Method for Creep Properties of Adhesives in Shear by Tension Loading (Metal-to-Metal)” or ASTM D 2293 “Standard Test Method for Creep Properties of Adhesives in Shear by Compression Loading (Metal-to-Metal).” In ASTM D 2294, the tension creep test apparatus consists of a hollow loading chamber, a solid extension rod with provisions for attachment of test specimens, and a spring. A testing machine is required to apply the static load, and a microscope is being suggested to measure the amount of creep shear strain. According to ASTM D 2293, the load conditions are adjusted in a less accurate manner by compressing a spring between two bushings to the desired load by tightening a nut. The applied load can be estimated by deflecting the spring of a given measured amount as predetermined from a calibration curve.

The standard ASTM D 4680 “Standard Test Method for Creep and Time to Failure of Adhesives in Static Shear by Compression Loading (Wood-to-Wood)” also applies a compressive force to shear specimens to monitor the creep properties of wood adhesives in lap shear geometry.

Since creep is considered as a key weakness of pressure-sensitive adhesives, various specific test methods and standards have been developed to evaluate the creep resistance of pressure-sensitive adhesives like in the European Standard EN 1943 (“Self-adhesive tapes. Measurement of static shear adhesion”), FINAT (Federation Internationale des Fabricants et Transformateurs d’Adhesives et Thermo-collants sur Papier et autres Supports), test method FTM 8 (Resistance to shear from a standard surface), or Pressure-Sensitive Tape Councils test method PSTC 107 (Harmonized International Standard for Shear Adhesion of Pressure-Sensitive Tape) by either monitoring the time- and load-dependent displacement of an adhesive specimen under shear load or simply recording the time to failure. The result of the so-called SAFT-test (“Shear Adhesion Failure Temperature”) indicates the temperature at which a sample has failed that has been subjected to an environment with steadily rising temperature under static shear load.

Figure 13 represents the typical course of a creep experiment using single lap shear specimen bonded with a viscoelastic acrylic adhesive under tensile load. The curve progression can be divided into three phases of creep. At the end of phase I, instantaneous elastic strain and delayed elastic strain are completed, and the creep progress in phase II is dominated by secondary creep. At the end of phase II, creep accelerates leading to failure of the specimen at the end of phase III.

Failure can either occur due to cohesive fracture of the adhesive, due to interfacial sliding, or due to adhesive debonding at or close to the adhesive substrate interface.

A set of creep experiments at different load levels can be used to build creep-strength-time curves indicating at which time- and load-related limits a failure under

**Fig. 13** Typical course of a creep experiment for single lap shear specimen with a viscoelastic acrylic adhesive (Geiß 1998)

static load condition is to be expected for a certain adhesive-substrate combination. The construction of a so-called “creep rupture envelope” by connecting the points of the onset of the tertiary creep stage is shown in Fig. 14.

The creep rupture envelope in Fig. 14 was obtained at a temperature of 60 °C. Creep rupture envelopes for the same type of adhesive joint at different temperatures may show different characteristics if, e.g., the failure mode is changed by the influence of heat.

The empirical prediction of long-term behavior from such technical test methods may often not lead to the desired level of certainty since the failure of specimens under static shear loads may involve random fracture mechanisms which cause a wide scattering of the results in terms of time to failure. In addition to this, the failure of viscoelastic adhesives in creep experiments often occurs when high strain values far beyond the limits of linear viscoelasticity have been reached which are not tolerable in most technical applications and therefore do often not contribute satisfactory to the application-related long-term predictability.

Excessive shear strain should generally be avoided in adhesive joints because cohesive failure is likely to occur once shear deformation leads to a buildup of tensile stress at the end of the overlap bond area. In practice, it has been found that strain in assemblies with rubbery moisture curing one-component polyurethane adhesives should be limited to values of shear strain  $\tan \gamma$  below 0.5. Specific viscoelastic pressure-sensitive tapes may even tolerate shear strains of  $\tan \gamma$  up to 2. The maximum tolerable strain of structural adhesive joints using adhesives with a highly crosslinking density, however, is typically more than one order of magnitude lower than that.

Due to the significance of limiting shear strain, creep data can be presented as iso-strain curves. This can be accomplished by taking stress-strain data from creep experiments at different stress levels and converting them to iso-strain lines (Fig. 15).

**Fig. 14** Creep-strength-time diagram based on a set of creep experiments at different levels of static load at a temperature of 60 °C (Geiß 1998)

The presentation of creep data in the manner according to Fig. 15 allows to easily read stress limits if a certain allowable application-related strain level due to creep must not be exceeded within a given timeframe. Other ways to present creep data include isochronous stress-strain diagrams (Fig. 10) or creep modulus-time diagrams (Fig. 12).

Attempts to project results from short-term creep tests to a longer timescale often fail because the increase of shear strain during a static load creep experiment will lead to a change of the state of stress in the adhesive joint and will eventually cause an excessive amount of superimposed tensile stress near the end of the overlap area. Therefore, the dotted lines in Fig. 15 merely represent a “guide to the eye” projection rather than a mathematically confirmed extrapolation.

The problem of changing the state of stress in a static long-term experiment is less in relaxation tests compared to creep tests. Since the strain in relaxation tests is to be maintained at a constant level throughout the test time, a better accessibility to a mathematically based extrapolation may often be achieved. Section “4.3” will further address this matter.

Beyond collecting empirical creep data for specific adhesives or adhesive joints, it is in some cases desirable to derive viscoelastic parameters in relation to the previously discussed mechanical substitute models of viscoelasticity from the test results. The challenge hereby is to distinctively separate instantaneous elastic and delayed elastic strain (primary creep) from non-recoverable strain (secondary creep) and to determine whether the principles of linear viscoelasticity may or may not be applied.

**Fig. 15** Load-dependent time to reach different deformation limits indicated by iso-strain curves derived from static load creep experiments in lap shear specimens with a viscoelastic acrylic adhesive (Geiß and Vogt 2007)

A good method to reduce the amount of test specimens needed to collect creep data on different stress levels is to take advantage of the so-called step-loading experiments. In an experiment with step loading, the stress is again and again increased after a certain period of time. The viscoelastic response in consequent load steps in Fig. 16 should be similar if the Boltzmann superposition principle can be applied and the material is behaving according to linear viscoelasticity.

In the experiment illustrated in Fig. 16, the first step (caused by a load of 32 N) has led to an initial deformation of the sample of a bit less than 4 mm. During the following load steps with a repeated stress growth of 125% of the preceding load, the additional creep response decreases with higher total strain values, and also the slope at the end of each step decreases, although the total stress becomes larger. This indicates that the viscoelastic parameters of the specific material at these levels of creep change due to a strain hardening type of behavior, and the creep response does not represent linear viscoelastic properties.

In some cases, it may be useful to dissent from the method of creep experiments under a constant static load and to subject the adhesive joint to a sequence of periodical static load events. The additional information obtained in this manner is the creep and the creep recovery behavior of an adhesive joint with viscoelastic properties (Fig. 17). The test in this case was carried out using single lap shear specimens and a time controlled mechanical lifting device to apply and remove a balanced weight causing a periodically repeating history of static load inputs.

**Fig. 16** Creep response of an acrylic viscoelastic adhesive in a step-loading experiment (Geiß 1998)

**Fig. 17** Creep and creep recovery of a lap shear specimen bonded with an adhesive based on a SIS block copolymer formulation (Geiß 1998)

The line connected by data points in Fig. 17 represents the experimental data, while the continuous curve relates to the numerically simulated behavior based on the four parameter Burgers model for viscoelasticity. The load history consists of repeatedly loading for 24 h followed by 24 h of recovery.

The steadily increasing residual strain after recovery gives a clear indication of the viscous dashpot properties  $\eta_1$  in the Maxwell section of the Burgers model. The  $E_1$  spring properties can easily be fitted according to the repeating elastic strain in the creep and creep recovery sequence. The parameters  $\eta_2$  and  $E_2$  in the Kelvin-Voigt part of the Burgers model could be adjusted to adequately fit the experimental data during the first two cycles.

In this specific test, an early indication of damage accumulation could already be observed in the third cycle by a deviation of the experimental data from the predicted behavior based on the Burgers parameters. In the following cycles, this deviation increased steadily, leading to the failure of the specimen during the seventh load cycle.

This example was intended to illustrate how a combination of experiment and simulation based on simple viscoelastic models can contribute to generate added value from creep experiments without expanding their complexity.

A recurring challenge in designing creep experiments is the choice of the load levels and width of their distribution. Quasi-static lap shear tests at low strain rates indicate the short-term load capacity of the joint. As a rule of thumb, the higher the strain rate dependency of the modulus and fracture strength of an adhesive is, the lower the static load as a percentage of the ultimate fracture strength should be chosen if no other application-related considerations govern the level of static load to be used in a specific experiment. Structural adhesives may have a static load-bearing capacity in the range of 70% to even 90% of their short-term strength. Creep resistance of pressure-sensitive adhesives may be limited to 20% of their short-term strength or even less.

To overcome the risk of investing efforts in creep experiments resulting in strain levels beyond the area of relevancy for a certain application, relaxation test methods may provide an effective alternative test procedure.

#### 34.4.3 Relaxation Test Methods with Adhesively Bonded Joints

In the engineering process of bonded structures, the limits for maximum tolerable deformations in a structure to maintain its functionality and appearance are often important for the design of the adhesive joint. The shear strain of adhesive joints is generally expressed as  $\tan \gamma = s/d$ , where  $s$  is the displacement of the adherends and  $d$  is the thickness of the adhesive layer. Once the admissible  $\tan \gamma$  deflection is established, relaxation tests may provide an effective method to determine the related static load capacity of an adhesive or adhesive joint or the required size of the bond area to support a given load under such limitations.

While creep experiments apply a constant load to the sample and follow the increase of strain over time, the relaxation method applies a fixed strain to the specimen at the beginning of the test and records the decrease in stress over time caused by relaxation of the adhesive polymer. The basic difference in creep (retardation) testing versus relaxation testing is illustrated in Fig. 18.

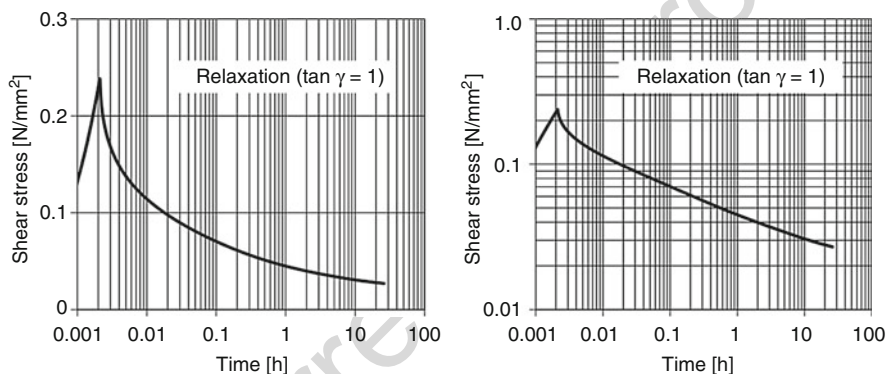

To obtain accurate relaxation data, the elastic behavior of the test instrument needs to be taken into account. The elastic compliance of a fixed test frame would generally influence the designated level of constant strain if the stress and the associated load of the test frame decrease during the course of the experiment. The following experimental relaxation data in Fig. 19 were therefore obtained in single overlap shear relaxation tests using a testing machine with noncontact video extensometry and closed-loop control to apply the initial strain at a predefined constant strain rate and then keep the true shear strain in the bond area on a precisely constant level throughout the test.

On the left side of Fig. 19, data have been plotted on a logarithmic timescale with linear ordinate units. Conversion to a double logarithmic scale on the right side of Fig. 19 leads to a linearization of the relaxation characteristic, which allows a better

**Fig. 18** Comparison of input and response in creep (retardation) and relaxation tests

**Fig. 19** Relaxation of shear-loaded adhesive joints with a viscoelastic acrylic adhesive, *left*: linear ordinate, *right*: logarithmic ordinate

projection and extrapolation of relaxation on a prolonged timescale. The relaxation data in Fig. 20 have been acquired in a similar manner starting from different shear strain levels  $\tan \gamma$ .

In the range of the applied strain values between  $\tan \gamma = 0.5$  and  $\tan \gamma = 1$ , a good linear conformity at times of relaxation beyond 1 h can be observed. Linearity in this case means that the decrease in shear stress as a function of time can be approximated by the following equation:

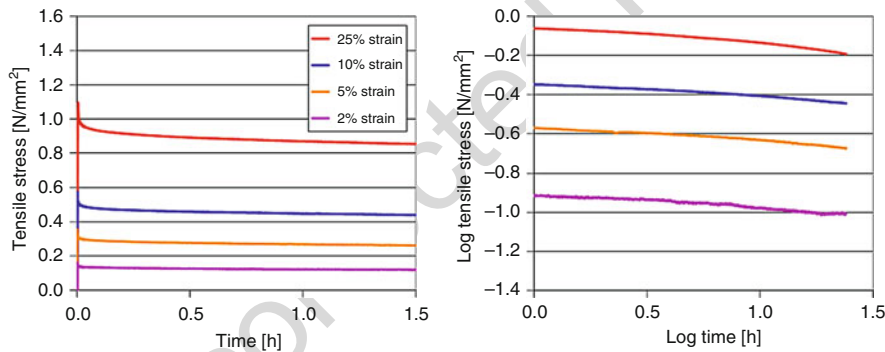

$$y(t) = b \cdot t^{(-1/a)} \quad (29)$$

On a double logarithmic scale, the equation transforms to

$$y(t) = (-1/a)t + b \quad (30)$$

**Fig. 20** Relaxation of shear-loaded adhesive joints from different strain levels with a viscoelastic acrylic adhesive

**Fig. 21** Relaxation behavior of an elastoplastic adhesive on a double logarithmic scale (Geiß and Vogt 2007)

If the creep behavior of an adhesive or adhesive joint meets this criterion, the  $-1/a$  and  $b$  parameters can easily be retrieved by linear regression. The factor  $b$  is proportional to the initial load applied to the specimen (elastic properties of the adhesive), and the slope parameter  $a$  relates to the relaxation properties of the adhesive.

The data in Fig. 21 have been obtained in relaxation experiments using bulk specimen of elastoplastic adhesives at initial strain levels ranging from 2% to 25%.

Similar to the shear stress relaxation of the adhesive joints in Fig. 20, the relaxation behavior in the long-term timescale in Fig. 21 exhibits a sufficient degree

**Table 2** Parameters obtained by linear regression of the relaxation curves in Fig. 21

Initial strain [%]	Linear regression parameters	
	$-1/a$	$\log b$
2	-0.0736	-0.9046
5	-0.0709	-0.5653
10	-0.0684	-0.3413
25	-0.0909	-0.0482

of linearity in the double logarithmic representation of the experimental data. The parameters obtained by linear regression are listed in Table 2.

It was found that in this case the parameter ( $-1/a$ ) relating to relaxation neither depended on the initial strain values up to 10% nor on the corresponding initial stresses from which the relaxation tests started. The initial stress levels calculated from the  $\log b$  parameter were in this case in good agreement with the actual measured stress values at the beginning of the relaxation experiments.

#### 34.4.4 Relation of Stress Relaxation and Static Load Creep

Taking into account the transferability of creep and relaxation results, the following considerations may be useful in predicting static load limits of adhesives or adhesive joints.

The experimental data of time-dependent stress from relaxation tests can be converted and applied to estimate maximum load values under creep conditions. This can be done considering the assumption that the declined value of shear stress after a specific time in the relaxation experiment will cause less deformation when this residual level of stress is constantly applied in a corresponding creep experiment.

To approve this concept experimentally, single overlap shear specimens were subjected to stress relaxation at room temperature after imposing an initial strain of  $\tan \gamma = 1$ . During relaxation, time-dependent stress values were determined for 0.5, 2, 8, and 16 h (Fig. 22).

The results of four corresponding creep experiments applying the time-dependent load values from Fig. 22 indicate that the predicted strain limit of  $\tan \gamma = 1$  was not exceeded in either one of the creep tests and the congruence between relaxation and creep becomes better in the long-term scale (Fig. 23).

All of the above conclusions have been drawn for isothermal conditions without considering a thermal fluctuation under creep conditions but which in practice represent the usual case during the service life of structural adhesive joints. Considering temperature effects in creep-dependent lifetime prediction can follow a worst-case scenario in which either the definition of the load-dependent fracture envelope or the test for compliance with predefined strain limits is carried out at the maximum

**Fig. 22** Relaxation data for aluminum lap shear specimens bonded with a viscoelastic acrylic adhesive (Geiß and Vogt 2005)

**Fig. 23** Results of creep experiments under static stress at ambient temperature corresponding to load values extracted from Fig. 22 (Geiß and Vogt 2005)

temperature to be expected during service life. This conservative approach is likely to lead to excessive contingency reserves.

Alternatively, extended effort must be taken to collect creep data in the above described manner at different temperatures relevant for a specific application and to then estimate total levels of creep under in service conditions based on the probability of different temperature exposures during service life using predictive numerical methods.

## 34.5 Predictive Methods

Long-term life prediction for adhesives and adhesive joints based on short-term laboratory tests remains a demanding challenge. Testing is generally carried out with the intention of simulating and often accelerating time-dependent effects that may happen to a joint during its lifetime under less severe conditions. Extrapolation methods generally intend to establish correlations involving temperature, time to rupture, and stress so that the least possible number of accelerated tests may be used to derive a sufficient lifetime prediction.

The basic starting point for building a descriptive creep function in correlation to experimental data for the purpose of extrapolation is the following equation:

$$\varepsilon(t) = F(\sigma, t, T) = f(\sigma) \cdot g(t) \cdot h(T) \quad (31)$$

Besides the level of stress, both time and temperature need to be explicitly included in the representation since both parameters significantly affect the creep response. The functions  $f(\sigma)$ ,  $g(t)$ , and  $h(T)$  are introduced on the basis of the assumption of superposition of the effects of stress, temperature, and time. While the viscoelastic models discussed in Sect. 2 may provide a starting point for establishing the function to describe the time- and stress-dependent part of the creep function, the time-temperature superposition equation of Williams, Landel, and Ferry (Sect. 2) should be considered for building time- and temperature-related descriptive empirical creep functions for the purpose of extrapolating and predicting creep behavior of a certain adhesive material or an adhesive joint. Due to the large bandwidth of adhesive mechanical polymer properties, no further generalized recommendation for a valid procedure can be given at this point.

It must further be pointed out that such predictive methods based on numerical evaluation can only be applied under the premise that no mechanisms of aging, being either independent or related to the presence of mechanical load, are superimposing the long-term behavior and thus the durability. Common detrimental environmental influences on the static load-bearing capacity of adhesive joints include an increase of compliance and reduction of the glass transition temperature due to absorption of humidity or water or swelling under the influence of other media. Other aging effects may include corrosive attack starting at the bondline, debonding at or close to the interface between adhesive and substrate, or chemical aging of the adhesive polymer under the influence of temperature, oxygen, or ultraviolet or other ionizing radiation. Further reference on aging of adhesively bonded joints is given in ► Chaps. 31, “Effect of Water and Mechanical Stress on Durability,” and ► “Effect of Radiation and Vacuum.”

## 34.6 Conclusions

The enhanced plasticity and toughness of modern adhesives has become an important property in applications where dissipation of energy in the case of impact, the ability to compensate thermal movement, or the reduction of vibration leads to added

value and improved service performance. Viscoelastic behavior can theoretically be predicted and analyzed by means of mechanical models including combinations of elastic and viscous elements to simulate the time-dependent viscoelastic stress-strain response to mechanical loads.

Due to the increased use of elastomer adhesives, there has been a strong need to develop experimental techniques leading to reliable engineering data in less time which generate materials data that can be implemented into modern design tools such as finite element simulation and used to predict the durability of adhesive joints under specific service conditions.

Creep experiments under constant load conditions are quite familiar and have been described in various international standards because they require rather little experimental equipment. The amount of material-specific data, which can be retrieved from such tests, is, however, limited, and the validity of long-term extrapolation remains often questionable.

Relaxation tests require a higher level of instrumental accuracy but may provide a better pathway in acquiring material-specific data from smaller number of individual tests and specimens. Since adhesive technical data sheets generally lack information on creep and relaxation properties, the design of structural adhesive joints to be used under static creep load conditions will require a significant effort and time for the acquisition and evaluation of experimental creep or relaxation data. Predictive numerical methods to extrapolate experimental creep data or to provide a lifetime prediction in terms of creep rupture probability need to consider time- and stress-related factors as well as the strong temperature dependency of creep-related phenomena. On the basis of the creep and relaxation functions derived from viscoelastic models in combination with shift factors based on the principle of time-temperature superposition, an adequate modeling of time- and temperature-dependent long-term stress-strain behavior becomes feasible.

Extrapolation of short-term data can only be made if it is known that the material is not subject to superimposed time-dependent changes in properties which may lead to a reduced load-bearing capacity and damage after a stable period. Extrapolation generally should not exceed more than 1 logarithmic unit of time beyond experimental data without adequate justification and in no case beyond 1.5 units as, e.g., recommended in the EOTA (European Organization for Technical Approvals) Guidance Document 003 "Assessment of working life of products" which is relevant for products of the building and construction industry.

**Abstract**

In all bonded assemblies, the durability of the adhesive or sealant joint is important to the integrity of the article concerned. The considerations of joint design, adhesive, sealant and substrate selection, surface preparation, and primer selection along with methods of application including mixing procedures, application techniques, and joint assembly are all reviewed. Methods of evaluation of durability and test regimes including exposure to elevated and reduced temperatures, UV radiation, moisture, saline solutions, stress, and fatigue, both

individually and combined in cycles, are considered. The relevance and application of these test condition to specific situations are discussed, including the role of antioxidants and cross-linking additives to improve durability. Reference is made to the corresponding standards according to the major standard organizations, such as the International Standards Organization (ISO), the European Committee for Standardization (CEN), and the British Standards Institute (BSI), and also to European directives and regulations and national legislation.

## 35.1 Introduction

A review of the literature shows that the majority of the published research relates to the study of the durability of structural adhesives and that there is little published specifically on the durability of nonstructural adhesives; however, the mechanisms and factors that lead to the failure of nonstructural adhesive bonds are the same as those for structural adhesives and are presented in detail elsewhere in this book. This chapter, therefore, illustrates the principle factors affecting durability, the available methods for estimating and evaluating durability, and the options for improving the performance of bonded materials utilizing examples from the world of adhesive and sealant applications. In conclusion, the importance of durability in the realm of building and construction is discussed in relation to the forthcoming EC Construction Products Regulation.

Structural adhesives are defined as adhesives that can resist substantial loads and that are responsible for the strength and stiffness of the structure (Adams et al. 1997) and are generally rated by their shear strength. Nonstructural adhesives then are lower strength materials and tend to be rated by their peel strength (Petrie 2007). However, this is a generalization that can be misleading as in both cases the adhesive is responsible for the structural integrity of the bond, if not necessarily the entire structure.

Durability is the ability to maintain the required performance over a given or long time, under the influence of the potential degradation factors, including temperature, humidity, water, UV radiation, abrasion, chemical attack, biological attack, corrosion, weathering, frost, freeze-thaw, and fatigue. Durability is, therefore, dependent on the intended use of the product and its service conditions, and the assessment of durability can relate to the bonded assembly as a whole or to its performance characteristics. In either case, the underlying assumption is that the performance will be maintained at an acceptable level, in relation to its initial performance, throughout its working life (EC Guidance Paper F 2004).

A large number of standard test methods and specifications have therefore been developed to define adhesive and sealant applications and performance requirements including durability. Many of these are application or market specific and designed around the intended use and service conditions, ranging from specifications for wall covering adhesives (BS 3046: 1981) to test methods for determination of adhesion and cohesion properties of sealants after exposure to heat water and artificial light through glass (BS EN ISO 11431: 2002).

## 35.2 Durability Considerations

Whenever an adhesive joint is made as part of a product or device, there is always concern about the joint durability whether this is in a box of breakfast cereal, the sole of a shoe, or an external panel of a motor car. The consequences of joint failure can, therefore, range from nuisance to endangering lives.

As already stated, the durability or permanence of a bonded assembly is dependent on the intended use and service conditions to which the bond will be exposed. However, the joint design, choice of substrates, adhesive selection, substrate preparation, and primer selection, where appropriate, plus the method of application and assembly all have significant impact on the service life of adhesively bonded materials. Most or all of these considerations are interdependent, for example, the joint design and substrates chosen will limit the range of suitable adhesives that can be employed. In a similar way, the durability of a sealed joint is only as good as the adhesion of the sealant (and primer) to the surfaces forming the joint. Primers and/or sealants will adhere to surfaces only if those surfaces are properly prepared. A very large proportion of all sealant joint failures result from poor or inadequate surface preparation.

### 35.2.1 Joint Design

Many factors need to be considered when designing a bonded assembly, which will utilize adhesive or sealant. They include the purpose of the joint and the stresses likely to be encountered, the substrates to be joined and their physical properties, such as coefficient(s) of linear expansion, the type of materials forming the joint, maximum and minimum temperatures predicted for the components and their heat capacity and conductivity, and any other external influences such as exposure to chemical attack (e.g., water, acids, solvents, etc.), physical movement from vibration, etc.

Joint geometry is a prime consideration, and bonded joints need to be designed so that loading stresses will be directed along the lines of the greatest strength of the adhesive or sealant. In general, joints may be subject to tensile, compressive, shear, or peel stresses, often in combination, and adhesives and sealants are strongest in shear, compression, and tension and perform less effectively under peel or cleavage loadings. Sufficient adhesive surface or bonded area must also be provided between the adherends to enable the transfer of forces via the bonded joint. In general adhesive joints are relatively low in cross-sectional area compared to sealant joints, and an additional consideration in sealant joint design is the designed movement accommodation required of the sealant. During their service life, sealants are subjected to mechanical stresses due to movement, and for a given amount of movement, wide joints will place less induced stress on the sealant than narrow joints, with implications for their durability. For example, consider a 5 mm movement in a joint:

10 mm wide bead – the movement is  $5/10 \times 100\% = 50\%$ .

20 mm wide bead – the movement is  $5/20 \times 100\% = 25\%$ .

### 35.2.2 Choice of Substrates and Adhesive Selection

In contrast to other traditional mechanical joining methods such as riveting, welding, and screwing, adhesive bonding has little or no adverse effect on the material characteristics of the surfaces to be joined. However, in general, in the area of nonstructural adhesives, designers do not consider that materials have to be bonded, paying more attention to appearance and other aesthetic properties, and consequently the service life of bonded assemblies can be severely limited by the choice of substrate. Materials that contain plasticizers, or processing oils, for example, or have a mismatch in their coefficient of thermal expansion can result in bond strength deterioration with many adhesive types in relatively short timescales. Plasticizers are a common source of nonstructural bond failures and are discussed in more detail below.

Formulators have developed many adhesive and sealants to suit most substrate types and properties, and adhesive selection is most commonly carried out by first considering the substrates to be bonded. Most manufacturers of adhesives and sealants publish guides of this type, and many can be found on the Internet to assist designers.

The choice of an adhesive or sealant for a specific situation will be governed by consideration of several key parameters in relation to the manufacturing process to be employed: the setting time required, the initial performance requirements, the durability and ultimate performance requirements, the total product and process costs, and the associated health, safety, and environmental hazards associated with the product use. Additionally, sealants are most often selected on the basis of the intended joint movement accommodation requirement.

The selection of adhesive is critical to fulfilling the design requirements in many applications, but in many industries, the adhesive component of the finished product represents a small percentage of the overall cost; however, its importance in terms of quality and durability of the finished products assumes much greater proportions. This is particularly the case in the manufacture of inflatable lifesaving equipment, such as life rafts and jackets. Solvent-borne polychloroprene adhesives are commonly used to bond rubberized fabrics in the manufacture of these items, and, for obvious reasons, all possible measures are utilized to ensure the durability of the bond. While the water resistance and general durability of correctly formulated polychloroprene adhesives are relatively good, the addition of isocyanate prepolymers, as part of the application process, to these systems is commonly employed to produce further cross-linking and enhanced longevity.

### 35.2.3 Plasticizer Content of Substrates

Many plastic polymers contain plasticizers to make them softer and more flexible as determined by the finished product requirement for a specific application. Plasticizers are generally high boiling point organic liquids with molecular weights in the 400+ region, which have a degree of compatibility with the polymer concerned. In

polyvinyl chloride, for example, the most commonly used plasticizers are the phthalate esters, such as dioctyl, dinonyl, and didecyl phthalate and their iso isomers. In the most flexible materials, commonly made from plastisols, where the polymer is dispersed in plasticizer and then heated to melt the polymer into the plasticizer, forming a homogeneous liquid, which forms a solid on cooling in a molding process, the plasticizer content can be in the order of 50% by weight. Since plasticizers are not bound chemically to the polymer and are held by relatively weak intermolecular forces, most are capable of migrating to the interface, where they can come into contact with the adhesive or sealant layers. Plasticizers also have an affinity for most adhesive polymers and can migrate across this interface resulting in softening of the adhesive or sealant and consequent reduction in physical properties and, in the worst case, cohesive adhesive failure. This migration of plasticizer into adhesive or sealant will also cause change in the physical properties of the plastic substrate itself such as dimensional changes and even surface stress cracking.

One application area where this is of particular relevance is the adhesive bonding of floor and wall covering materials, and the relative resistance of adhesive systems to plasticizer migration can be determined utilizing the standard method described in EN 1903: (2008), “Adhesives – Test method for adhesives for plastic or rubber floor coverings or wall coverings – Determination of dimensional changes after accelerated aging.” This method gives a measure of the suitability of a plastic or rubber floor or wall covering/adhesive combination by monitoring dimensional changes during defined conditioning sequences when bonded to a specific substrate. The floor or wall covering test pieces, with dimensions of  $(250 \pm 5) \text{ mm} \times (250 \pm 5) \text{ mm}$  or  $(300 \pm 5) \text{ mm} \times (300 \pm 5) \text{ mm}$ , are first preconditioned for 6 h at  $80 \text{ }^\circ\text{C} \pm 2 \text{ }^\circ\text{C}$  before measuring their dimensions and are then bonded to uncoated fiber cement panels using the test adhesives and dimensions measured again. The test assemblies are then stored at  $50 \text{ }^\circ\text{C}$  for a 13 day period each followed by 24 h conditioning at room temperature prior to measuring the dimensions again. The interpretation being that the more cycles to which the test pieces are exposed, without significant dimensional change, the more durable the adhesive and floor or wall covering combination will be in service.

### 35.2.4 Surface Preparation and Primer Selection

Correct surface preparation is critical to achieving optimum bond strength and joint reliability. Cleaners, such as surfactants and solvents, are used to ensure that surfaces to be bonded are clean and free from dust and other loose materials, grease, oils, and other impurities that may affect the adhesion and ultimate bond strength.

Pretreatments are also used to enhance bonding performance including mechanical treatments such as grinding and blasting to produce a rough surface texture and effectively increase the bonded area; physical treatments such as corona discharge, flame, or plasma treatments to improve bonding performance by increasing surface energies; and primers or adhesion promoters.

Primers and adhesion promoters are normally low-viscosity solutions of either isocyanate prepolymers or organosilanes, which function by surface penetration into and chemical adhesion to the substrate(s) and chemical adhesion to the subsequently applied adhesive or sealant, increasing bonding performance and durability. Again, formulators have developed ranges of primers to suit most adhesive or sealant and substrate combinations, and selection guides are widely available.

### **35.2.5 Methods of Application and Assembly**

Automated methods for preparation, adhesive application, and bond assembly give the best reproducibility and best control of durability; however, such automation is frequently not possible. Manufacturers' recommendations in data sheets and on containers should always be followed and particular attention paid to storage conditions, mixing procedures, adhesive or sealant application, and joint assembly.

#### **Storage Conditions**

Storage temperature extremes can cause problems, which limit the effectiveness and shorten the service life of adhesives and sealants. Temperatures below zero can irreparably damage emulsion adhesives and sealants causing agglomeration or coagulation of the polymer emulsion. Many modern products are made freeze-thaw stable by the addition of chemicals such as glycols, but generally prolonged storage at low temperatures is inadvisable. Conversely, high storage temperatures can lead to premature polymerization of reactive adhesives severely impeding bonding performance. High humidity can also have adverse effects; for example, adhesives supplied in powder form require adequate protection from moisture vapor during storage to prevent premature curing or agglomeration making use and application difficult.

#### **Mixing Procedures**

Adequate mixing of multicomponent adhesives and sealants requires particular attention. Unless supplied in pre-weighed kit form, the correct proportioning of components is essential, and the duration and intensity of mixing with the correct type of mixer should be utilized to produce a homogeneous mix that is not overheated and with minimal unintentional air entrainment. However, excessive shear during mixing can damage some types of emulsion adhesives and sealants.

#### **Application**

In all adhesive and sealant applications, the aim is to apply a uniform layer of material of the appropriate thickness across the entire area to be joined to achieve the optimum performance. In many manual or semiautomatic applications, this is achieved by using spacers or jigs to control product thickness. Pressure-fed application equipment is also often utilized to ensure a consistent flow of product.

## Joint Assembly

Once the adhesive or sealant has been applied to the substrate or substrates, the joint should be assembled within the allowable “open” or “assembly” time, that is, between the minimum and maximum recommended times. With solvent-borne contact adhesives, for example, sufficient time for solvent evaporation must be allowed to prevent solvent entrapment, which can lead to premature failure, especially when bonding impermeable substrates. The maximum open time with hot-melt adhesives, which set on cooling, can be very short and should be closely monitored.

Ambient conditions can also affect the bond formation process. For example, high relative humidity can lead to condensation of moisture on the exposed drying surface of a solvent-based adhesive, as the heat of evaporation of the solvent causes the temperature of the adhesive film to drop below the dew point of the surrounding atmosphere. Such a film of moisture will impede the coalescence of the two films of a contact adhesive.

## Workmanship

Quality of workmanship is obviously a key factor in the durability of bonded assemblies, and standard test methods are written in such a way to try to minimize any variability in laboratory evaluations. However, laboratory conditions cannot accurately reflect the actual application methods and conditions employed, and there have been some attempts to study the influence of workmanship on durability. One such study by Zhao and Zhang (1997) looked at the influence of workmanship on the bonding of ceramic tiles to external walls. In this study, they looked at three variables, tile setting pressure, adhesive inner cavity, and adhesive open time, and measured their effects on tile bonding or pull-off strength. Not surprisingly, their results indicated that the influences of these variables are significant and that when some or all of these factors appear simultaneously, the combined effect is cumulative in the reduction of pull-off strength.

---

## 35.3 Methods for Estimating and Evaluating Durability

Having taken into account the above considerations and completed the selection process, it is always desirable to know that the bonded assembly will meet the durability expectations of the product, that is, be “fit for purpose.” For this reason, adhesive selection is often made on the basis of past experience or “heritage data,” and a proven track record is recognized as a suitable method for demonstrating fitness for purpose. For example, the approved document in support of Regulation 7 of the UK Building Regulations – workmanship and materials – lists “past experience” as one of the ways of demonstrating fitness for the purpose of a material.

However, such historical data is frequently not available, and other methods of assessment need to be employed. Durability tests that measure an adhesive or sealant’s performance retention during exposure to the main elements of its service

environment have, therefore, been developed, and this is usually measured in some accelerated manner because natural processes are too time-consuming to allow qualification in an appropriate timescale.

At this point, it is worth noting that accelerated and natural aging tests do not always produce the same results. Ashcroft et al. (2001) undertook a comparison of aging joints in natural and laboratory conditions, with aluminum adherends, bonded with structural adhesives. A conclusion of their work was that there was no simple method of determining the long-term durability from accelerated tests and that excessive temperature and humidity will trigger degradation mechanisms, which are not representative. In general, accelerated aging tests tend to overestimate the reduction of joint strength. The published standard (ISO 9142 2003), Adhesives – Guide to the selection of standard laboratory aging conditions for testing bonded joints, which describes laboratory aging conditions under which adhesive joints may be exposed to various environmental influences, climatic or chemical, for the purpose of assessing the effects of such influences on certain properties, recognizes these limitations, warning in the introductory abstract that “The results obtained using the procedures described in this international standard are not necessarily applicable to the determination of the service life of a bonded assembly because there is no direct relation between the test results and the behavior of a bonded assembly over a period of time under service conditions. However, for certain specific applications, experience with the procedures may enable a correlation to be established.”

Obviously, the purpose of an accelerated aging test is to cause a more rapid deterioration of the bonded assembly, and by paying due consideration to the actual service conditions, the accelerated aging conditions can be selected to recreate as closely as possible the failure mechanisms that would be seen in those actual service conditions. The accelerated aging conditions usually selected involve some environmental factors, which the bonded assembly might encounter, such as elevated temperature, UV radiation, high humidity, water immersion, exposure to aqueous salt solutions in spray form, and/or combinations of these, which may be in periodic cycles, as well as other predictable service factors such as stress and fatigue, where normal service loads can be applied in combination with the environmental accelerating factors above, or extreme loads, beyond normal service, to induce premature degradation.

### 35.3.1 Elevated Temperature and UV Radiation

Perhaps the simplest durability evaluation is the exposure of hot-melt adhesives to elevated temperature for prolonged periods with their durability assessed by their color stability; the longer the period of exposure before significant discoloration occurs, the more durable the adhesive. While this test gives an indication of the ability of the adhesive to withstand long periods in the melt tank at or above the application temperature, it also gives an indication of the durability of the adhesive in

service. Discoloration of the adhesive can be particularly significant with light-colored substrates.

All polymers containing hydrogen undergo oxidation by a free radical chain mechanism; however, the rate at which oxidation occurs varies with the chemical structure of the polymer. Polymers that are commonly used in adhesive formulations differ considerably in their sensitivity to oxidation. Acrylates, for example, are highly resistant to oxidation and do not generally require antioxidants at ambient temperatures, whereas unsaturated elastomers are highly susceptible to oxidative decomposition and require a relatively high concentration of antioxidants for protection. Both heat and light accelerate the oxidation of polymers, both increase the rate of reaction, but heat also increases the rate of inward diffusion of oxygen and the loss of antioxidants and stabilizers from the adhesive or sealant by volatilization. Mechanical deformation of the end product during service (“fatigue”) also accelerates the oxidation of adhesives and sealants. Oxidation of the polymeric components results in a deterioration of the physical properties, which can ultimately lead to bond failures, and the addition of antioxidants and stabilizers to improve durability is normally necessary.

The deleterious effects of oxidation on polymer properties results from the breakdown of very unstable hydroperoxides in the polymer chain in the presence of light. This in turn leads to chain scission (molecular weight reduction) and the production of new free radicals which accelerate the oxidation process (Scott 1998).

Elevated temperature-accelerated aging techniques rely on the dependence of the rate of reaction on temperature as expressed in the Arrhenius equation, where the rate constant  $k$  of a reaction and the absolute temperature  $T$  are related using the gas constant  $R$ :

$$k = A \exp(-Ea/RT) \quad (1)$$

In its original form, the pre-exponential factor  $A$  and the activation energy  $Ea$  are considered to be temperature independent (IUPAC Compendium of Chemical Terminology 2nd Edition 1997).

Elevated temperature is often used to estimate the in-can stability of adhesives and sealant formulations. This is usually applied by a simple “rule of thumb” that says the reaction rate of the degradation mechanisms involved doubles for every 10 °C increase in temperature, and therefore 1 week storage at 50 °C approximates to 8 weeks at room temperature (20 °C). Application of this rule will likely be conservative in the prediction of shelf life and must be verified by real-time validation testing conducted at room temperature for the targeted shelf life.

One example of in-can stability testing is given in ISO 15908 (2002), Adhesives for thermoplastic piping systems – Test method for the determination of thermal stability of adhesives, where samples of the adhesives in their relevant packaging, a minimum three test pieces for each packaging and adhesive variant, are stored at room temperature (23 °C ± 2 °C and 50% relative humidity) and at elevated temperature (for 1 month at 50 °C ± 2 °C followed by 24 h at 23 °C ± 2 °C and 50% relative humidity). After this period, the adhesive viscosities are measured and

their performances determined by measurement of the shear strength of bonded relevant plastic pipe systems. A stable viscosity and maintenance of bonding performance is assumed to indicate in-can stability; however, the standard method also recognizes that actual shelf life (in-can stability) can only be verified by tests conducted at actual storage conditions for the targeted shelf life period.

### 35.3.2 Antioxidants and Stabilizers

Antioxidants and stabilizers are added to most polymer systems to improve durability. Antioxidants fall into two major categories, primary and secondary, (Petrie 2004) and within primary antioxidants, there are two main chemical types, hindered phenolics and aromatic amines. Primary antioxidants function by donating their reactive hydrogen to the peroxy free radicals so that the propagation of subsequent free radicals does not occur.

The most widely used antioxidants for polymer protection are phenolics. These products generally resist staining or discoloration. However, they may form quinoid structures upon oxidation, which lead to yellowing. Phenolic antioxidants include simple phenolics, bisphenolics, polyphenolics, and thiobisphenolics. Hindered phenolics, such as butylated hydroxytoluene (BHT), high molecular weight phenolics, and thiobisphenolics, are the most popular of the primary antioxidants. They are suitable as long-term stabilizers in almost all cases.

BHT has long been the workhorse of the antioxidant industry, and it possesses US Food and Drug Administration (FDA) approval for food contact. However, BHT is a relatively volatile material that is gradually being replaced by higher molecular weight antioxidants that resist migration. Thiobisphenolics can also act as peroxide decomposers (secondary antioxidants) at temperatures above 100 °C. Therefore, they are often found in higher-temperature applications.

Amines, normally arylamines, may be more effective than phenolics, but most are staining and discoloring and lack FDA approval for use in contact with food. Amines are commonly used in the rubber industry, but they also find uses in applications such as wire and cable formulations and in polyurethane polyols.

Secondary antioxidants are used in conjunction with primary antioxidants to provide added stability to the polymer. They function by decomposing any hydroperoxides to form nonreactive products. Typical secondary antioxidant compounds contain sulfur or phosphorous. The more popular secondary antioxidants are thioesters (thiodipropionic acid derivatives and polythiodipropionates) and organophosphites.

Organophosphites provide color stability but have a hygroscopic tendency. Hydrolysis of phosphites can ultimately lead to the formation of phosphoric acid, which can corrode processing equipment. Tris-nonylphenyl phosphite (TNPP) is the most commonly used organophosphite followed by tris(2,4-di-tert-butylphenyl) phosphite. Thioesters have high heat stability but have an inherent odor, which can be transferred to the host polymer.

The by-products of polymer degradation can also have a damaging effect on the durability of adhesive and sealant bonds necessitating the addition of specific stabilizers. For example, polychloroprene polymers can decompose by dehydrochlorination, liberating hydrochloric acid, which can attack the adhesive or sealant and the substrates. The addition of metal oxides, such as zinc oxide or magnesium oxide, which act as acid acceptors helps to overcome this problem.

### Pressure-Sensitive Adhesives

The use of pressure-sensitive adhesives (PSAs) in modern manufacturing has developed significantly in recent years. No longer are PSAs limited to temporary attachment applications, such as packaging tapes, but are increasingly being used in more sophisticated applications such as mobile telephones for the bonding of keypad switch assemblies. Pressure-sensitive applications have also been expanded to include a wide range of temperatures, ranging now from  $-40^{\circ}\text{C}$  to  $+120^{\circ}\text{C}$ . For example, airline baggage tag labels need to perform in low and high temperatures, often over a time period of a few hours. Some tapes intended for the construction or automotive markets need to perform at even higher-temperature extremes. So prediction of durability and service life has assumed greater significance to formulators of this type of adhesive.

PSAs are usually characterized by their three common properties of tack, peel resistance, and shear resistance, which can be determined by standard laboratory test procedures. Each of these properties is affected by temperature change. Indeed, as already noted, most adhesives exhibit different properties when subjected to temperature, and in the case of PSAs, the bond is almost always thermoplastic, softening at elevated temperature and becoming more brittle at lower temperatures. As the temperature increases, the adhesive mass softens and “wets” the substrate more rapidly and completely, and the tack and peel properties increase. At some point, however, the adhesive has softened to the point that its cohesive strength is less than the substrate adhesion, and the adhesive mass splits, failing cohesively, that is, the locus of failure has changed from adhesion to cohesive within the adhesive. As the temperature continues to increase, the adhesive mass continues to soften, and the tack and peel values continue to go down.

In testing shear resistance, one always looks for cohesive failure. As the temperature increases, shear resistance goes down as the adhesive mass softens. This reduction in shear resistance will be fairly slow and steady, to the point where the mass is so soft that it will not support a load for any appreciable time.

It is important, therefore, that adhesives be evaluated for performance over a wide temperature range and bearing in mind the difference between application temperature and end-use temperature. The application temperature, at which the adhesive is applied to a surface and is expected to achieve a bond, is, generally, limited to the lower end and a narrower band of the temperature range, whereas the end-use temperature, at which the adhesive must perform adequately once the bond is made, is usually at the extreme ends, both high and low, of the temperature scale.

In standard laboratory tests, the limits of application temperature are determined by placing the test samples and substrates at the selected temperature and allowing

439 them to equilibrate. Sample bonds are made at this temperature, and the laminated  
440 samples are allowed to reside for a specific period, after which performance prop-  
441 erties are measured at that temperature. The limits of end-use temperature can be  
442 determined by making the sample bonds at a temperature within the application  
443 temperature range and allowing the bond to build for a specified time at this  
444 temperature. After this residence period, the samples are placed at the test temper-  
445 ature for a period of time to achieve equilibrium and then the performance properties  
446 determined at that temperature. These test conditions are achieved by the use of  
447 environmental chambers, freezers, or ovens.

448 Alternative indications for durability of PSAs in specific applications can be  
449 obtained from modifications to these methods for determining performance prop-  
450 erties, and the two most commonly used tests are the peel adhesion failure time (PAFT)  
451 and shear adhesion failure temperature (SAFT).

452 The PAFT is determined using 25 mm strips of adhesive coated onto standard  
453 polyester film and bonded to standard stainless steel panels. The bonded assemblies  
454 are placed in a suitable enclosure to maintain the required test temperature and a  
455 weight (usually either 500 or 1,000 g) attached to the polyester film such that the  
456 assembly will peel in a 180° configuration. The time for the bond to fail at the test  
457 temperature is recorded, often using a suitable automatic recording device. Similarly,  
458 the SAFT is determined using a square adhesive contact area of 25 mm<sup>2</sup> applied on  
459 to a standard polyester film and bonded to standard stainless steel panels and then  
460 placed in an oven starting at 25 °C. A 500 g weight is applied, and the temperature is  
461 raised by 5 °C every 10 min and the point at which the sample fails is recorded.  
462 Alternatively, if appropriate, the actual substrates intended for the application  
463 concerned can be utilized to make the tests more meaningful to the end use.

464 Accelerated aging tests are also employed to estimate the durability of PSAs.  
465 While there is no standard set of aging conditions, 70 °C, the standard aging  
466 condition for rubbers, on which most original PSAs were based, is commonly  
467 used; however, other test temperatures may be used depending on the temperature  
468 sensitivity of the components to be bonded. Unapplied samples, meaning that the  
469 samples are aged with the release liner in place, after which the liner is removed and  
470 the samples are applied to the test surface to determine performance properties, will  
471 give an indication of the “shelf life” to end use, whereas applied samples, meaning  
472 that the samples are applied to the test surface for the aging period before the  
473 determination of performance properties, will give an indication of the service life  
474 of the product after it is bonded to a substrate.

475 While pressure-sensitive adhesive performance at various temperatures can be  
476 determined by practical tests, as described above, it is also possible to predict the  
477 temperature performance of pressure-sensitive adhesives. The polymers used in  
478 pressure-sensitive adhesives will have a variety of glass transition temperatures  
479 (T<sub>g</sub>), and for a pressure-sensitive adhesive to be effective, the formulated mass  
480 must have a T<sub>g</sub> of between 50 and 70 °C below the temperature at which the  
481 adhesive is to be used. At the same time, however, the T<sub>g</sub> cannot be so low that  
482 the adhesive mass is so soft that it fails cohesively even at room temperature. A  
483 variety of analytical techniques used to determine the T<sub>g</sub> of the adhesive mass

include differential scanning calorimetry (DSC), differential thermal analysis (DTA), and dynamic mechanical analysis (DMA). Of these, the most commonly used method is DMA. DMA will measure the bulk properties of the adhesive mass, which will include the base polymer and any additives in it. It does not take into consideration any interfacial relationships between the adhesive and the surfaces to which it is bonded.

DMA can determine the storage modulus ( $G'$ ) and loss modulus ( $G''$ ) of the adhesive mass by sweeping through a range of frequencies and temperatures. Dividing  $G''$  by  $G'$  yields the property called tan delta, and plotting tan delta against temperature will give peaks that relate to the  $T_g$  of the adhesive mass. The type of information developed by DMA and other thermal analytical techniques can, therefore, be used to formulate adhesives that will perform well at ambient conditions and at temperature extremes. However, final practical evaluations of the adhesive formulation, the substrates to be used in the application and the temperature ranges to be seen in the application, must be undertaken.

### 35.3.3 Water, Humidity, and Saline Solutions

Moisture ingress during service is thought to be responsible for many examples of premature joint failure. Accelerated aging tests are, therefore, commonly carried out by exposing joints or structures to either water immersion or water vapor. Moisture ingress in joints can occur either by bulk diffusion through permeable substrates or the adhesive or by wicking across an interface or through cracks or voids in the adhesive. Once present, water molecules can cause a modification in the adhesive mechanical properties, for example, by plasticization or by a reduction in the glass transition temperature. Alternatively, it is proposed that interfacial bonds can be disrupted or modification of the adherend surface can result, for example, by hydration of a metal.

The rate of water ingress by diffusion through the adhesive is principally determined by its diffusion coefficient. An increase in temperature will rapidly increase the rate of water uptake in line with Fickian diffusion models as the diffusion coefficient will increase significantly with temperature. Such a hot-wet environment is generally regarded as a very aggressive form of accelerated aging (Critchlow 2005).

The installation of exterior artificial sports surfaces is one application where water resistance is required. Adhesives are used in this process to bond seaming tape to artificial grass or other carpet materials at the joints between adjacent lengths of carpet, and there are performance specifications for these bonded assemblies set by the national or international sports governing bodies, such as rugby, football, or tennis. The durability of these installations is assessed in the laboratory by accelerated aging of test bonds of the substrates involved using elevated temperature and water immersion as described in EN 13744 (2004). Test joints are immersed in a water bath maintained at 70 °C for 336 h (14 days) before the physical properties of tensile and peel strength are determined by the standard method described in EN

12228 (2002) and compared with the properties determined with un-aged joints. In this example, the durability requirements are deemed to be satisfied if the minimum performance requirements are exceeded before and after accelerated aging. In other applications, a maximum allowable percentage deterioration in physical properties will constitute the specification requirement.

Adhesives for ceramic tiles are specified by the standard EN 12004 (2007) (Adhesives for tiles – Requirements, evaluation of conformity, classification, and designation) and include performance requirements for cementitious, dispersion, and reaction resin adhesive types for all internal and/or external walls and floor and ceiling applications. Annex ZA, of this standard, sets out the requirements, which address the provisions of the Construction Products Directive (see Sect. 4 below) and include assessments of durability. Compliance with these requirements confers a presumption of fitness for purpose for the applications and form part of a CE mark. In these cases, durability is assessed by elevated temperature and/or water immersion accelerated aging or freeze-thaw cycling of test specimens and then determining tensile or shear adhesion strength against minimum requirements.

Saline solutions are also commonly employed by immersion or spray to mimic sea, coastal, or road conditions. Initially developed to evaluate the corrosion resistance of coatings for metals, the salt spray test can be used to evaluate the durability of adhesive- and sealant-bonded assemblies. The apparatus for testing consists of a closed testing chamber, where a salted solution, most commonly a solution of sodium chloride, is sprayed by means of a nozzle. This produces a corroding environment in the chamber, and thus, pieces in it are attacked under this severe corroding atmosphere. Testing periods can range from a few hours (e.g., 8 or 24 h) to more than a month before the determination of physical properties for comparison with their initial values. Chamber construction, testing procedure, and testing parameters are standardized under national and international standards, which describe the necessary information to carry out the test and give the testing parameters such as temperature, air pressure of the sprayed solution, preparation of the spraying solution, concentration, pH, etc.

Salt spray testing is popular because it is cheap, quick, well standardized, and reasonably repeatable. There is, however, only a weak correlation between the duration in salt spray test and the expected life in service, since the corrosive processes involved are very complicated and can be influenced by many external factors. Nevertheless, salt spray test is widely used in the automotive, construction, and aerospace industries.

### 35.3.4 Stress and Fatigue

Stress- or fatigue-induced degradation of adhesive- and sealant-bonded assemblies in nonstructural applications is often characterized by cyclic loading of a test assembly. Polymeric materials, including adhesives and sealants, are viscoelastic in nature, and their responses in such tests tend to be time and frequency dependent. Higher frequencies often induce localized heat, resulting in temperature changes that

can dramatically affect the results, and slow frequencies can also result in poorer performance than expected due to creep rupture. Therefore, care is needed when specifying the temperature and frequency of testing regimes (Dillard 2005).

The lower-frequency “creep” or “creep-rupture” tests are time dependent. In these tests, joints are subjected to a nominally constant load. The tests may proceed for a chosen time period or may be continued until complete rupture occurs. For example, the durability of thermoplastic adhesives for nonstructural wood applications is classified in European standards EN 204 (2001) and EN 205 (2003) according to their ability to withstand various water treatments and relatively rapidly applied loads. However, an additional characteristic that can be specified is resistance to static load, which can be determined using the method described in EN 14256 (2007). This method is used to determine the ability of a test piece bonded with a thermoplastic adhesive, to support a given load for up to 21 days without fracture or excessive distortion, and specifies a mean survival time of 14 days.

### 35.3.5 Assessment by Combinations of Factors

Some durability evaluations use a combination of these elements of accelerated aging. For example, an indication of the durability of adhesives used for bonding thermoplastic pressure pipe systems is given in EN 14814 (2007), Adhesives for thermoplastic piping systems for fluids under pressure – Specifications, which references the test method given in ISO 9311-3, where test pipe assemblies incorporating adhesively bonded joints are subjected to internal hydrostatic pressures up to 3.2 times the nominal maximum operating pressure for 1,000 h without leaking. Passing this test regime is a requirement of the initial type tests to demonstrate compliance with the specification but is also expected to give an indication of the “in-service” performance of the system.

### Insulating Glass Units

Lowe et al. (1994) studied the water durability of insulating glass units manufactured with polysulfide sealants by accelerated aging of glass to sealant adhesive joints at 95% relative humidity in an environmental chamber set at 60 °C for up to 14 months. Among their conclusions were that the glass to sealant joints were weakened by this test regime; that the sealants absorbed large amounts of water, which attacks at the interface between the glass and sealant; and that the amount of interfacial failure increases with exposure. Studies such as this, in conjunction with those undertaken by sealant and raw material manufacturers, have been instrumental in the development of the standard for insulating glass units (double glazed units) EN 1279 (a standard in six parts published between 2002 and 2008) which describes how to assess durability by accelerated aging of test double glazed units. The function of the polymer sealant utilized to seal the edges of the insulating glass units is to hold the unit together and prevent the penetration of moisture into the unit and escape of insulating gases placed between the panes. Durability is evaluated by exposure to temperature and humidity cycles, which attempt to replicate the actual in-service

exposure conditions of glazing units in buildings, that is, elevated temperature combined with high humidity, along with low-temperature cycles, and interspersed with periods of longer duration with exposure to high humidity. The efficiency of the seal is then determined by measuring the amount of moisture that has penetrated into the unit, by gravimetric analysis of the desiccant, which is contained within the hollow aluminum spacer bar that forms the gap between the panes in the construction of the unit.

The rate of escape of insulating gas (usually argon or sulfur hexafluoride) through the sealant is also determined using gas chromatography by containing the test unit in a rig and sweeping the annular space around the unit with air into the chromatograph. The standard specifies maximum penetration levels and rates for both test regimes.

Nonstructural sealants for use in construction works are classified by their performance characteristics as determined according to ISO 11600. Sealant manufacturers, who adopt this classification scheme, use designations, which indicate the sealants end use (either general construction, type F, or glazing, type G), its movement accommodation capability (in the range 7.5–25%), its modulus (defined as high or low), and its elasticity or plasticity, totaling 11 sealant classes, with all these performance characteristics determined using specified test methods. This classification system is a helpful aid to specifiers who can match their design requirements to the sealant performance characteristics. Within Europe, this classification system is to be augmented with the affixation of a CE mark to indicate suitability for purpose and the performance requirements, including durability, for building applications defined in new standards currently being developed (FprEN 15651 parts 1 to 5: 2009). The durability clause in these new standards indicate that the sealant performance determined by classification to the appropriate ISO 11600 specification will indicate suitable durability of the sealant after aging. It also notes that nonstructural sealants are easy to use, ready to use, and easy to remove when any unavoidable or unexpected degradation arises.

## Electronics

There are numerous applications for adhesives in electronics manufacturing industries, some bringing additional property requirements for adhesive formulators, particularly those of conductivity and heat and stress dissipation. Licari and Swanson (2005) give a complete exposition on the subject.

To exhibit electrical conductivity, the adhesives typically employed, such as epoxy resins, need to be filled with electrically conductive particles, for example, metal powder like silver, because they are inherently insulators. The selection of an electrically conductive (or insulating) adhesive, therefore, is most often based on the adhesives' conductivity or resistivity and its ability to retain those properties for the expected service life of the electronic equipment. Accelerated aging tests have been developed by industry that can give indications of durability and also be used for qualification of adhesives. Typical regimes involve heat aging for 1,000 h at 150 °C, combined with any or all of the following: moisture exposure, thermal cycling, vibration, and thermal or mechanical shock, with the

performance expectation that bond strengths and electrical properties will be maintained throughout.

One major cause of failure in this field is large mismatch in the coefficient of thermal expansion of the substrates concerned, especially when bonded with high modulus adhesives, and so adhesives have been formulated from more elastomeric resins, which can effectively dissipate the stresses induced in these situations and can be demonstrated by the accelerated test cycles described above.

---

## **35.4 Durability and the Construction Products Regulation**

The largest commercial market for adhesives and sealants is their use in building and construction. The Construction Products Directive (89/106/EEC) (CPD) is currently undergoing review and will be remade as the Construction Products Regulation (CPR) probably coming into force in 2012 or 2013. European regulations, unlike directives, are translated directly into law in the member states without the need for national statutes and instruments (and the potential for differing national interpretations). Thus, the basic work requirements (formerly essential requirements in the CPD) of the CPR will become compulsory in all member states.

The CPD (and CPR) recognize that member states have provisions, including requirements, not only to building safety but also to health, durability, energy economy, protection of the environment, and other aspects important in the public interest. The articles of the Regulation require that these basic work requirements are satisfied during an economically reasonable working life, where the working life is the period of time during which the performance will be maintained at a level compatible with the fulfillment of the basic work requirements and an economically reasonable working life presumes that all relevant aspects are taken into account, such as costs of design, construction, and use; costs arising from hindrance of use; risks and consequences of failure of the works during its working life and costs of insurance covering these risks; planned partial renewal; costs of inspections, maintenance, care, and repair; costs of operation and administration; disposal; and environmental aspects.

For adhesive and sealant materials, their durability in service, in relation to these basic requirements, is connected with the characteristics of the products, and the mandates issued by the European Commission for the development of harmonized technical specifications (harmonized European Norms – hEN), that is, standards and, for certain products, European Technical Approvals (ETAs), also include durability aspects.

As a passport for a product to be marketed and used in the single market without the need for any other additional requirements, a CE mark may be affixed when it can be demonstrated that all the provisions of the CPR including these basic work requirements have been satisfied. Thus, standards and technical specifications must include provisions for the assessment of durability. A main route to this assessment involves the performance testing of a product to determine the variation in its characteristics under a given action or cycle of actions. However, the standard and

specification writers are required to strike a balance between the cost of testing and the additional information that can result from such tests.

For products that are covered by hENs, the specific durability assessment requirements are stated in Annex ZA of the standard, and the results of that durability assessment form part of the aforementioned CE mark.

### 35.4.1 Sustainability

The increasing concerns about the impact of the activities of man on the environment have brought new challenges to adhesive and sealant manufacturers as customers have begun to specify requirements relating to the sustainable consumption and production of the earth's resources. Such considerations relate not only to the raw materials used to manufacture the adhesive and sealant products but also to the end of life options, including recycling possibilities, of the products and articles made with them and their ultimate destination and impact on the environment. In order to minimize all these impacts, full life cycle analysis techniques are employed to identify where improvements can be made. As adhesives and sealants are most commonly employed to join dissimilar materials, so the ability to de-bond assemblies to facilitate recycling activities has become an additional consideration for the formulator and a new area for research workers and adds another new dimension to considerations of durability in-service, with the now required coexistence of durable, yet dismantle-able properties.

The dismantling and recycling of electrical appliances have received much publicity in the western world, particularly in relation to the exposure of workers in the developing world to the toxic chemicals, which are contained within them and are of relatively high value for recycling purposes. However, the promotion of waste recycling in the construction industry particularly in the west is becoming increasingly important, because of the dwindling availability of landfill sites. The building materials currently used in the market utilize a wide range of components from metals to inorganic and organic substances often to improve their strength, function, or aesthetic appearance, but their separation is often difficult to achieve, and combined materials cannot be recycled or reused. Obviously, in any manufacturing sector, if adhesively bonded joints can be made to separate easily by some method, the recycling of such combined materials becomes much easier, and new technologies have been developed in an attempt to satisfy this requirement. One of these technologies recognizes that hydrogen bonding and intermolecular forces are the main forces that join adherends and a method that extends intermolecular distance will facilitate bond dismantling. This is achieved by incorporating thermally expansive particles into the adhesive or sealant, such that when they are expanded by heating, typically above 100 °C, the intermolecular distance is extended by the expansive forces, bond strength is reduced, and the materials are separated. Ishikawa et al. (2005) conducted a study on these types of adhesive for use in the construction industry. They examined the durability of the bonded assemblies by accelerated aging tests at 60 °C and found that there is no deterioration in bonding performance

and that joints could be easily separated by heating between 150 and 180 °C. From these studies, they were able to conclude that durability and dismantle ability were able to coexist in the systems tested.

---

## 35.5 Conclusions

This chapter describes and discusses the main factors affecting the durability of nonstructural adhesives and sealants, and the methods used for their estimation, and their applicability to actual service life prediction. The major conclusions that can be drawn are the following:

1. Appropriate adhesive and sealant selection, which takes into account the properties of the materials to be joined and the expected service conditions and service life, is essential to ensure the durability of bonded assemblies, and much advice and assistance is available from manufacturers.
2. Standard test procedures have been developed to assist this selection process and predict durability in the absence of “heritage” data to establish suitability for purpose. However, these standard test methods rely on acceleration techniques to produce deterioration of properties in reduced timescales, which may induce mechanisms and pathways that are not present under “normal” service conditions. So these tests need to be supported by determinations conducted under “normal” service conditions.
3. Durability and its estimation are becoming increasingly important in all industrial manufacturing sectors for the calculation of economic service life of products including their human health and environmental impacts and cost of maintenance. This is particularly relevant in the construction industry.

**Abstract**

A chapter on adhesive storage should be closely aligned with the current market practice. As such, a major part of this chapter focuses on the shelf life and safety aspect of adhesives. The adhesive shelf life is dependent on the adhesive system and the storage conditions, in particular, the temperature. For a stronger emphasis on the effect of temperature on adhesive shelf life, this chapter is subdivided into *Storage at Room Temperature* and *Storage at Low Temperature*.

Due to the flammability and possible health hazards of solvent-based adhesives and majority of the chemically reactive adhesives, their storage usually requires special safety measures.

Adhesive manufacturers are required to provide information on the shelf life and storage conditions in the product technical data sheet, as well as a description of the possible hazards in the safety data sheet (Material Safety Data Sheet, MSDS), e.g., in the event of a fire.

Due to the wide range of adhesive systems available, it is not possible to devise a standard storage guideline applicable to all adhesives. In this chapter, adhesives are divided into four categories: solvent-based, water-based, hot-melt, and reactive adhesives. For some adhesives, their physical characteristics should also be considered (e.g., liquid or solid in the form of powder, granules, or film). Considering the variety of adhesive systems, it is necessary to provide a short introduction on the adhesive to indicate the type of packaging and storage conditions needed and its potential hazards.

Similarly, in cases where the adhesive shelf life may be extended through storage at low temperatures, it should also be indicated on the packaging, although this applies to limited adhesive systems and applications. In order to explain the quantitative effect of low temperatures on adhesive storage, a brief subtopic on activation energy and temperature-dependent chemical reaction (Arrhenius equation) is provided.

---

## **36.1 Introduction**

### **36.1.1 Basics of Adhesive Storage**

The proper storage of an adhesive is a prerequisite to maintain the adhesive properties for the adhesion process and, beyond that, for the final bond performance (bonding strength, heat resistance, and other specific properties). The significance of the appropriate storage conditions is usually presented in the quality assurance documentation of the adhesive. Essentially, the adhesive is guaranteed by the manufacturer throughout the shelf life under the storage conditions specified in the product technical data sheet. The optimization of the adhesive shelf life normally commences with the adhesive development, with storage stability tests integral to the design specifications.

As a rule, manufacturers are required to inform customers of the adhesive shelf life under the recommended conditions in the product information. Within this period, the specified adhesive properties should be guaranteed for delivery as well as for the final bond performance after appropriate processing steps. The manufacturing date, shelf life, and suitable storage temperature of the adhesive should also be indicated on the packaging. While many products can be stored at room temperature, some may require low temperatures for a prolonged shelf life. The aspect of storage at low temperatures will be addressed separately.

Besides complying with international and national laws and regulations, institutional measures to ensure environmental protection and occupational health and safety must also be adhered to during adhesive storage. They are applicable throughout the supply chain, from production to delivery by the adhesive manufacturer, to distribution by the agent if necessary, and, finally, to the end user after processing. In the European standard, EN 12701 (European Standard 2001) titled “Determination of words and phrases relating to the product life of structural adhesives and related materials,” definitions and requirements applicable to structural adhesives with storage life limited by possible change of properties are clearly specified.

The compliance with safety procedures constitutes another notable aspect of adhesive storage. A series of adhesives are classified as hazardous materials due to the presence of highly flammable solvents or components presenting health hazards such as cyanoacrylates or acrylates containing high monomer contents. In addition, hardeners of reactive adhesives such as isocyanates, amines, or peroxides should be considered. An important reference is the REACH (Registration, Evaluation, Authorization and Restriction of Chemicals -EC 1907/2006) regulation, implemented by the European Parliament in 2007 to ensure that manufacturers take the responsibility to manage risks from chemicals and to provide safety information on the chemicals.

It is also an international practice to include exposure controls and other measures in the safety data sheet, so as to ensure the safety of personnel handling of the adhesives. The manufacturers are responsible for compiling the necessary documents and are required to provide them to customers at all times.

Special provisions and measures regarding the storage facilities of adhesives are established according to building and environmental regulations. Among them, fire control, which includes firefighting equipment, evacuation plan, and fire engine access route, is an important point for consideration. At the same time, attention should be accorded to the prevention of water pollution which may be caused by the leaching of hazardous materials into groundwater.

This chapter mainly covers the aspect of adhesive storage, according to the industrial standard. The storage of adhesives in households or offices, usually in small quantities (e.g., in tubes), is mostly subjected to other conditions and regulations.

### 36.1.2 Classification of Adhesives Based on Storage Criterion

Due to the existence of different adhesive systems and the potential hazards associated with each system, there are different types of packaging as well as storage conditions and shelf life. Adhesives can be classified according to specific criterion and properties. In the literature, one can find various classifications based on the assembly process, delivery form, adhesion mechanism, or application. Within the same adhesive group, the adhesives can be further categorized based on their physical states or characteristics: liquid, paste, or solid (through viscosity measurements and rheological characterization) or solvent based, water based, or those

without volatile content (through solid content measurements). Another classification can be made based on the adhesion mechanism: physically dried adhesives from solution, solidified hot-melt adhesive, or chemically cross-linked single- and two-component reactive adhesives.

This chapter attempts to classify the different adhesives based on a few key points concerning storage. Based on storage criterion, adhesives can be classified into four main groups: solvent-based, water-based, hot-melt, and reactive adhesives. These groups mainly differ in their shelf life and potential hazards. Nonetheless, within such classifications, overlaps are possible. For instance, there are reactive hot-melt adhesives and reactive solvent-based adhesives.

Other considerations include the delivery form and packaging, which differentiate solid adhesives from liquid adhesives. Liquid adhesives are usually stored in sealed packaging, containers, barrels, or tanks at room temperature between 18 °C and 25 °C. Homogeneous products can be stored for a year or more due to the limited physical or chemical changes within the system. For nonhomogeneous products, due to the possible sedimentation of fillers or segregation of different phases during storage, stirring is usually necessary to return the system to its original state before use. Any premature chemical reactions caused by inappropriate storage conditions (e.g., higher temperature or longer duration) are irreversible, and they usually render the adhesives ineffective or unusable.

Solid adhesives such as hot melts are relatively easier to handle during packaging and storage, whether they are in the form of blocks, in crushed form as granules, in powdered form in cartons or sacks, or in the form of rolled sheets.

During the storage of reactive adhesives, the influence of humidity is another important consideration besides temperature, especially for moisture-sensitive bonding agents such as cyanoacrylates or single-component polyurethanes, which harden upon contact with moisture, like hardeners of reactive adhesives. Among special reactive adhesives are those which react under anaerobic conditions or in UV light and require storage under oxygen-rich or dark conditions, respectively. The packaging of such adhesives should also be adequate to prevent any undesired chemical reactions before use.

Reactive adhesives which are particularly sensitive require storage in a conditioned environment, with regulated temperature and humidity. To achieve fast adhesion during mass production, highly reactive adhesives containing catalysts are often required. However, they are not suitable for room temperature storage. Instead, low temperatures are required. Special measures of low-temperature storage and the affected adhesive groups will be addressed in Sect. 3.

---

## 36.2 Storage at Room Temperature

The term “room temperature” is sometimes misused. It was meant to define the temperature in a conditioned room, usually enclosed, such as an office or a work area, e.g., laboratory. The temperature range may vary according to the location, e.g., as narrow as 20–23 °C in a measurement laboratory or as wide as 18–25 °C in rooms

where temperature sensitivity is not as crucial, such as storage hall for general goods. Unless specified, room temperature mentioned in this chapter refers to a temperature range of 18–25 °C.

Additionally, it is a basic condition in adhesive storage to keep the adhesive in its original sealed packaging before use, as far as possible, even if humidity does not always appear to influence the adhesive shelf life.

## 36.2.1 Solvent-Based Adhesives

### Solvent-Based Adhesive Group

This class of adhesives consists of solutions of polymers, resins, and, where applicable, other additives in organic solvents. They have low to moderate viscosities and solid contents ranging from 15% to 40% in weight, which correspond to solvent contents ranging from 60% to 85% in weight. They are applied as PSA or contact adhesives.

The base polymer should be soluble in common solvents. The rate of dissolution is dependent on the polarities of both the base polymer and the solvent and the molecular weight of the polymer. Predominantly, acrylate, polyvinyl acetate, natural or synthetic rubber, polychloroprene, polyurethane, polyvinylpyrrolidone, or polyvinylchloride (PVC) constitute the base polymer for such adhesives. Nonetheless, solutions combining phenolic resins and rubber are also used.

Common solvents used are those which are easily available and cost effective. They should have a good solubility but low toxicity. Therefore, the use of chlorinated solvents such as dichloromethane or trichloroethylene has been effectively banned in the EU since December 2010 despite their good solubility, as they may be carcinogenic or pose health risks (e.g., optic neuropathy).

In general, the following solvents are used: petroleum naphtha 60/95, petroleum naphtha 80/110, ethyl acetate, acetone (dimethyl ketone), butanone (methyl ethyl ketone), toluene (methylbenzene), ethanol, isopropanol, or sometimes tetrahydrofuran, which is a suitable solvent for PVC. For adhesive storage, key data of the corresponding solvents such as boiling point, flash point, and the rate of evaporation are necessary. Table 1 shows a summary of these data for the solvents mentioned above. (Flash point refers to the lowest temperature at which a volatile liquid can vaporize to form an ignitable mixture in air.)

The rate of evaporation is a ratio of the time required to evaporate a measured amount of liquid to that of a reference liquid (ethyl ether).

### Storage and Shelf Life

Storage vessels of solvent-based adhesives which include jerry cans, drums, and containers with capacities of up to 30, 200, and 1,000 L, respectively, are made of metals such as aluminum or steel. Drums either have a sealable lid or are sealed but equipped with a faucet outlet. Sealed drums should only be stored upright. Otherwise, the drum lid may be easily damaged on contact with adhesives, especially those containing aggressive solvents, causing the contents to leak. Plastic vessels are

**Table 1** Properties of solvents used in solvent-based adhesives

Solvent	Boiling point (°C) at 1,010 mBar	Flash point (°C) according to DIN EN 22719	Rate of evaporation ethyl ether = 1
Acetone	56	−19	2.1
Butanone	80	−1	6
Ethanol	78	+12	62
Ethyl acetate	77	−4	2.9
Isopropanol	82	+12	11
Tetrahydrofuran	66	−17	2.3
Toluene	111	−6	6

not suitable as storage containers for solvent-based adhesives, as solvents may diffuse through the container walls – unless they are protected by a barrier coating. Solvent-based adhesives are generally stable during storage, as they hardly undergo alterations as homogeneous solutions in sealed vessels. Hence, they usually have a recommended shelf life of up to 2 years. However, for some, the viscosity may change gradually with time. Though uncommon, some solvent-based adhesives may contain fillers or reactive components, which affect the storage stability through phase separation or cross-linking.

**Hazard Potential**

Solvent-based adhesives are classified as hazardous goods, as they contain a significant portion of highly flammable solvents. Thus, it is essential to comply with laws and regulations concerning fire prevention and firefighting.

Adhesive containers should be labeled with the appropriate hazard symbols. In storage facilities, no ignition sources should be present or allowed to come into contact with solvents or their fumes, and the generation of sparks should be avoided. Additionally, it is necessary for all electrical equipment to be explosion proof and all containers should be earthed. It is also mandatory for personnel to be equipped with safety shoes having conductive soles to minimize the accumulation of static electricity. Similarly, production equipment or vehicles should not generate any sparks.

The maximum quantity of solvent-based adhesives allowed in a storage room is limited (to 10,000 L in Germany). In an “active storage,” where the containers with adhesives would be opened or siphoned, an exhaust system must be installed to minimize the accumulation of solvent fumes. Secondary containment is often necessary to prevent the adhesives from entering the earth or groundwater in the event of a spill as shown in Fig. 1.

Further information on this aspect may be obtained from national or international regulations such as REACH (the new European law concerning chemicals) or specialized contributions from corporate entities such as *Fundamentals of Hazardous Materials by Denios, Germany* *Fundamentals of Hazardous Materials* (2009/2010).

**Fig. 1** Storage of flammable solvents and solvent-based adhesives in a protective storage chamber (Photo: Denios)

## **36.2.2 Water-Based Dispersion Adhesive**

### **Water-Based Adhesive Group**

Water-based dispersion adhesives consist of oligomers dispersed in water with surfactants as dispersing agents and stabilizers. Before dispersions, natural rubber latex and casein were used to manufacture such adhesives. Currently, polyvinyl acetate (PVAc) and polyacrylate serve as synthetic base polymers for water-based PSA, while polychloroprene and thermoplastic polyurethane serve the same purpose for water-based contact adhesives.

Compared to solvent-based adhesives, water-based dispersion adhesives have several advantages: environmentally friendly and nonflammable. In addition, a larger quantity of the adhesive can be dispersed in water without a significant increase in the viscosity. Thus, a solid content of 40–70% in weight is common, and this is almost twice of that compared to solvent-based adhesives.

### **Storage and Shelf Life**

Water-based dispersion adhesives are mostly stored in plastic containers. Smaller containers with capacities of up to 30 L are made of polyethylene (PE), while larger containers which come in 100-L vessels or up to 800-L containers are made of polypropylene (PP). To ensure stability, the container thickness should be

proportional to its size. In fact, such containers are often made of glass fiber-reinforced polypropylene. Larger containers can also be stabilized using metal casings or cages.

However, one drawback of water-based dispersion adhesives is the limited storage stability due to various influencing factors. In particular, they must be protected from frost, as freezing usually causes irreversible damage to the dispersions.

Furthermore, the stability of such dispersions is pH dependent. In fact, many of them (except PVAc dispersions) coagulate in neutral or acidic conditions, leading to the failure of the adhesive system. This can be avoided by the addition of neutralizing agents such as ammonium hydroxide or alkali hydroxides with pH values in the range of 9–10.

Water-based dispersion adhesives also face the problem of possible contamination through microbial attacks, especially when industrial water or mains water is used during their production. During microbial attacks, dispersions undergo partial coagulation, resulting in brownish discoloration and a strong odor. With that, the adhesive becomes unusable. Thus, a microbiological analysis is necessary to determine the bacteria count before storage.

With that in mind, most manufacturers of water-based dispersion adhesives recommend storage durations of 6–12 months at 5–25 °C.

### **Hazard Potential**

As water-based dispersion adhesives do not pose any health hazards and are non-flammable, there is no critical concern associated with their storage. Despite so, precautions relating to the concerned chemicals and information provided in the safety data sheets should be taken note of, in the event of a spill. Contact with the skin and splashes into the eye should also be avoided, like most chemicals. Upon contact with chemicals such as ammonia, some dispersion adhesives emit an odor. For environmental concerns, contaminants such as alkaline or acidic materials should not be discharged into the groundwater.

## **36.2.3 Hot-Melt Adhesive**

### **Hot-Melt Adhesive Group**

Hot-melt adhesives range from viscous to solid forms in storage at room temperature. To allow proper application during the adhesion process, they have to be melted at elevated temperatures. Following that, they solidify on cooling to form strong bonds between the substrates. Polymers such as ethylene-vinyl acetate, polyamide, and polyester constitute the base polymers of harder hot-melt adhesives with higher melting points, while the softer ones consist of polyacrylates, styrene-butadiene copolymers, or thermoplastic polyurethane. However, as such polymers exhibit lower adhesion and tack properties, they are usually used in combination with tackifiers. While the soft and viscous hot-melt adhesives exhibit better tack than solid ones, the solid hot-melt adhesives provide a stronger bonding.

There are different delivery forms available: soft hot-melt adhesives are preferably packed into compact blocks or cartons, while highly viscous hot-melt granules are usually powdered with fine mineral powder such as talcum or silica to inhibit the

clumping of the granules. This allows them to remain fit for storage. In contrast, as solid hot-melt adhesives do not form clumps easily, they are available in the form of powder, granules, or to some extent, sticks. Hot-melt adhesives also exist as films on release paper, wound into rolls. Such films can be pre-cut into sheets, which are used immediately for mass productions, instead of being stored for later use.

### Storage and Shelf Life

During manufacture, hot-melt adhesives are mostly filled in their molten state at high temperatures, after which they solidify upon cooling. They are available in compact forms in 200-L vessels or in cartons, which are coated with release agents, and are finally delivered as blocks. Pressure vessels are often used as special storage containers as they are suitable for adhesive storage under pressure, after the heating and melting of the adhesives. Many of these adhesives undergo crystallization during cooling after manufacture. However, this does not impact the adhesion properties, as crystallization is reversed during the subsequent heating process before bonding. Such reversible behavior is characteristic for thermoplastic materials.

Powdered and granulated hot-melt adhesives are usually prepared by crushing the solid form and then preferably packed and stored in 25-kg paper sacks. As hot-melt adhesives are sensitive to moisture, the paper sacks should be coated with polyethylene (PE) to prevent deterioration by the diffusion of moisture through the paper sacks. Polyamide is not used as a moisture barrier because it can absorb up to 3% weight of water during extended storage. Polyester is also not an option due to similar reason, though it has a lower moisture absorption capacity. The larger the surface area of the particle or smaller the particle size, the faster is the rate of absorption. During subsequent heating between 150 °C and 180 °C, the presence of moisture in the adhesive leads to the formation of bubbles or foam in the adhesive joint, which reduces the adhesive stability and leads to quality problems.

During production of hot-melt films, hot-melt adhesives undergo heat extrusion and cooling on release-coated paper or film. When soluble polymers such as thermoplastic polyurethane are used, the solution can be coated onto the release paper, dried, and converted into a larger roll, before it is slit into smaller rolls. A large roll may measure 250 µm in thickness (with release paper), 2000 m in length, 2 m in width, and weigh up to 1 t. Hot-melt adhesives tend to flow under high pressure loads even at room temperature. Thus, large rolls should only be stored for a short period of time on a flat support or upright manner, otherwise deformation would occur. For longer storage durations, the problem may be avoided by fixing the roll on a rotating rack, which allows it to slowly rotate continuously, as shown in Fig. 2.

For adhesive tapes with liner, regardless of the size of the rolls, humidity should be taken into consideration. At a high humidity, the paper within the liner absorbs moisture from the environment despite the silicon interface, especially after drying. When this occurs, the paper tends to swell. This affects the structure of the paper, which may then be transferred to the adhesive film. However, this concerns only the outermost layers of the roll. This effect can be avoided either by air-tight packing of individual rolls or the conditioning of the entire storage room to a temperature of 20–23 °C and a humidity which is lower than 50%.

**Fig. 2** Rotating racks for adhesive jumbo rolls in a temperature-regulated storage hall (Photo: tesa Werk Offenburg)

In general, by adhering to the moisture-related measures, hot-melt adhesives can be stored unchanged for a long period of time. The recommended shelf life of hot-melt adhesives ranges from 18 to 24 months, provided they are stored at 10–25 °C, under dry conditions.

### **Hazard Potential**

Since most hot-melt adhesives do not contain volatile components, they are not highly flammable and do not pose any health hazard during normal handling. As such, they are also used in packaging for grocery. Unlike the rest, no special measures are required for an incident-free storage.

## **36.2.4 Reactive Adhesives**

### **Reactive Adhesive Group**

Reactive adhesives comprise all adhesives which undergo a chemical reaction during the adhesion process and in doing so, solidify. Single-component systems can react chemically in the presence of external influences such as heat, UV light, moisture, or anaerobic conditions. On the other hand, two-component systems usually react through the mixing of reactive components, e.g., resins and catalysts, at room

temperature without external influences. During storage and before processing, reactive adhesives often exist in forms ranging from liquid to paste.

The most important types of two-component adhesives are moisture-sensitive polyurethane, comprising polyol resin and isocyanate catalyst, and heat-sensitive epoxy, comprising bisphenol-A or bisphenol-F resins and polyamide catalyst. Both single- and two-component adhesive systems are available in the market. Single-component reactive adhesives, which include cyanoacrylate and silicone, are also widely known, with the latter often being used as a sealant.

A particular adhesive group used for heat-resistant bonding is the single-component reactive adhesive, formulated as a combination of phenolic resin and nitrile rubber, in the form of heat-activated films (HAF). These contain latent hardeners for the phenolic resins, which are activated at temperatures above 120 °C. The advantages include clean and precise handling.

UV-sensitive and anaerobic-sensitive adhesives also belong to the reactive adhesive systems, which should be stored under chilled conditions.

### **Storage and Shelf Life of Two-Component Reactive Adhesives**

Resins and hardeners of two-component adhesives should be stored in separate metal drums, jerry cans, vessels, or larger containers. The quantity of each component to be stored is determined according to their mixing ratio. Polyurethanes and epoxy resins differ in the type of chemical reactions they undergo during the hardening process. On top of that, both systems are used in combination with different hardeners and have different storage requirements.

Polyurethanes are traditionally produced from the reaction of isocyanates and polyols.

Isocyanates (e.g., methylene diphenyl diisocyanate [MDI]), the most commonly used hardeners for polyurethanes have low viscosities and undergo crystallization in chilled conditions below 15 °C. At temperatures above 40 °C, isocyanates undergo a chemical reaction (i.e., dimerization), which increases their viscosities. In addition, upon exposure to moisture, they react with water molecules to produce polyurea and carbon dioxide gas, which results in outgassing and the formation of a layer of film. To prevent such occurrence, isocyanates must be stored at temperatures in the range of 20–35 °C and in the absence of moisture. Under these conditions, the shelf life is approximately 6 months.

Polyols, unlike isocyanates, are generally chemically stable. However, in many instances, they contain additives such as catalysts, fillers, and pigments for special applications. During storage, mineral fillers may sediment at different rates depending on their densities and the viscosity of the bulk solution. In such situations, the material should be stirred immediately before use to ensure homogeneity. However, this should be done without generating entrapped air in the mixture. Hence, it is essential to notify the user with a “Stir before use” label on the container.

Epoxy resins comprise bisphenol diglycidyl ethers. Having moderate to high viscosities, they are mostly delivered in jerry cans or vessels. While pure epoxy resins tend to crystallize upon storage for longer durations, this phenomenon can be reduced by

mixing bisphenol-A with bisphenol-F. Often, such adhesives are also loaded with fillers. Hence, they should be monitored for any sedimentation during storage.

Hardeners are mostly polyether amines or similar amine composites. They have moderate to high viscosities and a typical amine smell.

The storage of resins and hardeners in sealed containers is less critical compared to that of polyurethanes, as every component is chemically consistent. Thus, they can be stored for 12 months at temperatures between 20 °C and 25 °C.

### **Storage and Shelf Life of Single-Component Reactive Adhesives**

Single-component polyurethanes consist of prepolymers, a fraction of which is pre-reacted polyurethanes with terminal isocyanate groups. Due to their moisture sensitivity, they have to be stored away from moisture or possible contact with water, preferably in metal containers. They require similar storage conditions as MDI hardeners, although in the reduced forms, they are less reactive. In the absence of moisture, the viscosity increases during storage. As such, manufacturers usually recommend a shelf life of 3–6 months at 20–25 °C.

Single-component epoxy resins contain dicyandiamide as latent hardeners, which are activated at high temperatures – usually above 150 °C. As such, they belong to the class of heat-activated adhesives. They are available in viscous or paste forms, and those of even higher viscosities are available as films on release paper.

Apart from hardeners, some adhesives in this category also contain an additional activator, with which a faster rate of reaction can be achieved. This effectively shortens the duration needed for the adhesion process or lowers the activation temperature. However, this also leads to reduced storage stability of the adhesive.

Heat-activated films (HAF) can be stored for 12–18 months under dry conditions at room temperature, depending on the type of phenolic resins present in the system. For special applications, such as in the electronic industry, clean room environment and subsequent dust-proof packaging and storage are necessary.

Cyanoacrylate belongs to the single-component reactive adhesives. Due to its fast-acting characteristic, it is commonly known as “superglue.” In the presence of water, it undergoes rapid polymerization, causing the adhesive to set. Thus, it must be stored in leak-proof containers, completely protected from moisture or water during its storage. Otherwise, it may react prematurely and become unusable. This is guaranteed by the manufacturers through the use of suitable packaging, usually in small quantities from 5 g to 5 kg. When stored in their original packaging in dry conditions at 20–23 °C, the shelf life ranges from 6 to 12 months.

Anaerobic adhesives are derived from dimethacrylate esters and are often low in viscosities. They react only in the absence of oxygen and when in contact with a metal surface at the same time. In order to prevent premature polymerization, these adhesives should be packed in a way which allows them to be in constant contact with oxygen. Having a diffusion-resistant packaging can also ensure that oxygen does not diffuse out of the packaging during storage. They are mainly used as bolt adhesives or for the sealing and securing of mechanical devices. These adhesives should be stored in a cool environment. For instance, they can be stored at 5 °C in their original sealed packaging for 1 year.

UV-sensitive adhesives are based on acrylate-modified epoxy resins, polyurethanes, and, among others, polymers. They are single-component reactive adhesives, which undergo rapid polymerization upon irradiation with UV light with wavelengths ranging from 400 to 500 nm. These adhesives should be stored in small opaque containers of up to 50 mL in volume. They can be stored in their original containers for 6 months at 10–25 °C.

### **Hazard Potential**

Due to their reactivity, reactive adhesives and hardeners have to be stored according to special regulatory requirements. The containers of such materials should be labeled with the appropriate warning symbols and possible hazards associated with the content, as indicated in the safety data sheets. Nonetheless, under normal storage in their original packaging, they are not expected to pose any hazards.

Nonetheless, mandatory precautions to contain a spill due to leaking or damaged packaging are necessary. Such precautions include secondary containment (e.g., trays) and spill kits or absorbents at accessible locations to soak up hazardous liquids for subsequent disposal. Personnel handling spilled adhesives should also be equipped with personal protective equipment (PPE) such as coats or gowns, gloves, safety goggles, and respiratory apparatus. In general, any contact with reactive adhesives should be avoided. While cyanoacrylates bond to the skin in seconds, epoxy resins and polyurethanes can trigger allergies. Other hazardous adhesive raw materials include hardeners used in the manufacture of polyurethanes. One example is methylene diphenyl diisocyanate (MDI), which poses health risks due to occupational exposure such as respiratory tract irritation and sensitization.

A more critical situation would be that of a fire. Suitable extinguishing agents or fire extinguishers should be available to combat fires which are small enough. Beyond that, larger fires may lead to uncontrollable chemical reactions with the accumulation of toxic by-products. For instance, single-component epoxy resins may trigger strong exothermic reactions with promoters at temperatures above 120 °C. In the presence of more than 1 kg of the materials, such exothermic reactions can hardly be extinguished. As a result, the surrounding may be heated up to temperatures of 500 °C or higher. Thus, in the event of a fire, the fire response team must be immediately summoned. The team should also be informed of the materials involved and provided with their safety data sheets.

---

## **36.3 Storage at Low Temperatures**

### **36.3.1 Basics of Adhesive Storage at Low Temperatures**

The main reason for adhesive storage under cool or cold conditions is to extend the adhesive shelf life. For some adhesives, storage at low temperature is absolutely necessary, while for some, it is recommended where longer storage durations are necessary. However, there are also some adhesives which can be damaged when stored under cold conditions.

For adhesives requiring storage at low temperatures, the same conditions should also apply during transportation from manufacturers to the customers. In the event that the adhesives are exported out of cold or temperate climates to warmer ones, insulated containers are essential.

To achieve the desired cooling, filled adhesive containers are stored in cooling chambers or freezers. In doing so, the cooling capacity of the adhesive should be balanced with the cooling efficiency and the temperature of the cooling system. As liquid adhesives are cooled, physical effects such as an increase in viscosity may occur through a reduction in the rate of filler sedimentation. Further cooling may even halt the sedimentation of the fillers. At the same time, solute components may crystallize out of the adhesive. Most importantly, cooling retards the chemical cross-linking reactions, thereby enhancing the adhesive shelf life.

The cooling of adhesives for storage followed by reconditioning to room temperature before use usually incurs additional costs, and for larger adhesive quantities, this may be a very time-consuming process. The tempering of full containers or vessels may take up to a few days depending on the temperature difference within the contents, especially when the bulk material is not stirred. Large rolls of reactive adhesive films, requiring storage at low temperatures, have similar behaviors. In practice, the conditioning of cooled adhesives before handling may take longer than expected, as the application of heat has to be conducted with caution. Overheating may lead to unwanted outcomes such as premature cross-linking in reactive adhesives or elevated vapor pressures, which present a flash fire hazard in the presence of solvent-based adhesives. Another effect is the condensation of water vapor on the cooled packaging, as the adhesives are brought into warm conditions. If the adhesives are applied too fast before conditioning, the condensed water droplets may lead to defective bonding between the adhesives and the substrates. These points should be taken into consideration during a good logistic practice.

The need for storage at low temperatures only concerns a small group of the commonly available adhesives in the market. In Sect. 1.2, adhesives are categorized into four groups: solvent-based, water-based, hot-melt, and reactive adhesives. In this section, key points of storage at low temperatures will be addressed based on these categories.

Most adhesives requiring cool or cold storage conditions are reactive adhesives, many of which are single-component adhesives. For some, cross-linking reactions begin even at room temperature, thus compromising the adhesive shelf life. Apart from fluid adhesives, this problem also concerns reactive adhesive films and pre-pregs (pre-impregnated sheets).

Unlike reactive adhesives, solvent-based adhesives seldom require such storage conditions as the reaction rates of reactive components, such as polyurethanes, epoxies, and phenolic resins, can be distinctly lowered by dilution with solvents. Thus, storage at low temperatures is only occasionally recommended for solvent-based adhesives. For normal storage in storage halls with higher ambient conditions, the temperature should be conditioned to a level not beyond the upper limit of room temperature, i.e., 25 °C (with the exception of up to 30 °C, depending on the solvent) through cooling.

Hot-melt adhesives do not require storage at low temperatures, because being pure thermoplastic materials, they are neither chemically reactive nor do they undergo physical changes at room temperature. Furthermore, they do not emit solvent vapors or other gases during their storage. Thus, at room temperature, these adhesives remain unchanged and can be stored for extended periods of time.

In contrast to reactive adhesives, water-based dispersion adhesives generally cannot withstand such storage conditions and must be protected from low temperatures. In such dispersions, water acts as the carrier medium, in which the adhesive components are dispersed as microspheres. Thus, when water freezes at 0 °C, phase separation occurs. As the water crystallizes and the adhesive components separate from the liquid medium and condense, the adhesive coagulates, as shown in Fig. 3a, b. When this

**Fig. 3** (a) Effect of cold storage on a water-based acrylic dispersion adhesive, (b) coagulation of water-based acrylic dispersion adhesive due to cold storage

happens, the adhesive becomes unusable. Hence, water-based dispersion adhesives are mostly stored at room temperature. Nonetheless, some manufacturers recommend storage temperatures between 5 and 25 °C to inhibit microbial attacks.

### 36.3.2 Temperature and Reactivity: The Arrhenius Equation

The shelf life of reactive adhesives can be extended by reducing their reactivity (i.e., rate of collision of reacting molecules per unit time). This can be achieved by increasing the free path of the molecules, through the dilution of the adhesive. However, for the dilution to be effective for this purpose, a reduction of the solid content by approximately 30–40% is necessary. Hence, in practice, dilution is only used as a means to reduce the adhesive viscosity. A more effective way to reduce the reactivity would be to decrease the mobility of the reacting molecules through cooling.

The Arrhenius equation describes the dependence of the chemical rate constant on the absolute temperature as follows:

$$k = A \cdot e^{\frac{-E_A}{RT}}, \quad (1)$$

where

$k$  is the rate constant of the reaction.

$A$  is the pre-exponent to indicate the number of molecular collisions per unit time.

$E_A$  is the activation energy of the reaction (J mol<sup>-1</sup>).

$R$  is the gas constant, with a value of 8.314 (J mol<sup>-1</sup> K<sup>-1</sup>).

$T$  is the absolute temperature (K<sup>-1</sup>).

Most chemical reactions have similar dependence on temperature: the reaction rate doubles with every 10 °C increase in temperature and halves with every 10 °C drop in temperature. In practice, this could translate, for instance, to an adhesive having a shelf life twice as long when stored at a temperature of 10 °C instead of 20 °C. Figure 4 shows the relationship between the temperature and the shelf life of an adhesive, with different reaction rate constants.

Figure 5 shows the influence of storage time and temperature of a one-component reactive adhesive on the peel strength of bonded electronic composites, from which the corresponding storage shelf life was deduced. In this example, a heat-activated adhesive (epoxy resin/dicyandiamide) was used for bonding polyimide film to stiff printed circuit material. Before its use, the adhesive was stored over a long period of time at 23 °C, 15 °C, and 5 °C. The specified peel strength for the application was 15 N cm<sup>-1</sup> (L-peel test according IPC-TM-650 2.4.9). The peel strength was measured at an interval of 2 months. Based on the specified peel strength of 15 N cm<sup>-1</sup>, the corresponding shelf life at each storage temperature was recorded, as shown in Table 2.

In general, the trend observed fulfills the law of Arrhenius.

**Fig. 4** Reactive adhesives: shelf life as a function of temperature, with different reaction rate constants

**Fig. 5** Reactive adhesives: influence of storage time and temperature on peel strength

**Table 2** Effect of storage temperature of reactive adhesive on shelf life

Storage temperature	Shelf life
23 °C	5.5 months
15 °C	9 months
5 °C	16 months

t.1  
t.2  
t.3  
t.4

**36.3.3 Storage Between Freezing Point and Room Temperature**

A temperature range between freezing point and room temperature is adequate to accommodate the majority of the adhesives which require storage at low temperatures. This can be described as “storage under cool conditions” in contrast to storage under 0 °C, which is described as “storage under cold conditions.” Some manufacturers or suppliers provide only general storage instructions such as “cool and dry” or “cool and frost-free” instead of the exact storage temperature and duration, while some provide only a temperature range. The wide variety of adhesive types adds yet another dimension to the storage temperature. The following list (Table 3) shows a selection of some of the typical adhesive groups with the appropriate storage conditions.

**36.3.4 Storage Below Freezing Point**

Adhesives which require storage below freezing point are usually stored at temperatures between −20 °C and −25 °C. Such conditions are generally necessary for reactive adhesives, due to two main reasons as follows.

First, for normal reactive single-component adhesives, they are usually stored in large quantities after manufacture for a significant period of time, before they are filled into smaller quantities and delivered to the market. Hence, to eliminate any undesired chemical reactions during storage, low storage temperatures are essential. This group of adhesives includes cyanoacrylates and UV-sensitive epoxy resins. When stored at −20 °C, in dark conditions, they have a minimum shelf life of approximately 2 years.

Second, highly reactive single-component adhesives, such as catalyzed epoxy resins in the form of films, are viable at room temperature for only a few days. However, at −20 °C, they can be stored for approximately 6 months.

This category of adhesives also includes prepregs, which are used in the aviation industry for the construction of aircraft, e.g., to bond the molded parts together. Prepregs are made of woven glass fibers, or more recently carbon fibers, which have been soaked in and pre-reacted with a mixture of epoxy resins and hardeners. They usually undergo temporary storage at −20 °C and are conditioned to room temperature before use, where they are assembled with the substrates and cured. Apart from epoxy resins, phenolic resins can also be used as raw materials for prepregs.

**Table 3** Storage of different types of adhesives

Water-based dispersion adhesives	5–25 °C (Cooling chamber/room temperature)
Cyanoacrylate adhesives	5–15 °C (Cooling chamber/fridge)
Single-component adhesives polyurethane	15–25 °C (Cooling chamber/room temperature)
Methyl methacrylate adhesives	0–5 °C (Cooling chamber/fridge)
Phenolbutyral adhesive films	5–10 °C (Cooling chamber)
Phenolic resin/rubber adhesive films	5–15 °C (Cooling chamber)
UV-sensitive epoxy adhesives	5–15 °C (Fridge, dark)

## 36.4 Conclusion

In summary, this chapter has shown that, while the compliance to recommended measures during adhesive storage is absolutely necessary, it is usually manageable. The different types of storage and the corresponding shelf lives for different groups of adhesives and composites have also been addressed. In addition, the need to consider the potential hazards of the adhesives or their components during storage and transport is highlighted.

Generally, external influences on the adhesive characteristics during storage, such as temperature, humidity, and other physical effects, are controllable. Where necessary, measures such as suitable packaging and containers, as well as the conditioning of the storage halls, should be implemented.

On top of that, adhesive storage should also be taken into consideration in the development of new adhesives. Therefore, new adhesives should not only be tested against their applications but also their storability and shelf lives, before they are launched in the market. While such tests usually constitute the most time-consuming step during the design process, shortening the time taken for this step during the development phase could potentially result in customer claims later on.

It is a common practice to subject new products or bound parts to accelerated aging in order to simulate storage over long periods of time. This can be achieved through oven storage or environmental cycling tests for a defined period such as 6 weeks. Such tests are often helpful, except when there are other influencing factors apart from temperature and humidity. In such circumstances, it is difficult to establish the exact storage stability.

During storage, any unintended chemical reactions within the adhesives can also lead to problems during or after processing. Hence, new raw materials should be evaluated for potentially undesired chemical reactions to avoid disappointment when such problems arise during the storage of the end products.

Such measures also apply when changes to the adhesive contents are required, for instance, when replacements of hazardous raw materials with environmental-friendly substitutes are called for. In particular, there is an increasing drive toward the use of halogen-free adhesives in the electronic and automotive industries. In general, any change in adhesive formulations would require a series of testing for the storage stability, besides the standard property test profiles.

Currently, another challenge is the desire of many industries to have an adhesive with a shorter wetting-out time for the adhesion process and, yet, better adhesion properties. This would require a highly reactive adhesive, which normally requires storage at low temperatures to guarantee a reasonably long shelf life.

## Abstract

Adhesives are used today with increasing volumes in many applications in different industries and are supplied to the end customers in various forms. Very common are liquid adhesives, pastes, mastics, as well as adhesive films or tapes. Less common are powder systems for coating purposes. Adhesives are used where more conventional mechanical or thermal joining technologies can't be used because the joint area is not accessible (e.g., for a spot welding or riveting gun), entire areas need to be bonded (tile or carpet bonding), or if improved mechanical joint performance is required. Improved mechanical performance could be increased joint stiffness, longtime durability, or corrosion resistance under environmental exposure.

Bonding with adhesives is not a simple operation, and a lot of preparation work is necessary before the adhesive can be applied to the designated bonding area (Shields J, Adhesives handbook. Butterworths, London, 1985). A chain of preparation processes is required. It starts with the mixing of the adhesive and its storage before the transfer to the customer. At the customer, the adhesives need to be transferred to the operation area. The substrates to which the adhesive will be applied have to be well prepared. The final process step includes the dispensing of the adhesive to the substrate and the joining of the parts which are intended to be bonded. Some adhesive formulations require an accurate metering of different components. Some, sensitive adhesive operations require a monitoring of the application, e.g., by vision systems, to guarantee the correctness of the application. Each of the steps is important and contributes equally to the quality of the final adhesive application. See below the summary of the different process preparation steps:

1. Adhesive mixing at the supplier
2. Packaging of the adhesive at the supplier
3. Adhesive storage at the supplier or the customer
4. Transferring the adhesive from the storage to the application area
5. Substrate preparation
6. Metering and dispensing the adhesive
7. Quality control

Depending for which application, in which industry, and by which end customers adhesives are used, different application techniques and dispensing and metering devices are chosen.

For smaller bonding operations like sealing work at construction sites, repair work at car garages, or to fix tiles to a floor, adhesives are typically manually applied out of smaller containers like cartridges. If adhesives are used in a larger scale, like at an automotive line, for example, for metal bonding reasons or to bond windows to the frame of a car, a robot application is used, which pumps the adhesive out of drums and transfers it to a dozer and a gun for the final application. The adhesive itself can be applied in different ways like as a simple bead, sprayed, extruded, or by air assistance, called swirling. Which technique is used depends on factors like the application, the rheological property of the adhesive, and the application temperature. Therefore, the rheological properties of the adhesive formulation need to be tailored to the application. Lower viscous adhesives can be applied by spraying or extrusion beside the simple bead application. Higher viscous adhesives are often limited to bead application, or the application temperature needs to be significantly increased to be applicable by other methods.

This chapter will discuss in further detail each item of the process chain: the storage of adhesives, the transfer to the application area, the different metering and dispensing technologies, the used mixing equipments, the substrate preparation, and the quality control. Proposals are made regarding people education and how to create a safe working environment.

---

## 37.1 Introduction

Adhesives are used for many applications in a lot of different industries like in automotive (Symietz and Lutz 2007), marine, packaging, or building and construction (see Part I, Applications).

Typical applications examples are:

- Bonding of car bodies
- Bonding of structural parts in airplanes (National Research Council 1976)
- Applying foils on new cars for protecting during transport
- Lamination of composites like GFC (glass fiber composites)
- Coating of cans, tubes, or pipes
- Chemical-resistant flooring
- Labeling in the food or packaging industry
- Packaging of food or pharmaceuticals

Adhesives are used to bond various different substrates such as metal, glass, wood, or plastic among many others (Houwink 1967). The appropriate adhesive and its chemistry have to be chosen in dependence of the application and the substrate which is bonded. A wide range of different chemistries are used to formulate adhesives. The chemical nature of the adhesive defines its field of application.

Most adhesives which are used in the industry today are using epoxy, polyurethane, acrylic, and silicone or rubber chemistry.

One- or two-part adhesives are dominantly applied, although there are multiple-component adhesive systems in use as well. One-part adhesives are commonly supplied with an inhibited curing system which can be activated, e.g., by heat or by UV radiation. Two-part adhesives are supplied with separate components, one is the resin component and the other the hardener component. The latter contains reactive chemicals, which enable cross-linking and polymer building of the resin part through a chemical reaction of different functional groups.

The hardening of the adhesives happens either through a chemical reaction as described above or through simply physically binding to the surface. The chemical reaction in case of a one-part adhesive depends on the chemical nature of the adhesive (Habenicht 1990). So do polyurethane- or silicone-based adhesives cure in the presence of moisture, whereas cyan-acrylic-based adhesives are inhibited by the presence of oxygen and cure under nonaerobic conditions. Other adhesives like epoxy one-part adhesives cure with heat. Two-part adhesives contain, beside the resin part, a hardener part which consists of reactive molecules or polymers which react together with the resin part. Typical examples are epoxy- or acrylic-based adhesive formulations.

In the following a summary of properties for some representative adhesive systems is given:

- Epoxies adhere very well to a lot of different substrates like steel (Symietz and Lutz 5/2008), aluminum, stone, or wood. They offer a high bonding strength, are resistant to chemicals, and show a good heat resistance. Epoxies are used to fill gaps and larger volumes and are applied in thinner layers. They can be formulated in different viscosities, low or high, and with different filler levels. Epoxies typically cure with heat or can be formulated as two-component products which cure in the presence of a separate hardener component.
- Polyurethanes are polymers which are very flexible and tough and which show a very good performance under peel loading and good adhesion to nonpolar substrates like plastic or rubber, as well as to paints and ceramics. They mostly cure with humidity which can cause curing issues in case of extreme humidity conditions.
- Acrylics can be cured in different ways like with peroxides or with UV light. The curing is much faster than the curing of epoxy or of polyurethane adhesives. Acrylics are used to fill gaps and to bond plastic or metal parts. They offer a good environmental and heat stability and show a good performance under peel and shear loading. It needs to be considered that acrylics can be incompatible with some metals which are used in dispensing equipments. Acrylics can be formulated to pressure-sensitive adhesives which adhere to surfaces simply by applying some pressure during the application.

Adhesives are used in applications where other joining methods cannot be used or because they offer unique performance features like a high strength combined with

high flexibility and superior durability (Lees (1997)). It is therefore very important to prepare the adhesive bonding as accurate as possible to take the best advantage of this bonding technology.

---

## 37.2 Training and Education

Many people may think that bonding by using adhesives just requires applying the adhesive to the bonding area and it will stick. But the use of adhesives for bonding purposes requires a well-defined process including steps like:

- The correct choice of the adhesive
- Correct handling of the adhesive
- Correct mixing and metering
- Preparation of the surface where the adhesive is applied to
- Quality checks to guarantee the constant quality of the bond
- Use of curing sources for one-component adhesives like ovens or radiation sources

All this requires a certain level of know-how, not only of the chemist or engineer but also of the worker who is daily working with the adhesive. In addition, the suppliers of the substrates like the metal or plastic suppliers or the suppliers of the lubricants need a fundamental understanding about the adhesives, the necessary preparation prior to the application, and about the application itself.

Training is required for all the people who are involved in the application of the adhesive. The workers who are daily dealing with the adhesive have to be instructed before using the adhesives and regularly trained as well.

There are institutes at universities who are offering a certified education in adhesive technology and their application.

A good educational background prevents from making mistakes in the preparation of the adhesive and the substrate, helps to choose the right adhesive solution, and helps to apply it correctly. Education is further discussed in ► Chap. 41, “Processing Quality Control.”

---

## 37.3 Health and Safety Aspects

Adhesives are a blend of different chemicals and therefore potentially hazardous to the environment and the user. The information about the risk can be found on the labels and the material safety data sheets. According to their risk and health, ranking precautions have to be taken to create a safe working environment. Health and safety aspects are further developed in ► Chap. 39, “Environment and Safety.”

Figure 1 below shows what typically can be found on labels and in material safety data sheets and what will change in the near future.

New GHS/CLP Regulation (future)	CHIP Regulations actually being used in Europe
Applies to both the supply/use and transportation of chemicals	Applises only to supply and use of chemicals
Aligning supply with transport regulation	Supply labeling and transport labeling are different
GHS - Pictograms wiht a white background and red border 	Orange Hazard Symbols 
Term "Mixture"	Term "Preparation"
Term "hazardous"	Term "dangerous"
H-Phrases / Statements	Risk (R) phrases with the code numbers, e.g. R43
P-Phrases / Statements (5 types)	Safety (S) phrases with the code numbers; e.g. S24, S37

**Fig. 1** Change from old CHIP (Chemicals Hazard Information and Packaging) to new GHS (Globally Harmonized System of Classification and Labeling of Chemicals) regulation

**37.3.1 Preventive Measures While Storing the Adhesive**

Adhesives are filled in different packaging forms and sizes. Used commonly for smaller volumes are cartridges, bottles, or tubes and for bigger volumes pails or drums.

Generally all containers should be stored in a dry and cool place, preferably below 25 °C. Some reactive or solvent-containing adhesives would require cooler storage, preferably temperatures below 10 °C or even below 0 °C. If not, the adhesive viscosity could increase during storage, which could negatively influence its application characteristics, physical properties like adhesion, or even mechanical properties like joint durability. For some adhesive systems, like water-containing products, too low storage temperatures on the other side could lead to crystallization.

The adhesive containers ideally should be stored in dependence of their used chemistry. The same chemistry should be stored together; for example, epoxy adhesives should be stored separately from acrylic adhesives. The adhesive containers should be stored above collecting trays to prevent pollution in case of a leakage or spill. Depending on their hazardous potential, adhesives need to be stored in special places:

- Flammable material should be stored in rooms which are especially fire resistant and explosion protected.
- Adhesives which have a strong odor should be stored in a room with special ventilation.

**37.3.2 Preventive Measures While Working with the Adhesive**

An adequate personal protection should be used if working with adhesives. The safety data sheet has to be consulted to obtain detailed information about the

precautions which have to be taken if working with the specific adhesive. The given shelf lives should be respected or the adhesive supplier consulted if any adhesive is applied beyond the shelf life.

The personal protection should at least consist of:

- Protecting glasses or goggles
- Long-sleeved lab coats
- Gloves

Gloves should be changed regularly and the used ones should be disposed. The material the gloves are made of should prevent the penetration of the adhesive through the glove to the skin. Latex gloves, for example, are not recommended to be used if working with epoxy adhesives. In this case nitrile gloves should be chosen. The lab coat should be regularly and professionally cleaned. The thickness of the coat should be thick enough to prevent the adhesive from migrating through the woven to the skin. Respiration masks might be used for solvent-containing adhesives, adhesives with strong odor, or if special substrate preparations are needed, which require the use of wet chemistry.

Adhesives are chemical blends using different organic polymers. Some examples of special preventive measures, which are recommended to be taken in dependence of the chemistry of the adhesive, are listed below:

- Some adhesives, like epoxy-, rubber- or acrylic resin-based formulations, are skin sensitizing and require the use of special gloves.
- Acrylic-based adhesives and hardener compounds of two-part formulations can have a strong odor and would require working under proper ventilation.
- Solvent-containing adhesives contain flammable solvents and must be kept away from any heating source, would require working under proper ventilation, or for some instances would require the use of respiration masks.

### 37.3.3 Preventive Measures While Processing

Adhesives can be applied automatically by pumping the material out of a pail or drum and transfer it through hoses and possibly a dozer to the nozzle. The adhesive is applied from the nozzle to the substrate. Certain pressures and temperatures are applied to guarantee a good flow of the adhesive from the pail or drum over the dozer to the nozzle.

The following precautions are recommended to be taken during processing of the adhesive:

- Avoid an overheating of the adhesive which could lead to an increase of the viscosity and eventually can block the hoses or the dozer.
- Shield the equipment properly because it is under pressure.

- Switch of the heat and pressure after longer breaks like overnight or over the weekend.
- Use heated follower plates in case the adhesive viscosity is that high that it cannot be applied at ambient temperatures. Do not use heated pail or drum jackets.
- Work on specially sealed floors or use collection trays to be prepared in case of a spill.

On the other hand, larger amounts of adhesives are commonly manually applied like in case of applying chemical-resistant floor protections or for tile as well as carpet bonding. In such cases, special masks should be worn in addition to the other recommended equipments to protect against the odor of the adhesive or against evaporation of a solvent.

After the application of the adhesive, other operations can be additionally applied like spot welding in case of joining doors for cars or grinding of parts after the repair of cars. In such cases, special precautions need to be taken in addition like:

- Installing a proper ventilation if thermal joining methods are applied through the adhesive
- Wearing dust masks during the grinding operation
- Wearing any other protective equipments like long-sleeved lab coats or any eye protection like goggles

---

## 37.4 Mixing of Adhesives

Adhesives consist of different raw materials. Organic monomers and polymers usually are the main part of a formulation and mostly contribute to the adhesives' mechanical and physical performance. In addition to the organic part of a formulation, other raw materials like inorganic mineral fillers or solvents are used. For reactive adhesives, curing agents and accelerators are added to the formulation to cross-link the organic part of the formulation, for example, at ambient or higher temperatures or in the presence of humidity, heat, or UV light.

In single-component adhesives, all the raw materials are added in one component. In two-part adhesives, the formulation is separated into two components. One part, usually called part A, contains the organic resins, and the other part, called part B, contains the hardener and accelerator.

Adhesives are mixed at the supplier and filled in either smaller container sizes like cartridges or in bigger sizes like pails and drums. For some applications the adhesive bulk and other components like the hardener part or solvents are mixed at the end user just before the application.

The correct mixing of the adhesive is a precondition to achieve a good homogeneity of the mixture and to obtain the best mechanical performance of the bond. There are many different kinds of mixers and stirring elements available on the market. Which kind of mixer is adequate depends on chemical nature of the adhesive, the viscosity of the adhesive, and its sensitivity to external factors like

humidity or oxygen. It is proposed to investigate together with the equipment supplier which equipment suits best for the intended application.

Mixers which are used in the laboratory or the ones which are used for manufacturing could be very similar in their design. There is not much principal difference with regard to the different elements a mixer consists of.

A mixer typically consists of a vessel in which the mixing happens. For laboratory purposes it can be a disposable small container like a simple metal can. The vessel can be surrounded by a heated jacket to allow heating or cooling during the mixing operation. A gear drives the stirring elements. There are many different stirring elements on the market. Which one is chosen depends on many different factors like what kind of adhesive is formulated, how high the viscosity is, or how shear sensitive the formulation is. Ideally, the mixer is connected to a vacuum pump and can be flushed with inert media like nitrogen. In addition, the entire equipment can contain a discharge valve, a vapor filter, and a control panel. A window to watch the mixing is recommended and commonly used. For easy access for maintenance and inspection reasons, the mixer usually is equipped with a lifting column. Figure 2 shows a lab planetary mixer like it is used to formulate smaller quantities of higher viscous adhesives.

**Fig. 2** Lab mixer with lift and planetary agitators, used to formulate adhesive samples of about 400 g

Different mixing methods are described in this section. ► Chapter 38, “Equipment for Adhesive Bonding,” also describes the mixing of adhesives but focuses on the equipment itself.

### 37.4.1 Vacuum Mixing

Vacuum mixing is defined as such: mixing in a closed system under an internal pressure which is significantly lower than atmospheric pressure.

Mixing under vacuum has an important influence on the adhesive’s end performance. It helps to reduce the porosity of a cured adhesive and therefore helps to maximize properties like strength and durability (Angos 2007). But, for some formulations like those which are based on cyan-acrylics, the presence of oxygen can be necessary for the stability of the product.

Mixing in many cases happens under vacuum for the following additional reasons:

- Deaeration to obtain a void-free product
- Obtain an oxygen-free product, to prevent a decomposition in the presence of oxygen in case of sensitive formulation ingredients
- To prevent a possible chemical reactions or a microbiological growth
- Prevent contact of the mixture with water, in case of ingredients which can react in the presence of water
- Dewatering or evaporating solvents of heat-sensitive formulations
- To more easily change the physical state from, for example, a paste to a dry powder or from a slurry to a paste
- For dosing of light powders or pastes into the formulation
- Acceleration of mixing through, e.g., better and faster wetting of powders
- Better dispersion of smaller-volume ingredients
- A lower-density material is obtained, and therefore smaller volumes need to be handled

Because of all the listed benefits it offers, vacuum mixing is mostly used for the mixing of adhesives at the adhesive supplier.

### 37.4.2 Continuous and Batch Process

The mixing equipment can be divided into continuous types and batch types. In a laboratory, batch-type equipments are dominantly used. Although in an adhesive production both types are in operation, the batch-type equipment is more commonly used. A lot of adhesives like epoxy-based adhesives are mixed in a batch-type procedure.

Batch systems can be either stationary or transportable, whereas continuous systems are stationary only. The dosing of the raw materials happens sequentially and

contributes significantly to the overall batch time. The raw material can be added either manually or automatically. Automatic dosing is used if the adhesives are produced on a regular base, the same raw materials are used, and the volumes are high.

A continuous system is a fully automatic operation. The raw materials are added once and not sequentially like if using the batch process. The most important unit of this system is the metering unit. It must be carefully calibrated and regularly inspected.

A batch system is the most precise operation, because each ingredient is added separately and is accurately balanced.

### 37.4.3 Vertical and Horizontal Mixing

In theory the mixing of the adhesive can be done vertically, horizontally or centrifugally. The mixing speed can be varied and adjusted to the product properties. The size of the vessel depends on the volume which will be mixed. It can vary from a few hundred grams for laboratory purposes to about 50–500 kg for upscaling purposes or to about 800 l to about 30,000 l for manufacturing.

In vertical mixers the rotor is installed in a 90° angle to the bottom of the vessel, and for horizontal mixers, the rotor is parallel to the ground. The cylindrical vessel form is used for horizontal mixers. In case of vertical mixers, it can have a conical or a cylindrical form.

Vertical mixers are very frequently used for laboratory purposes, because they are somehow easier to operate and require less space. For the manufacturing of bigger volumes, the choice of the mixer type depends on items like how the raw materials like to be charged and the final product likes to be discharged, and it depends on the available floor space. Figure 3a shows a planetary mixer head and butterfly agitators,

**Fig. 3** Head and agitators of a planetary mixer which are used in production (a) and in a laboratory (b) to mix adhesive formulations. Butterfly agitators are used for the manufacturing mixer and finger blade agitators for the laboratory mixer. The production mixer has a volume capacity of about 1 t and the laboratory mixer of about 10 kg

and Fig. 3b shows a pilot mixer. Both are used to mix adhesive formulations of higher viscosities.

#### 37.4.4 Kneader

For very high viscous materials, kneaders are preferably used. They usually contain a kind of sigma blades, which are able to cut materials like solid rubbers apart and can knead them effectively. An extrusion screw is discharging the material out of the vessel.

Figure 4 shows a kneader which is used in a laboratory for mixing of very viscous adhesives like rubber- or polyurethane-based adhesive formulations.

#### 37.4.5 Agitator Design

The design of the agitator should be in line with the required mixing function and the expected result of the mixing. For making simple blends, dispersions, or for making adhesives, a different agitator design will be chosen. Adhesive formulations can differ a lot with regard to their viscosity and flow behavior. Depending on the used type of polymers, their molecular weight, and depending on the used fillers, as well as on the ratio of organic polymer to mineral filler, the viscosity can vary from very low to very high. The flow behavior of low viscous materials is totally different from the flow characteristics of higher viscous products (Alhofen 2005).

Important factors for the decision of which agitator would suit best are:

- The viscosity of the mixture
- The shear rate which needs to be applied
- The nature of the ingredients (e.g., shear sensitive or not)
- The heat stability of the adhesive formulation

**Fig. 4** Laboratory kneader

**Fig. 5** Two anchor agitators with different shapes

For very low viscous formulations, a simple anchor stirrer can be chosen. Figure 5 shows two anchor agitators, which only differ in their shape.

However, most adhesive formulations require, because of their higher viscosity, agitators which offer a higher shear and flow.

The following needs to be considered:

- Higher viscous materials do not flow easily and need a special stirring equipment which possibly rotates and travels through each point of the vessel.
- The agitator should offer a good heat transfer in the mixture, especially for higher viscous materials, to avoid local overheating.
- The agitator gear needs to cope with the high load of a high viscous material.

There exist many different agitator designs which are suitable to mix higher viscosities. Some of them are described in more detail below.

Stationary high-shear agitators are used for materials with medium to high viscosities and for materials which flow well:

- High-speed dispersers are used if medium shear and a higher flow is required.
- Rotor-stator mixers can be used alternatively but offer a higher shear and a lower flow.

Figure 6 shows a photo of a high-speed disperser.

These systems are able to mix even higher viscosities if combined with an anchor blade in addition. Such systems are available as dual- or triple-shaft mixers. The slower-moving anchor removes the material from the vessel wall and the bottom and transports it to the high-shear agitator. Obviously, triple-shaft systems are able to

**Fig. 6** High-speed disperser

412 handle even higher viscosities than dual-shaft systems. Because of the slow-moving  
413 anchor, the system is limited to well-flowing mixtures.

414 In case of planetary agitators, the blades are moving through the material and each  
415 agitator can move on its own axis. Such planetary agitators are suitable for higher  
416 viscous and not easily flowing materials. Double planetary mixers are typically used  
417 for mixing of materials like adhesives, sealants, dental pastes, composites, foams,  
418 plastisols, or metal slurries. A scraping blade is commonly used in addition to  
419 remove the material from the vessel wall during mixing. Planetary agitators are  
420 most efficient at high viscosities because the shear rate in the paste increases  
421 proportionally with the increasing material viscosity.

422 Different blades can be used. Typical agitator designs are finger blades, older  
423 rectangular-shaped blades, and newer HV blades. The latter are able to even mix formu-  
424 lations of highest viscosities, which usually are mixed by using a kneader or an extruder.

425 Figure 7 shows a photo of finger blade agitators used in a planetary laboratory  
426 mixer.

#### 427 **37.4.6 Centrifugal Mixing**

428 Centrifugal mixing is used for high-speed mixing and was originally developed for  
429 dental materials. Disposal cups are used for the mixing of the adhesives. The cup and

**Fig. 7** Finger blade agitators which are used in a planetary laboratory mixer, including a scraper blade

a mixing arm are rotating in opposite directions at high-speed rates of up to 3,000 rounds per minute. Figure 8 shows the mixing chamber and the mixing cup of a speed mixer which is used in the laboratory for the development of adhesives. The biggest advantage over vertical or horizontal mixing is the required mixing time. It varies from a few seconds to a few minutes only. On the other hand, the volume which can be handled is limited which is a clear disadvantage over the other mixing technologies. It varies, depending on the speed mixer model, from a few hundred grams to about 3 kg. Speed mixing is mainly used for lab screening purposes in combination with a design of experiments. Many different cup dimensions are available. Direct mixing in convenient cartridges or syringes is possible.

### 37.5 Adhesive Storage

The manufactured adhesive can be stored in different packaging forms, like for smaller quantities in cartridges, tubes, or bottles and for bigger scales in pails or drums. Adhesive films are systems which consist of an adhesive dry film applied to a paper, a glass fiber, or an aluminum foil and are usually stored in boxes.

**Fig. 8** Mixing chamber of a speed mixer including a mixing cup

A correct storage is very important to conserve the adhesive properties until the material is supplied to the end user and to avoid any loss of performance, change in rheological properties, or to avoid a possible decomposition of the material through an inappropriate storage. Adhesive storage is treated in more detail in ► [Chap. 36, “Storage of Adhesives.”](#)

### 37.5.1 Storage Condition

The applied storage conditions depend on the adhesive formulation, specifically the chemical nature of the resins, and in case of reactive adhesives, it additionally depends on which curing and accelerator system is used.

Generally, the filled adhesive should be stored in a safe environment, not exposed to heat, to humidity, or, for light-sensitive adhesives, not exposed to light. Good ventilation should be given. The specific storage conditions are commonly written on the labels and can be read in the material data sheets.

Two- or multiple-part formulations have a significantly longer shelf life than one-component adhesives with integrated curing agent and accelerator (Lutz and Brändli 3/2010). The shelf life of one-component adhesives strongly depends on the chemical nature of the formulation and on the acceleration system. Multiple-part adhesives have a shelf life of about 6–24 months and single part of about 3–12 months only. The shelf life can be prolonged by a time factor of about 2–4 for one-part adhesives, through storage in a refrigerator below 10 °C or by freezing below 0 °C. Excluded from cooled storage are products which are known to show phenomena during storage, like phase separation, crystallization, or sedimentation of ingredients of the formulation.

Some examples of adhesive formulations which require special storage conditions are given below:

**Fig. 9** Shelf life of two epoxy adhesive formulations. Formulation B is significantly more stable than formulation A

- Reactive one-part adhesives, which can increase in viscosity over time depending on temperature, should be stored under air conditioning or in a cooled warehouse. Examples are accelerated one-part epoxy or rubber-based adhesives.
- Some adhesive formulations may tend to crystallize during storage and would require a storage above a certain temperature.
- Adhesives which cure with humidity like polyurethane or silicone adhesives should be stored in a dry environment.
- UV light-curable epoxy or acrylic adhesives should be stored out of light.
- Because of their strong odor, acrylic adhesives should be stored in a room with good ventilation.

Figure 9 shows the viscosity stability over time at 23 °C storage for two one-part epoxy adhesive formulations. Adhesive B increases only very little in viscosity over time and therefore is significantly more stable than adhesive A. Adhesive A would need to be stored in a cooled area, like in a fridge or an air-conditioned warehouse.

Figure 10 shows the decrease of the lap-shear strength of shear specimens which are bonded with one-part epoxy adhesives and stored under 80% relative humidity at 23 °C before being cured. Adhesive B shows a much better resistance to water absorption than adhesive A. If using adhesive A for bonding, the joint should be cured quickly, at least before about 1 week after the application of the adhesive. Adhesive B could stay uncured for about 6–8 weeks.

**Fig. 10** Decrease of lap-shear strength of humidity-exposed lap-shear specimen

**37.5.2 Packaging Size**

The size of the container should be chosen based on the adhesive consumption. If only small volumes are used, small packaging sizes like cartridges, bottles, or tubes should be chosen. Adhesives have a specific shelf life, and the use of bigger packaging sizes for small-volume applications would inevitably lead to disposing significant amounts of adhesive. If large amounts of adhesives are consumed, the application typically is done out of pails or drums using pumps which transfer the adhesive through hoses from the drum to the nozzle where the adhesive is applied to the bonding area.

**37.5.3 Packaging Material**

Depending on the chemical nature of the adhesive or of the hardener compound in case of two-part systems, the material used for the container, for example, cartridges, can be different. Corrosive materials, for example, the hardener compound of a two-part epoxy system, should not be stored in metal containers. Cartridges or bottles made out of plastic are mostly used. Humidity-sensitive adhesives like polyurethane adhesives should be stored in containers which show a low diffusion rate of water. Aluminum cartridges or especially, e.g., metal-coated plastic containers are preferred in this case over simple plastic ones. Special plastic bags which contain, for example, an aluminum liner are recommended to be used for pails or

drums. The plastic inliner prevents on one hand the contamination of the drum or pail with adhesive, which saves cleaning costs, and on the other hand limits the water diffusion into the material. The adhesives should be shipped in a package which is sealed in a way that no material could leak in case of a damage of the container.

## 37.6 Dispensing of Adhesives

Adhesives can be applied in a lot of different ways to the bonding area. The used methods for dispensing depend on which kind of adhesives is applied, whether one- or two-part adhesives are used, and how much adhesive needs to be applied. In this section, dispensing methods are described.

### 37.6.1 Single-Component Dispensing

For most of the manual operations, the use of smaller packaging sizes like cartridges, bottles, tubes, or even syringes are fully sufficient.

For cartridges, there is a broad range of different sizes, and they are made out of different materials like plastic or aluminum. The adhesive is statically applied through a nozzle by using a handgun. Different sizes and shapes of nozzles exist for simple bead application or for the extrusion of the adhesive. Different handguns are available: manual operated ones as well as pneumatically or electrically operated handguns. Which handgun suits depends on how much pressure can be applied for the application. Applying too high pressures could damage the cartridge which could result in a leakage. The viscosity of the material determines the amount of pressure which needs to be applied. High viscous materials can be applied by using a heated gun, or the cartridge can be stored in a cartridge oven before the application.

For bottles, there are special bottle dispensers in use like simple hand pumps or volumetric dispenser. Adhesive dispenser controllers are used to offer a high accuracy to meet customer requirements for multivalve dosing or coating or spray operations. Figure 11 below shows typical dispensing equipment for one- and two-part adhesive formulations. It contains a cartridge gun, cartridges, and a nozzle.

### 37.6.2 Two-Component Dispensing

Two-component adhesives are commonly filled in dual cartridges. Depending on the mixing ratio, the sizes for each of the two cartridges are different. Typical mixing ratios are 1:1, 2:1, 4:1, or even 10:1. Special handguns have to be used. There is a new system for two-part applications which is a kind of mono-cartridge including two separate chambers. The benefit is that normal handguns can be used. The nozzle used for applying two-part adhesives is a cylindrical tube, which contains the mixing

**Fig. 11** Cartridge gun, plastic nozzle, aluminum cartridge for dispensing of one-component adhesives and mono-cartridge for dosing two-part adhesives

**Fig. 12** Typical cartridge guns and statically mixers for dispensing of two-part adhesives. Bigger (a) and smaller (b) packaging size

elements. The elements are stationary parts that force the materials to combine as they travel through the length of the mixer. The length of the nozzle and amount of mixing elements vary, and the adequate type is typically recommended by the adhesive supplier. Special guns which can dynamically mix the two components in a special mixing chamber are also used, before applying it through the nozzle. Such dynamic mixing is preferably used for high viscous two-part adhesive formulations like some polyurethane adhesives used for car windscreen bonding or for structural bonding in trim shop.

Figure 12 shows two typical handguns, a bigger- and a smaller-size one, which are commonly used for applying two-part adhesives. Figure 13 shows two different cartridge systems, which are used to store two-part adhesives. One is a mono-cartridge with two separate chambers in one cartridge; the other is a double-cartridge

**Fig. 13** Mono-cartridge TAHM™ system as supplied by Nordson with two chambers (a) and double Mixpac cartridge systems as supplied by Sulzer for applying two-part adhesive formulations: 2:1 mixing ratio, 215 ml and 15 ml volume (b)

system with two separate cartridges for components A and B. Figures 14 and 15 show different kind of static mixers as well as different mixing elements. Figure 16 shows a dynamic mixing element used for mixing of two-part formulations.

**Fig. 15** Different mixing elements, as supplied by Sulzer Mixpac and used for static mixing of two-part adhesive products

**Fig. 16** Dynamic mixing element for mixing two-part formulations

### 37.6.3 Hot Melt Dispensing

Hot melt adhesives are very high viscous formulations and can only be applied at high temperatures. Special heated handguns (glue guns) can be used, or the cartridges can be heated in a special cartridge oven to lower the material's viscosity before the application (Satriana 1974). Figure 17 shows a cartridge oven and a heated cartridge gun.

### 37.6.4 Higher-Volume Dispensing

For higher-volume applications or continuous operations like applications at car manufacturers or in the building and construction industry, the adhesive is applied out of pails or drums. Typical pails contain about 25–50 l of material and drums about 200 l. It is recommended to use plastic liners to avoid a pollution of the drum or pail. In this case the drum or pail can be reused and just the plastic bag needs to be disposed. Figure 18 shows a typically used pail with a plastic liner. Some of the inliner may contain an aluminum foil which prevents water penetration through the inliner to the bulk adhesive. Such systems are applied in case of water-sensitive materials like polyurethane-based adhesives.

**Fig. 17** Cartridge oven (a) and heated gun (b)

**Fig. 18** Pail and inliner for adhesive storage

## **37.7 Mixing and Metering of the Adhesives Before the Application**

One-part adhesive formulations do not require a special mixing process prior to the application, but two- or multiple-part adhesives need to be mixed before the application of the adhesive.

Mistakes in mixing definitely have a negative effect on the quality of the bond. For example, if not applying the correct ratio of A to B component, this can give low initial strength values and bad results with regard to the longtime durability of the bond. There are several mixing and dispensing options, and each offers advantages and disadvantages.

### **37.7.1 Low- to Medium-Volume Application**

Most suppliers supply their multiple-component systems in prepacked forms like in cartridges. No metering is necessary in this case.

For adequate automatic mixing, there are mixing devices for application out of dual cartridges like handguns or automatic guns and static or dynamic mixers. Static mixers like described above are by far mostly used.

The following points are crucial for a good mixing of two-component adhesive systems:

- The rheological properties of both components A and B should be adjusted in a way that both components mix well.
- The length of the static mixer and the number of mixing elements should be defined depending on the formulation.
- Before applying the static mixer, both components A and B need to be equally balanced.
- The first few grams of material after mixing should be disposed.
- Regularly change the static mixer and dispose the old one.

Possible application issues are:

- The adhesive can cure at the cartridge nozzle, and this could result in a leak at the cartridge plunger.
- The application itself is limited to low viscosities; high viscous materials are difficult to dispense by using handguns.
- If using automatic guns in combination with a high viscous material, the high pressure during the application can damage the cartridge plunger, and this can result in a leakage of the adhesive.

Figure 19 shows the content of a typical two-part adhesive set which is used for the repair of parts of a car. It shows which different kinds of guns can be used and

**Fig. 19** Typical two-part adhesive set for manual applications

**Fig. 20** Balancing components A and B before applying the static mixer (a). Dispose the first few grams of material (b)

contain, beside the adhesive cartridge, a bottle of activator and cloths to apply it and to wipe it off the substrate.

Figure 20 below shows two important preparation steps before the application of a two-part material. Figure 20a shows the balancing of both components before

**Fig. 21** Application of a two-part epoxy adhesive used for the body repair of cars

**Fig. 22** Adhesive bond line after salt spray testing

617 putting the static mixer on, and Fig. 20b shows the disposal of the first grams of  
618 material before the adhesive is applied to the substrate.

619 Figure 21 shows a typical bonding operation performed in garages for the repair of  
620 car bodies (Lutz 6/2009). The adhesive, in this case, is manually applied by using a  
621 cartridge gun and a static mixer, which are described above. The adhesive used for this  
622 application is a structural two-part epoxy adhesive, applied with a mixing ratio of 2:1.

623 Figure 22 shows an adhesively bonded joint after 480 h of salt spray testing. The  
624 bonded surface shows no trace of corrosion compared to the surrounding area and

**Fig. 23** Spot-weld sealed by using a two-part adhesive

demonstrates the corrosion resistance and sealing potential of the applied adhesive. Figure 23 shows the use of mixed joining technologies, spot welding, and adhesive bonding. In this case, adhesives not only offer strength but also seal the spot-weld against possible galvanic corrosion.

### 37.7.2 Medium- to Large-Volume Application

For medium- to large-adhesive applications, metering and mixing dispense systems are used for applying adhesives like epoxy, polyurethane, polyester, or silicone formulations. Such systems offer an accurate measure, mixing and dispensing for two-part adhesives, and an accurate dispensing for one-part products. There are different models in use like reciprocation or rotary dispensing units.

The following metering principles are used:

- Positive rod displacement
- Piston displacement
- Double-action piston metering
- Piston cup metering
- Dual reciprocating piston metering
- Gear metering

The metering system which is used depends on the kind of adhesive and the application.

## 37.8 Transferring the Product

The transferring of the adhesives out of drums and pails is commonly done by using a follower plate combined with a pulping or gear pump. The product is further transferred through pipes and possibly a dozer to a nozzle which applies the adhesive to the area to bond. Gear pumps can have certain disadvantages like:

- Bringing shear stress into the adhesive, which could negatively influence the rheological properties of the material
- Because high-shear stress brings heat into an adhesive mixture, the viscosity of a reactive adhesive can increase considerably through a starting polymerization, and, as a result, pipes and dozers can be blocked

Depending on the adhesive’s viscosity, the material has to be heated to offer a good material flow. For this purpose the follower plate and each section of the application equipment can be heated. The heat should be switched off in case of longer breaks. Heated drums or pail jackets are not recommended to be used because if the temperature is not carefully controlled, too much heat can be transferred into the material which eventually can lead to a burning of the material as a result of an exothermic reaction.

In simple application equipments, the adhesive flows through a pipe to a gun and is manually applied. More sophisticated equipments use a dozer which controls the applied volume and the pressure and applies the adhesive very accurately through a nozzle. If temperature is required for a good material flow, ideally a temperature gradient, with a gradually increasing temperature from the follower plate over the dozer to the nozzle, is applied. The dozer can vary in volume and in pressure which can be used. The amount of necessary pressure depends on the rheological adhesive properties and on the application. Ideally, first in-first out dozer is used to avoid an adhesive plaque building in the dozer through an increase of the adhesive’s viscosity over time, which eventually can block the dozer after a certain time of operation.

Figure 24 shows a heated application equipment which is commonly used to apply one-part adhesives, like in the automotive industry for car body bonding.

Figure 25 shows the flow of the material from the pumping of the material out of the pail or drum, over the material transfer in the hoses to the dozer and the final

**Fig. 24** Application equipment as supplied by SCA Schucker and which is used to apply one-part adhesives

**Fig. 25** Material flow and applied heat per section

**Fig. 26** Gun system to apply one-part adhesives

transfer to the nozzle. If heating is required, the temperature is gradually increased as shown.

Figure 26 shows a dozer and gun system which is used to apply one-part adhesives. The dozer controls the applied adhesive volume, and the gun finally

**Fig. 27** Hydraulic dosing station

applies the adhesive to the bonding area. Hydraulic, pneumatic, or electronic dosing systems are in use. Hydraulic and electronic dozers are preferred over pneumatic systems because more pressure can be applied and the application can be run faster. Electronic systems have an advantage over hydraulic systems because they do not require space for an aggregate.

Figure 27 shows a hydraulic dosing station. In blue, incoming material into the dozer and in red material which is transferred out of the dozer and to the nozzle.

The application out of the nozzle to the bonding area can happen in different forms. It depends on the applied pressure and the dimension of the nozzle. Since the application part is discussed in more detail in ► [Chap. 38, “Equipment for Adhesive Bonding,”](#) only a few automatic application methods are briefly described hereunder.

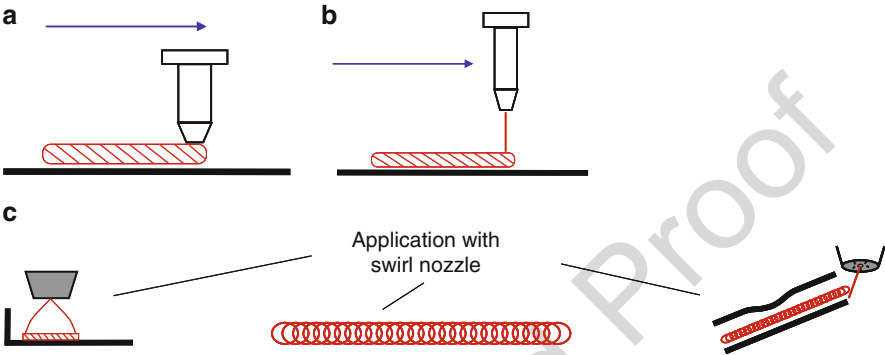

There are some application methods which are frequently used in the industry: bead, swirl, spray, jet-spray application, or extrusion. Which one is used depends on the application and on the rheological properties of the material. Higher viscous materials are not easy to spray but applicable as a bead or by extrusion. Lower viscous materials are applicable faster by using methods like jet spraying or swirling, which are commonly used in the application of structural adhesives to bond car bodies.

Table 1 summarizes the applied conditions for each application technology. The adhesive can be applied much faster, if using the air-assisted swirl or the jet-spray method compared to a simple bead application which saves a significant amount of process time. The swirl technique is limited with regard to the applicable volume, which is less compared to the applied volume of other technologies. Because the application is assisted by air, entrapped air can lead to the occurrence of bubbles at the bond surface after the curing of the adhesive.

The nozzle diameters and the applied dozer pressures differ a lot in dependence of the used technology. In particular the smaller nozzle diameters which are used for the

**Table 1** Application parameters for different application techniques

Application type	Nozzle diameter	Pressure	Distance to surface	Application speed
Bead	1–3 mm	10–20 bar	About the diameter of the bead: 2–5 mm	150–300 mm/s
Swirl	0.8–1.2 mm	10–120 bar	20–40 mm	200–600 mm/s
Jet spray	0.5–0.8 mm	100–200 bar	5–20 mm	300–600 mm/s

**Fig. 28** Different application technologies: bead application (a), jet-spray application (b), and swirl application (c)

jet-spray application can cause issues with blocked nozzles, if the fillers which are used for the adhesive formulation are not below a certain particle diameter or if they tend to form agglomerates.

Figure 28 shows the principles of the discussed application technologies.

### 37.9 Substrate Preparation

The preparation of the substrate before the application of the adhesive is very important for the quality of the bond and the performance of the bond during operation (Metals Handbook 1982). A good preparation is a guaranty for a maximum bonding strength, best fatigue durability, and best resistance to environmental factors like the exposure of the bond to humidity, heat, UV light, and salt.

The required surface preparation depends on which substrate will be bonded and which kind of adhesive is applied. Some metals, for example, have oxide layers like aluminum, magnesium, or titanium. In this case, the surface preparation focuses on stabilizing the oxide layer.

Depending on the chemistry of the adhesive, the adhesion to different substrates and the tolerance for surface contamination are different. Epoxy- and acrylic-based adhesives bond well to a variety of different surfaces like metals, aluminum, or composites and tolerate some degree of surface contamination like oil if cured by

heat. They are not adhering well to low-energy surfaces like plastic. Two-part epoxy formulations need a cleaning of the surface to remove any contamination. Special two-part acrylic-epoxy hybrid adhesives are able to bond even on oily polar surfaces like metals. Newly developed purely epoxy-based two-component adhesives have been developed which are capable to absorb surface oils. But there is a time limitation after which the adhesive needs to be subjected to heat to facilitate the oil absorption into the adhesive. The application of heat at temperatures typically above 100 °C and below 140 °C should be done after several hours. Some uniquely catalyzed acrylic two-part formulations bond well to nonpolar surfaces like plastic.

Polyurethane-based adhesives adhere well to coated or painted surfaces like on ceramic-coated glass, electro-coated or painted metal, or to plasma-treated low-energy surfaces. Usually a primer or an activator is applied to the surface before adding the adhesive.

This section gives a brief overview of the substrate preparation and is treated in more detail in ► [Chap. 8, “Surface Treatments of Selected Materials.”](#)

### 37.9.1 Preparation of Steel Substrates

Beside stainless steel, most adhesives, especially epoxy- and acrylic-based ones, bond well to steel surfaces. The steel substrates can differ in strength, surface topography, and their composition.

The preparation for bonding is different whether one-part heat-curing adhesives or two-part formulations are used. In the case of one-part epoxy adhesives, the surface just needs to be cleaned from any contamination like dust. Oil is tolerated in an amount lower than about 3 g/m<sup>2</sup>. Higher viscous oils like dry lubes are tolerated up to about 2 g/m<sup>2</sup>. In case of applying two-part formulations, with the exception of acrylic-epoxy hybrids, oil and any other contaminations need to be carefully removed.

For a better long-term durability of the bond, for example, a better resistance against galvanic corrosion, a coating of the steel surface is recommended. This coating is usually a zinc coating (galvanized steel), either hot-dipped zinc or electro-galvanized zinc coating, and is used in many industries like in the automotive industry. The quality of the zinc layer has to be high to offer a good durability and corrosion resistance of the adhesive bond. The achievable mechanical strength values are high and often even higher than the strength values for the non-coated steel. An insufficient quality of the zinc layer often results in a delaminating of the zinc layer under loading of the bond. The adhesion, especially of the e-coat, the filler, and the paint, can be further optimized by applying crystals, like zinc and iron phosphates, to the metal surface. This treatment, called phosphating, is often used, for example, in the automotive industry.

In addition to the above-described metal coating, organic methods can be used like epoxy coating, e-coating, or the application of paint. In this case, the achievable bond strength values strongly relate to the quality of the coating and are generally

lower than the strength values for the non-coated steel. Not all adhesives adhere well to painted surfaces, and their adhesion has to be tested in advance (Dettner 1991).

### 37.9.2 Preparation of Aluminum Substrates

Aluminum substrates are available in different alloys and surface topographies as sheet panels or casting parts. To prevent the aluminum oxide layer from undefined growth, a special surface treatment of the aluminum is necessary.

The cleaning of the surface can be done thermally, chemically, or electrochemically. It is necessary for the following reasons:

- Remove oil and surface contamination.
- Remove aluminum fines.
- Remove surface enrichments of trace elements.
- Remove the not perfect natural oxide layer.

Thermal cleaning is done by coil annealing in a furnace. The chemical cleaning can be done by immersion of the coil into an acidic or alkaline solution. Alternatively, the solution can be sprayed on the coil. The electrochemical cleaning is done in sulfuric or phosphoric solutions.

In addition to the cleaning of the surface, a chemical conversion treatment or an anodizing process can be applied which offers more homogenous surface properties. The oxide layer is stabilized, and the adhesion of the adhesive, the primer, or the paint is improved. Anodizing is commonly used to prepare aluminum for bonding in the aerospace industry.

The chemical conversion of the aluminum surface happens in the presence of titanium and fluoride ions in a sulfuric solution. Some treatments use zirconium ions together with titanium ions. The sulfuric acid and the fluoride ions are pickling the surface, and the metal salts are responsible for the passivation of the surface. The titanium and zirconium ions react with the aluminum oxide on the surface and form a mixed oxide layer. Like the cleaning process, it can be applied by an immersion or by a spray process. Figure 29 shows the simplified chemical formula for the mixed oxide layer.

Figure 30 shows a microscope picture of a cut image of an aluminum sample which has been prepared using titanium and zirconium surface treatment.

**Fig. 29** Simplified chemical formula of the mixed oxide layer

**Fig. 30** Cut image of an aluminum sample passivated by using titanium and zirconium surface treatment

### 37.9.3 Preparation of Magnesium Substrates

Chromate conversion coatings are effective treatments for magnesium and are applied before the adhesive bonding or the paint, but the chemistry used is harmful and restricted by regulations. The alternatives to the chromate treatment and the treatment process for magnesium are discussed below in further detail (Skar and Albright (2002)).

Generally the pretreatment of magnesium includes the following steps:

1. Treatment of the magnesium cast: e.g., machining, deburring, or grinding.
2. Rinse with water (omitted in case of a no-rinse process).
3. Cleaning with alkaline solution.
4. Rinse with water.
5. Optional: activation by acidic pickling.
6. Applying the conversion coating.
7. Rinse with water (omitted in case of a no-rinse process).
8. Rinse with deionized water.
9. Drying at 90–105 °C.
10. Applying the adhesive or the paint.

After the machining and the deburring, the die cast part is cleaned by using an alkaline solution. In some cases there can be an etching or pickling step applied before the conversion treatment. The conversion coating can be applied like for aluminum by immersion into a bath or by spraying.

The cleaning of magnesium casts happens in an alkaline solution. In the case of magnesium, there is an optimum pH range of about 10–11 in which the etching rate shows the highest value. Below or above that range, the etching is less effective because of a lower etching rate. For aluminum, the etching rate increases with an increasing pH.

The acidic pickling can be done by using acidic solutions of different acids like sulfuric acid, phosphoric acid, hydrofluoric acid, nitric acid, or chromic acid. The etching depth can vary from a few micrometers only to about 50 μm. The etching rate depends on which acid is used; it is high for sulfuric acid and low for nitric acid.

In the case of chromate treatment, the magnesium oxide on the surface reacts together with chromate ions to form a chemical complex and establishes a defined surface film of magnesium and chromium chromate.

As alternative to a chromate treatment (Gehmecker 1994), other chemical coatings can be chosen like:

- Similar to aluminum treatment: titanium and zirconium fluorides
- Phosphate or phosphate-permanganate solutions
- Solutions containing vanadate, manganate, and molybdate

The chromate treatment alternatives offer a similar good adhesion of the adhesive if, in addition, a cleaning and pickling process is used. If pickling is not done, the chromate treatment offers the best adhesion performance. A proposed combination is using a cleaner with a pH of about 9–11 and an acidic pickling. The alternative treatments are missing the self-healing and inhibiting effect of the chromate layer, which offers an additional corrosion protection. An exception is the mixed metal treatment. The performance of the different treatments was tested by performing accelerated corrosion tests. The loss in bonding strength was by far lower than the loss of strength of not treated lap-shear specimen. Table 2 lists some commercially available conversion treatments for magnesium.

Beside the chemical treatment, anodizing is an effective treatment method too. The magnesium part is the anode in an electrochemical cell and dissolves into magnesium ions. Together with electrolyte, a defined oxide and hydroxide layer is

**Table 2** Commercially available chromate-free conversion treatments

Supplier	Treatment	Type
AHC Oberflächentechnik GmbH	MagPass™	Vanadate, molybdate, and manganate solution
Chemetall GmbH	Gardobond (TM)X4707	Titanium-zirconium hexafluorides
	Gardobond (TM)X4740	Zirconium hexafluorides
Henkel	Alodine(TM) 5200	Titanium and/or zirconium oxyfluoro compounds with polymer additions
	Alodine(TM) 4850	Same as above
	Alodine(TM) 400	Same as above
	Alodine(TM) 160	Zirconium fluorides and magnesium oxides

845 formed on the magnesium surface. If phosphates, fluorides, silicates, or chromates  
846 are present in the electrolyte, they will be incorporated into the surface layer.

#### 847 **37.9.4 Preparation of Low-Energy Substrates**

848 Plastics can be either thermoset or thermoplastic materials. Examples for thermoset  
849 materials are polymerized epoxy, polyester, or phenolic resins, which do not melt  
850 after being cross-linked. Thermoplastics are materials like polyolefins, for example,  
851 polyethylene or polypropylene, polycarbonates, polyamides (e.g., nylon), or acrylo-  
852 nitrile butadiene styrene (ABS). Thermoplastic materials are increasingly used in  
853 industries like in automotive for reasons like weight saving. Thermoplastic materials  
854 like polyethylene or polypropylene exhibit low surface energies and are by far less  
855 polar than other substrates like steel or aluminum. Polar functions like oxides or  
856 hydroxides are missing at the surface. For good adhesion of low-energy surfaces, a  
857 good surface preparation is necessary to offer a good initial and also durable  
858 adhesion (Korane 2000).

859 For the following reasons, a surface preparation is strongly recommended:

- 860 • Removal of possible contaminations like release agents or oils
- 861 • Increase the surface energy of the substrates, by adding more polarity to the  
862 surface
- 863 • Adding texturing to the surface, to increase the available bonding surface

864 The preparation of plastic parts can be done by different methods (Bienak 2009).  
865 Those methods are summarized below in more detail.

866 Cleaning of the surface can be done by using solvents or special pastes which  
867 remove possible contaminations like oils or release agents.

868 The surface can be abraded to remove contaminations but also to offer a  
869 textured surface, which increases the bonding area. Different abrasion methods  
870 can be used.

871 A flame treatment oxidizes the surface and creates polar oxide groups on the  
872 surface. The surface energy is increased and the adhesion improved. Figure 31  
873 shows the plasma treatment of a polypropylene surface. Plasma is generally gener-  
874 ated by adding energy into a gas, so that it becomes ionized. It can be used for the  
875 cleaning of the surface but also can create polar groups on plastic substrates similar  
876 to flame treatment. Low-pressure or atmospheric pressure plasma is generated by  
877 applying a high voltage. The plasma contains free electrons, which are accelerated  
878 and create ions from the gas. In contact with any kind of surface, the energy of the  
879 plasma is transferred and causes reactions on the surface in a way that radicals are  
880 formed on the substrate surface. Those radicals can react with oxygen or different  
881 gases, like nitrogen or argon, and form functional groups on the surface. Polar  
882 functional groups like carbonyl, carboxyl, or hydroxyl are formed. The surface can  
883 be additionally activated through the cleavage of carbon bonds by UV radiation.

**Fig. 31** Atmospheric plasma treatment of a polypropylene surface (Source Plasmatreat GmbH, Germany)

Corona treatment uses a high-frequency discharge at about 15–25 kHz. The energy transfer to the substrate is high in this particular case due to oscillating electrons between the electrodes.

## 37.10 Quality Control

The quality of the bond needs to be audited in order to guarantee its performance. This is very important because adhesives are applied today in critical areas where a long lifetime of the bond is required. The application itself can be controlled by accurate metering and dispensing and by using dosing systems. The right equipment makes certain that the correct amount and mixing ratio are used and that the adhesive is applied exactly there, where it should be applied. In case of any incorrect dosing, the system will stop the application and will give a warning. The application can be controlled further by using vision systems, which are monitoring the application and control the positioning of the adhesive and any inconsistency within the adhesive bead. Such systems are, for example, in use in the automotive industry to control sensitive adhesive applications in the body shop.

Figure 32 shows a vision system which is installed directly at the application nozzle and controls the bead structure as well as the positioning of the bead on the metal sheet. Any failure, like bead disruptions, will be corrected in a second application step. Similar systems are used, for example, in the packaging industry to control the application of the glue to corrugated paper.

Another, but deconstructive, method is the control of the bond by dismantling the part and by visible inspection of the bond. This part's audit can be done regularly like once a day, a week, or a month depending on the importance of the application. Car bodies or parts of a body, which are using adhesive bonding in addition to older methods like spot welding, are regularly put apart for inspection purposes.

**Fig. 32** Vision systems as supplied by QUISS GmbH to the automotive industry

Quality control is discussed in more detail in ► [Chap. 41, “Processing Quality Control.”](#)

### 37.11 Conclusion

Adhesives are widely used in many industries for various different applications like in the automotive industry for bonding entire car bodies, or in the packaging industry for attaching labels, or for various applications in households. Many more examples could be listed. The adhesive bonding technology offers a lot of advantages over other more conventional joining methods.

Because one finds so many examples where the performance of the final product relies much on the performance of the adhesive bond, like in glued car bodies, the process of preparation before the application of the adhesives contributes a lot to the final quality of the bond.

Failure in mixing or in metering, as well as in dispensing, can result in a disastrous performance of the adhesive bond during usage. Each step of the described process chain needs a careful preparation and execution. The people who are working either in the developing or in the manufacturing stage of the adhesive bonding process or are applying the adhesives should be trained how to correctly use the material and how to prepare the substrates to achieve the best initial and long-term bonding performance. The precautions which should be taken to work safely should be well understood.

**Abstract**

This chapter describes the equipment required for manual adhesive bonding processes. For some readers, the comments about equipment may seem trivial,

M. Peschka (✉)  
Fraunhofer Institute, Bremen, Germany  
e-mail: [manfred.peschka@purenum.de](mailto:manfred.peschka@purenum.de)

but they are important as nonobservance of these points can in practice lead to flawed bonded joints.

The individual components which make up mixing and dosing systems have been described and their special features outlined in an attempt to quantify the hitherto qualitative descriptions that have prevailed in the literature.

Thereafter, some basics of automation and robotics are outlined with a special excursion on the topic parameters affecting accuracy. Terminal opportunities of accelerated curing are explained using the examples of UV radiation and inductive heating.

---

## 38.1 Introduction

The equipment required for manual adhesive bonding processes will first of all be described. For some readers the comments about equipment may seem trivial, but they are important. This is because nonobservance of these points can in practice lead to flawed bonded joints.

The individual components which make up mixing and dosing systems will then be described and their special features outlined. This is an attempt to quantify the hitherto qualitative descriptions that have prevailed in the literature.

Thereafter some basics of automation and robotics are outlined with a special excursion on the topic parameters affecting accuracy.

Finally the opportunities of accelerated curing are explained using the examples of UV radiation and inductive heating.

---

## 38.2 Manual Processing

The properties of a bonded joint are created during a production process. Chemical reactions convert the starting materials (monomers, prepolymers) into a cured adhesive film. The adhesion to the substrates and the cohesion can, however, easily be inadvertently influenced. This is the reason why a bonding process must be strictly carried out in accordance with prespecified conditions. In practice, the individual workers are a significant variable, and this is a further reason why industrial bonding processes are being increasingly automated. The manual processing of adhesive systems therefore puts very high requirements on the persons undertaking the work and on their understanding of adhesive bonding processes.

Not least for this reason, a group of experts under leadership of Fraunhofer IFAM developed a series of training courses for training personnel in all aspects of adhesive bonding. These courses have been accredited Europewide and successfully running for more than 10 years. Three course levels are offered, reflecting the differing responsibilities of the relevant personnel:

- European Adhesive Bonder (course duration: 1 week)
- European Adhesive Specialist (course duration: 3 × 1 week)
- European Adhesive Engineer (course duration: 8 × 1 week)

The courses conclude with an examination before an independent examination committee. Successful completion of a course ensures the participants are able to effectively apply adhesive bonding technology in their work area. All persons who are involved in adhesive bonding technology are highly recommended to take the relevant training courses.

In order to be able to keep the workplace clean, it is sensible to work on a base mat made of strong paper or foil. This can be disposed of after completing the work, meaning that a clean workplace is once again available for the next bonding task.

Before starting the actual bonding work, all the required auxiliary processing materials including cleaning agents should be gathered together. In order to weigh out the components of a two-component adhesive, a suitable balance must be used. The resolution of the balance must be an order of magnitude higher than the required accuracy of the weighing. It must be ensured that the balance is horizontally positioned.

Beakers that are used for mixing components must have smooth edges and be resistant to the adhesives and cleaning agents. Experience has shown that Polypropylene beakers are ideal. Spatulas made of high-grade steel are particularly good for mixing. When mixing, ensure that material on the edge and base of the beaker is constantly included in the mixing process. A mixture is homogenous when it has a uniform color and there are no streaks.

Cartridge guns are suitable for applying one-component adhesives. These guns can be mechanically or pneumatically operated. Similar cartridge guns are available for processing 2-C adhesives which are packaged in special twin cartridges. In combination with static mixers, this means that possible faults due to an incorrect mixing ratio and inhomogeneous mixing are avoided.

The following equipment is required to monitor the ambient conditions and time:

Thermometer  
Hygrometer  
Laboratory clock

### 38.3 General Design of a Metering and Mixing Machine

The machine-processing of adhesives involves a number of different tasks:

- Maintaining a stock of adhesive (or the components).
- Removal of the adhesive (or components) from a storage container.
- Transporting the adhesive (or the components).

**Fig. 1** 2-C dosing system (schematic representation)

- Dosing the adhesive (or the components).
- Mixing the adhesive – if the adhesive consists of several components.
- Applying the adhesive.

The word “dosing” here has different meanings. Sometimes it refers to the measuring out of quantities of the two components to get the correct mixing ratio, other times it refers to the measuring out of the total quantity of adhesive to be applied. To avoid ambiguity, a proposal is made here: Dosing will be used to refer to the measuring out of the components (2-C) prior to mixing. Applying is used to refer to the application of the correct amount of adhesive to the substrate.

The simplest conceivable machine dosing system consists of a storage container under a defined pressure. When an opening is released, the adhesive flows, and the flow rate depends on the viscosity of the adhesive and the geometry of the opening (diameter and length). This type of application system is often used for micro-production, whereby defined pressure impulses are passed to a cartridge using a pressure/time controlled unit.

Additional components such as pumps and valves are necessary when applying larger volumes of adhesive. The following figure shows the schematic representation of a dosing and mixing system (Fig. 1).

### 38.4 Components Required for the Machine-Processing of Adhesives

This section attempts to specify the features of the various machine components. In some cases, however, the indicated ranges are exceeded.

**Fig. 2** Fundamental structure of a RAM

#### 38.4.1 Drum Presses (RAM)

The adhesive is compressed using a drum follower plate. Via a telescope frame, pressure can be exerted on the surface of the adhesive by the follower plate, so that the adhesive flows into the center to the pump.

The plate is pressed against the surface of the adhesive. In the car manufacturing industry, and indeed anywhere where uninterrupted production must be guaranteed, the feed containers are present in duplicate. When a storage container becomes empty, the second container is automatically brought into operation. Whilst the production continues, the empty container can be changed (Fig. 2).

#### 38.4.2 Pressure Containers

These can also act as intermediate containers to allow uninterrupted operation of the plant. If equipped with a riser pressure, containers cover the original barrel ensuring a contamination-free operation. They are not suitable for all viscosities.

#### 38.4.3 Pumps

Pumps are required for transporting the adhesives or their components over large distances (= feed pumps) and for exact volumetric dosing (= dosing pumps). In this section, the key features of different types of pumps will be outlined.

- There must always be pressure on the inlet side(!), *not* self-priming
- Virtually pulsation-free adhesive metering
- Permanent metering
- Use of filler-containing adhesives possible (Mohs' hardness < 5!)
- Operating pressure up to max. 100 bar
- Metering output proportional to the drive speed
- Heatable systems available
- Viscosities: low( $\approx 10_1$  mPas) to high ( $\approx 10^5$  mPas)
- Slip increases with duration of use, not detectable from outside

**Fig. 3** Gear pump – design, function, and characteristics

### 143 Gear Pumps

144 This type of pump is also used in many other technical areas. It transports a fluid by  
 145 creating defined partial volumes between the sled wall and one tooth respectively of  
 146 the two gear wheels. The rotation of the gears carries these partial volumes from the  
 147 intake side to the discharge side. Gear pumps are used as both feed pumps and  
 148 dosing pumps. They are usually driven by an electric motor. As the speed of an  
 149 electric drive can be very easily controlled, very precise dosing is possible using gear  
 150 pumps. The features are summarized in Fig. 3.

### 151 Double Acting Piston Pumps

152 These pumps are often used for processing highly viscous adhesives. The design of a  
 153 twin piston pump is schematically shown in Fig. 4. The special feature of a twin  
 154 piston pump is that it transports materials in both movement directions. This is  
 155 achieved due to the fact that the two chambers, which are separated by the piston, are  
 156 kept in phase with each other by a nonreturn valve, and the cross-section of the lower  
 157 chamber is twice as large as the cross-section of the upper chamber. When the pump  
 158 is at the bottom dead center, both nonreturn valves close (= piston valve and foot  
 159 valve). If the piston now moves upwards, the foot valve opens and the lower  
 160 chamber is filled. Simultaneously, the adhesive in the upper chamber is transported  
 161 via the outlet into the connected pipe system. After reaching the top dead center and  
 162 reversal of movement of the piston, the piston valve opens and the foot valve closes.

- Self-priming
- Slight pressure lost on movement reversal (ca. 5–10%)
- Permanent metering
- Abrasive filler-containing adhesives can be processed (Mohs' hardness >5)
- Operating pressure up to 400 bar
- Metering proportional to the speed of the piston
- Heatable systems available
- Viscosity range: ca.  $10^1$ – $10^6$  mPas
- Wear cannot be detected from outside in every case

**Fig. 4** Double acting piston pump – design, function, and characteristics

The upwards movement of the piston forces the volume of adhesive from the lower chamber into the upper chamber. As the cross-section of the upper chamber is only half that of the lower chamber, not only the upper chamber is filled but the excess adhesive is transported via the outlet into the pipe system. At the moment of reversal of movement at the dead centers of the piston pump, there are short periods of lower pressure at the outlet, which is due to the switching time of the nonreturn valves.

These pumps are used as both feed pumps and dosing pumps. The drive system in most cases is pneumatic. Hydraulic drive systems are used when there are very demanding requirements. When used as a dosing pump, it must be remembered that the fleeting low pressure at the points of reversal is accompanied by a decrease in the applied quantity. The accuracy of gear pumps cannot be achieved.

### Single Acting Piston Pumps

These pumps are used as very accurate dosing pumps for high viscosity and/or abrasive adhesives (adhesives with abrasive fillers). The design and operation are explained in Fig. 5. When the inlet valve opens, the pump is filled due to the pressure to which the material is exposed. On reaching the top dead center, the inlet valve closes and the piston is moved until the desired dosing pressure is reached. The opening of the outlet valve starts the application process, which must be completed before the bottom dead center is reached. Before starting the next application process, the pump has to be filled again. The drive is pneumatic when the accuracy

- Self-priming
- Pulsation-free metering
- Limited metering volume
- Abrasive filler-containing adhesives can be processed (Mohs' hardness >5)
- Operating pressure up to 400 bar
- Metering proportional to the speed of the plunger
- Heatable systems available
- Viscosity range: ca.  $10^1$ – $10^6$  mPas
- Wear can be detected from outside

**Fig. 5** Single acting piston pump – design, function, and characteristics

requirements are low. For higher accuracy applications, hydraulic or electric drives are used. Since about 2005, electric drive systems, with a three-phase servo motor and a recirculating ball screw, have rapidly driven hydraulic drives out of the marketplace. Their advantages are their cleanliness (no droplets of hydraulic oil!) and favorable cost. Electric drives are available as standard modules. Single action piston pumps are the standard for chassis production (body in white).

### Eccentric Screw Pumps

These pumps are widely used for dispensing a wide variety of chemical and food media. They have been used for applying adhesives since the start of the third century AD. The design and operation are explained in Fig. 6. The advantage of these pumps is that they can be operated without valves. Defined partial volumes form between the rotor and stator, and these are transported along the axis of the rotor by rotation. At the end of the adhesive application, a short reversal of the rotor promotes breaking of the adhesive thread. These pumps are driven by electric motors. When operating these pumps, special attention must be paid to a number of points:

- If possible, the first filling of the pump should be undertaken manually. Dry running of the rotor destroys the stator.
- When cleaning the pump, ensure that the solvent being used for the cleaning is compatible with the material from which the stator is made. Depending on the application, the manufacturers provide stators made of different elastomers.

The simple mechanical design and the relatively small pressure loss when pumping highly viscous adhesives mean that these pumps are particularly attractive for highly integrated production lines.

- Self priming
- Pulsation-free metering
- Permanent metering
- Abrasive filler-containing adhesives can be processed (Mohs' hardness >5)
- Operating pressure up to 100 bar
- Metering proportional to the drive speed
- Viscosity range: ca.  $10^1$ – $10^6$  mPas
- Wear can not be detected from outside

**Fig. 6** Eccentric screw pump – design, function, and characteristics

## Other Types of Pumps

In addition to the pump types which have been mentioned, other pumps are also used for transporting and dosing adhesives for special areas of application. Only brief mention of these pumps is therefore appropriate here.

Diaphragm pumps are mainly used as feed pumps for low-viscosity and medium-viscosity adhesives. In these pumps, the pump chamber is defined by a diaphragm. The fluid is transported via two nonreturn valves, which act as input and output valves, and the oscillating motion of the diaphragm.

Peristaltic pumps are usually used for process engineering applications. These pumps are occasionally used in cases where small amounts of low-viscosity adhesives have to be applied. The flexible tube is pinched by cams or rollers and the adhesive therein becomes trapped ("occluded"). Due to the rotation of the cams or rollers, the adhesive is transported from the inlet to the outlet of the pump. The benefit of peristaltic pumps is that the actual pump mechanism does not come into contact with the medium being pumped.

### 38.4.4 Valves

Valves are used to control the flow of an adhesive in a pipe system. They are present as inlet and outlet valves on pumps. Application valves are often the last component of the adhesive delivery section.

#### Needle valves

This type of valve is by far the most common type of valve in use. A circular valve seat is closed by a suitable valve needle (Fig. 7). By movement of the valve needle in

**Fig. 7** Needle valve – design, function, and characteristics

the direction of the longitudinal axis, the cross-section of the valve seat is opened and the adhesive is able to flow. The drive for the opening and closing movement can be pneumatic, pneumatic/spring force, hydraulic, or electromagnetic. Depending on the nature of the adhesive being processed (viscosity, fillers) and the boundary conditions for the process (pressure, temperature), there is a wide choice of cross-sectional area and materials (elastomers or hard metal) for the valve seat.

### Snuff-Back Valve

The kinematics of the opening and closing motion of a snuff-back valve is precisely the reverse of that of a needle seat valve (Fig. 8). To open the valve the piston is moved forward and this opens the valve cross-section. To close the valve, the piston is retracted until the free cross-section of the valve seat is closed. This generates a slight vacuum in the outlet needle, allowing effective thread break of the adhesive at the end of the application. The sealing of the valve on the outer surface of a cylinder is more technically demanding than sealing a needle seat. The pressure region in which absolute sealing can be guaranteed is therefore limited. In industrial practice this type of valve is only used in a few very special applications.

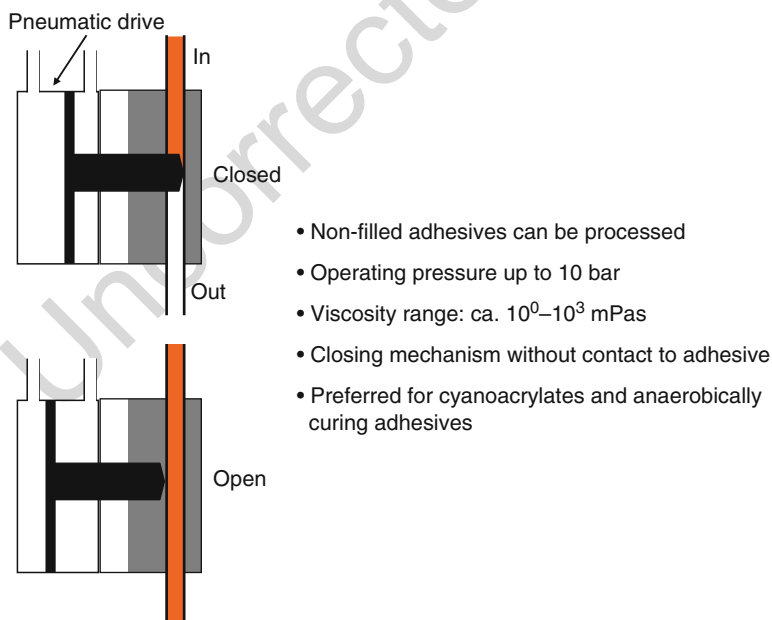

### Pinch Valve

Pinch valves are used for low-viscosity adhesives which are processed in the pressure range up to 10 bar (Fig. 9). The tube cross-section is pinched in such a way by a pneumatically driven lever that the flow of adhesive is stopped. The

**Fig. 8** Snuff-back valve – design, function, and characteristics

**Fig. 9** Pinch valve – design, function, and characteristics

248 advantage is that the actual valve mechanism does not come into contact with the  
 249 adhesive. This type of valve is preferred for processing anaerobically curing adhe-  
 250 sives and cyanoacrylates.

### 251 38.4.5 Mixing Devices

#### 252 Static Mixing Devices

253 A static mixer consists of a smooth-walled tube which contains an arrangement  
 254 of elements for customized routing of the flow (Fig. 10). The name indicates that  
 255 the individual elements of the mixer do not move but are static in the mixing  
 256 tube. The energy required for the mixing is extracted from the flow energy. The  
 257 most familiar type of static mixer is the Kenics mixer which was developed back  
 258 in the 1970s. Right-handed and left-handed mixing elements split the flow of  
 259 adhesive and ensure a doubling of the number of layers at each mixing element.  
 260 The number of layers is given by  $2^n$ , where  $n$  is the number of mixing elements.  
 261 At the end of the mixing tube, layers can no longer be detected, namely, the  
 262 mixture is homogenous. There are a large number of different designs (number  
 263 of mixing elements and diameter of the mixing tube) for different mixing tasks.  
 264 When commissioning a new dosing and mixing plant, an important task is to  
 265 determine which mixer gives satisfactory results. The smallest possible mixer  
 266 which gives a homogenous mixture is chosen here, in order to minimize the

- Fixed mixing elements in the tube => “static” mixer
- Mixing energy is removed from the flow
- Alternating clockwise and anticlockwise mixing elements split the flow of adhesive into layers until it is homogenous
- Number of layers:  $2^n$  ( $n$  –number of mixing elements)
- For poorly miscible adhesive components, the process of introducing the two components into the mixer has increased importance
- Favorable-cost mixer, maintenance-free
- Cannot be adjusted
- Many variants and sizes for adapting to the mixing task
- Mixing ratio range: ca 100:100 ... 100:3
- Viscosity differences of the components up to ca. 10

Figure courtesy of Nordson EFD

**Fig. 10** Static mixing device – design, function, and characteristics

volume of waste. Static mixers are normally not rinsed and are discarded at the end of a production run.

It is claimed in the literature that static mixers can only be used for mixing ratios of the order of 1:1 and for components having similar viscosities. In practice, this has long been disproved. Adhesives with mixing ratios of 10:1 and with a similarly large difference in the viscosities of the components have been successfully mixed, demonstrating the effectiveness of static mixers.

### Dynamic Mixing Devices

A dynamic mixer automates the process of manual mixing in a beaker (Fig. 11). The adhesive components are introduced into the mixing chamber in the correct mixing ratio. An externally driven mixing element mixes the two components until they are homogenous at the outlet nozzle. The name indicates that a moving (rotating) mixing element is used for the mixing process. The energy required for mixing is supplied from outside. Depending on the operating conditions, this leads to a temperature increase in the adhesive and a concomitant decrease in the pot life. There is a vast array of different sizes and designs available for different applications. When starting up the system, the speed of the mixing element is increased until the components are homogeneously mixed. A further increase in the speed does not improve the homogeneity of the mixture. Moreover, the increased energy input unnecessarily shortens the pot life. A dynamic mixer must also be rinsed at intervals during the ongoing production, in order to prevent closing of the outlet opening. This produces

**Fig. 11** Dynamic mixing device – design, function, and characteristics

hazardous waste which must be disposed of accordingly. The limits on the mixing ratio which can be processed and the viscosity differences between the adhesive components are broader than for static mixers.

---

## **38.5 Computational Fluid Dynamics (CFD) as a Tool for the Further Development of Metering Components**

Starting in the 1960s, industrial adhesive bonding technology began to switch over from purely manual processing to machine processing. The current state of technology today has largely developed in an empirical way. Dosing technology and the adhesives themselves have largely developed during the past 50 years. On reflection it is clear that:

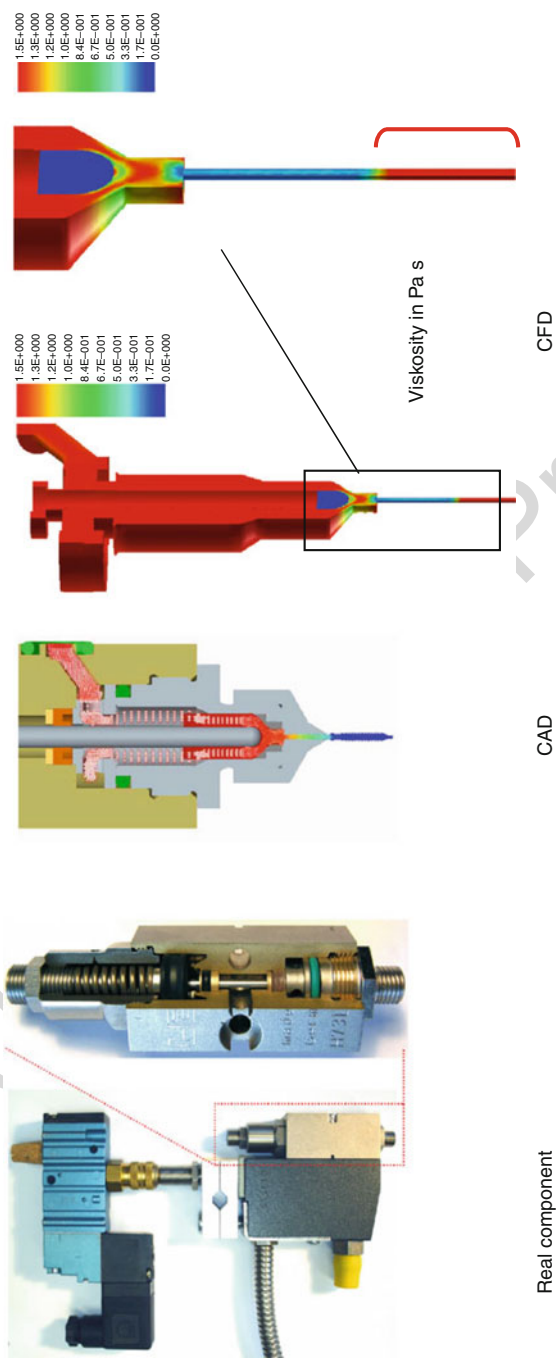

- The complexity of adhesives has continuously increased. The formulations are composed of an increasing number of individual substances, and this is placing ever high requirements on the dosing technology.
- It is also evident that industrial processes are becoming shorter, with an increased degree of automation.

Both these trends will probably continue in the future, meaning that an understanding of the interplay between the adhesives and the processing machinery is absolutely vital. The challenges involved here can no longer be solved using empirical approaches. Accurate analysis of the flow conditions inside dosing machinery and customization of the rheological properties for special plant components will determine whether a system (adhesive plus processing plant) can be operated in an effective way.

One tool that can help solve these challenges is to employ Computational Fluid Dynamics simulation. This gives an insight into the inside of dosing and mixing plants. The processes involved can be studied in quasi slow motion and this provides valuable information about the various flow anomalies which are constantly observed in practice.

The underlying Finite Volume Method divides the system geometry into small (linked) partial volumes of the same magnitude analogue to the well-known finite elements in CAD (Computer Aided Design). The differential equations that describe the flow are converted in this way into difference equations (integrals to be summed). These can then be solved as a linear equation system using a high-performance Solver. If this calculation is repeated for each time step, the result is a description of the time-dependent transient flow.

Figure 12 shows, by way of example, the inside of a needle valve which is commonly used as an application valve for hot melts. As the flow channel is rotation-symmetric, it suffices to consider half the cross-section in order to describe the flow.

## **38.6 Automation and Robotics**

### **38.6.1 Prerequisites for Automating Adhesive Application**

When an adhesive is manually processed and manually applied, there is a control system with closed loop between the dosing and mixing plant on the one hand and the worker on the other hand. The speed with which the worker moves the application nozzle across the workpiece determines, together with the machine settings, the cross-section of the applied adhesive bead. Small machine deviations are recognized by the worker automatically and are unconsciously corrected. This control system with closed loop is absent if the application of the adhesive is also automated. An automatic moving system solely travels a programmed distance at a programmed speed. Inaccuracies of the dosing and mixing plant are not automatically corrected. The moving system does not recognize these errors. In order for the desired results to be achieved with automatic application, a number of measures must therefore be taken:

- The accuracy of the dosing and mixing plant must be adapted to the requirements of the automatic application (in most cases the accuracy must be increased).
- The control system of the dosing plant must contain control loops that allow monitoring of the dosing and mixing processes, so that the control system recognizes deviations from the set value and can identify these as errors.
- The control systems of the dosing and mixing plant and the robotic system must communicate with each other via an interface.

A further consideration is what variant is most suitable for the planned production:

1. The robot moves the adhesive nozzle across a stationary component.
2. The robot moves the component across a stationary nozzle.

In the second case, the robot can also join the component after the adhesive application. It must be noted that this type of production has longer cycle times than application with a moving nozzle. Certainly, the number of robots and handling robots is lower. This is ultimately a question of economics, which should be clarified at an early stage of the project.

### **38.6.2 Parameters Affecting Accuracy and Methods of Compensation**

In order to discuss the factors which affect the dosing accuracy assume that a pneumatically driven piston dosing pump is being used. The free cross-sections of the piston dosing pump and pneumatic motor define the transmission ratio. For example a transmission ratio of 20:1, setting the air pressure at the inlet of the

pneumatic motor to 2 bar gives a material pressure in the piston dosing pump of 40 bar. This material pressure is constant in the whole system, including the downstream pipe system. If the outlet valve is now opened, there is a pressure drop across the pipe system, which to a first approximation can be calculated according to the Bernoulli's principle. For simplicity here it is assumed that the adhesive is a Newtonian fluid and that there is laminar flow. According to Bernoulli, the pressure drop for laminar tubular flow is given by:

$$\Delta p = \frac{128 \cdot l \cdot \eta \cdot Q}{\pi \cdot d^4}$$

where:

$\eta$  = viscosity of the fluid

$Q$  = volume flow rate

$l$  = length of the tube

$d$  = diameter of the tube

The viscosity is the only variable here. The viscosity in turn depends on the temperature. Independent by of the absolute viscosities of the different adhesives, the temperature-dependent change is ca. 5% per degree Celsius. For the dosing plant under consideration with a pneumatically driven piston dosing pump, this means that fluctuations in the adhesive temperature directly cause fluctuations in the discharge rate. A temperature change of 1 °C leads to a ca. 5% change in the applied amount of adhesive.

For a pneumatic drive, automatic adjustment of the compressed air supply to the accuracy demanded by a specific application requires disproportionately high complexity. In practice, a pneumatic piston dosing pump does not possess such temperature compensation. This type of plant is only used with a robot in situations where fluctuations of the application rate are not a criterion for exclusion.

For hydraulic dosing plants, the dosing pressure can be controlled very precisely via a servo valve in the hydraulic system. If the adhesive temperature is measured and if the hydraulic pressure, and hence the dosing pressure, is adapted to the measured values, then good temperature compensation for the temperature-dependent flow properties of the adhesive can be achieved.

Rotatory dosing pumps such as gear pumps or eccentric screw pumps which are electrically driven do not have the aforementioned drawbacks. The control occurs internally in the drive system. The pump size (in ccm/revolution), the transmission ratio and the individually determined slip-factor allow exact correlation between the speed of the drive and the resulting volume flow. The internal control loop of the electrical drive adjusts the set value. The control loop usually consists of an incremental counter, which monitors the speed within the work cycle (2–5 ms). If a difference between the actual increment and the set increment is recorded (contouring error), the power uptake of the motor is adjusted with the aim of no longer having a difference at the end of the next cycle (cycle time). Factors such as viscosity changes in the adhesive result in altered power uptake by the drive.

The pressure in the plant is not specified, rather it independently sets itself based on the resistance to flow.

A widely used means to improve the accuracy of dosing plants is to minimize the length of pipe between the dosing plant and the application valve. In the extreme case that means dosing plants having an application valve flanged onto its outlet. This design describes the current state of technology for manufacturing automobile bodies (body in white).

### **38.6.3 Dosing Accuracy (Dynamic Behavior of a Two-Component Metering and Mixing Machine)**

The processing of two-component (2-C) adhesives requires synchronous flow of the two components. The spotlight here generally falls on the accuracy of the dosing unit. The dosing unit is, however, only one part of a total system in which the adhesive components and their flow behavior play a major role.

The dosing process is an intermittent process. Features of this process are that the adhesive components undergo an abrupt change from a state of non-flow to a state of flow at the start of the dosing, and vice-versa at the end of the dosing process. Consistent and synchronous dosing is only possible if the two components of the adhesive have identical pressures at the point where they flow together in the processing plant. Only then will there be an even flow of the components and compliance with the prescribed mixing ratio. If this condition is not met, one of the two components will be over-dosed.

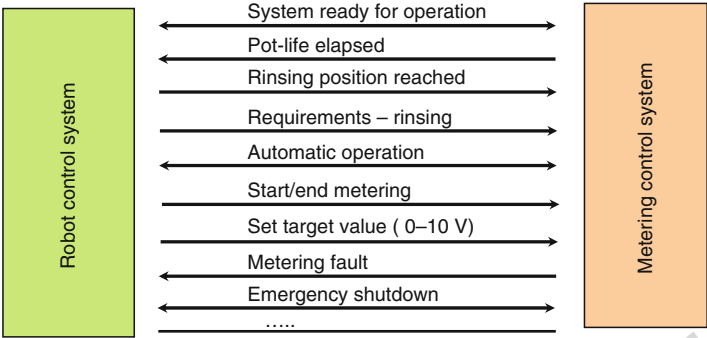

The point at which the two components flow together is not accessible experimentally. Up until now, no statements have been able to be made about how synchronous the two components flow, in particular at the start of the dosing process. It is known from the literature (Sauer 1989) that the period of time from the start of the dosing to the moment of establishment of a steady state of flow is the order of a second.

A second is a short time. However, when one considers the typical application rates of up to 400 mm/s currently used or highly dynamic processes with application times of just a few seconds then that one second becomes very significant. For this reason, detailed information is desired about the interactions between an electrically-driven – and hence high-precision – adhesive processing unit and nonlinear fluids (adhesive components), in particular at the start of the dosing.

The main difficulty in trying to evaluate the quality of the dosing unit (quality = accuracy with which the prescribed mixing ratio is complied with over the duration of the dosing process) is the lack of accessibility to take measurements. In practice the dosed components flow into a mixer at whose outlet the mixing ratio cannot be measured. Therefore the dosing unit has to be separated from the mixer. By a special designed nozzle, access to the outlet can be gained (see Fig. 13).

The specially designed nozzle allows separate application of the two components and also allows the pressures in the line system of the dosing unit to be set the same, as is the case for operation with a directly flanged mixing unit. This so ensures there

**Fig. 13** Schematic representation of the experimental access to the interface between the dosing unit and mixer

is no falsification due to different pressures between the start of the operation and taking measurements.

The measurements themselves were performed contactless using a laser scanner (see schematic representation in Fig. 14). As part of the studies to determine the suitability of the measuring equipment, the effects of various parameters were evaluated:

- Shadow;
- Undercut of the applied bead;
- Color of the adhesive components (possibly require a modified exposure time)

These preliminary studies used a cured 1-C adhesive to determine the accuracy of the measuring method using an analytical microscope. Following the contactless measurements, thin discs were taken from the adhesive bead to accurately examine the cross-section under the microscope. This showed up the following deviations:

- Effect of shadow: Not measurable
- Effect of the undercut: +0.82% ... +1.15%
- Effect of the color: –1.55% ... –2.64% (see also Fig. 15)

The effect of the undercut on the mixing ratio measurement will be smaller in practice than the individually measured values because the deviations for the two components are of the same order of magnitude and so cancel each other out. Only for mixing ratios far from 1:1 would there be an effect on the overall result, and even this would be less than 1%.

Depending on the color of the adhesive bead, its cross-section is underestimated to a differing extent. Considering, however, the practically common combination of black and white (having deviations of –2.36% and –2.64%, respectively), these

**Fig. 14** Schematic representation of the measuring method (Source: Mikro-Epsilon)

deviations cancel each other out. To achieve good measurement results with minimal scatter, different exposure times must, however, be chosen for these two colors. As such, this color combination represents a challenge because in order to determine the mixing ratio both beads (black and white) must be measured simultaneously. A compromise must be found here for the exposure time.

### Measurement of the Mixing Ratio

Figure 16 below shows the experimental set-up. The equipment was firmly secured on a coordinate table. The application base was moved at a constant speed below the special nozzle.

Figure 17 shows an example signal plot, with time resolution of the dynamic behavior of the two individual components compared with the machine operation.

It can be seen that after 0.1 s, the metering machine achieves steady state. There is a difference in time (delay) of 0.4 s until the components are applied. A small difference in time (delay) between the onsets of dosing of the two components is without significance. It also can be seen that a modification of the diameters of

**Fig. 15** Effect of the color of the adhesive beads on the measurement results

**Fig. 16** Schematic representation of the dosing unit for time-resolved measurement of the mixing ratio (*left*) and taking actual measurements (*right*)

**Fig. 17** Example signal plot for adhesive flow (mixing ratio 2:1) compared with dosing pump motor operation

internal piping (3.5 mm vs. 4.5 mm) in this case has no influence on components flow. After ca. 0.35 s, a steady state of flow is established for component B. Steady state of flow (component A) is established after ca. 0.9 s. This means that the prescribed mixed ratio is established ca. 0.9 s after the start of application and ca. 1.3 s after start of dosing.

A very interesting aspect can be seen as well: While preparing the test the calibration of the metering pumps was not performed properly. This led to an improper function of pump A delivering ca. 20% less than required. Without the new measuring method this mistake would not be able to detect!

Further detailed measurements using different adhesives have resulted in the following findings:

- The non-steady state at the start of the dosing (= a state in which the mixing ratio lies outside the range prescribed by the adhesive manufacturer) can last up to 1.3 s.
- The duration of the non-steady state is largely determined by the differing flow behavior of the two adhesive components.

The overall system can be optimized by having detailed knowledge of that system, which comprises the processing units and adhesive components. The differing flow behavior of the adhesive components can be compensated by controlling the dosing unit. The signal plot provides accurate data about the required delay of the dosing pumps in order to guarantee synchronous dosing of the two components. The acceleration rates to achieve the prescribed mixing ratio were realized by altering the acceleration of the drive motors such that there was equivalent acceleration of the two components.

The new measuring method has a number of different uses:

- Verification of a dosing rate agreed between an equipment manufacturer and user
- Identification of the causes of production faults
- Development of customized dosing technology and specific adaptation of an overall system

**38.7 Interface Between the Robot Control and Metering Control**

An interface allows communication between the control systems of the mixing and dosing plant and the robot. The exchange of signals replaces the person-machine control loop for manual application. In addition to general signals such as “emergency-stop” or “automatic operation,” individual signals adapted for specific task are exchanged. An example is shown in Fig. 18. The directions of the arrows indicate the directions of the signals. For example, the signal “ready for operation” is sent in one direction: from the dosing plant control system to the robot control system. For the robot control system this means that only when this signal is received can the automatic process be started. The “emergency-stop” signal is sent in both directions. If the emergency-stop button on the dosing control is pressed, not only must the dosing plant stop immediately but also the robot. An analogous situation arises when the emergency-stop button is pressed on the robot control.

**38.7.1 Accelerated Curing**

A demand of the industrial practice is that the time for curing an adhesive should be as short as possible. But often different requirements of the complete process anticipate the use of a quick curing adhesive. For this reason, methods were developed enabling the user to handle the adhesive as long as needed and to cure within seconds or minutes after having joint the adherends.

**38.7.2 UV-Radiation**

The intensity of electromagnetic radiation increases with decreasing wavelength. High-energy, short-wave radiation in the UVA and UVB regions can excite electrons

**Fig. 18** Example of an interface

in the outer shells of atoms and hence result in rapid chemical reactions. This mechanism is utilized for curing specially formulated adhesives. At least one of the two substrates must be permeable for the radiation. Note that materials which are transparent to the human eye are not necessarily permeable for UV radiation.

Curing can take place in three different ways:

*Via radicals:* UV acrylates cure via a radical reaction within seconds. The reaction is inhibited by oxygen. This means that adhesive which emanates from the joint forms a sticky surface. To avoid this, the curing can be carried out under a protective gas atmosphere. The UV absorption normally takes place in the wavelength region between 320 and 450 nm.

*Via cations:* UV epoxides cure rapidly via a cationic reaction (ca. 30–90 s). Oxygen does not inhibit the reaction. Adhesive which emanates from the joint forms a dry surface. The UV absorption is usually in the wavelength region between 320 and 450 nm.

*Dual cure:* A combination of UV curing and another curing mechanism (anaerobic, thermal, moisture-activated) is able to cure the adhesive film at points which are not accessible to the UV radiation (“shadow curing”). The UV absorption normally takes place in the wavelength region between 320 and 450 nm.

UV radiation is invisible to the human eye but can irritate and damage the eyes. There is a risk of blindness and also skin irritation (sunburn). In addition to UV radiation, UV emitters also emit a large amount of visible light. The resulting brightness can also lead to eye damage if emitters are not properly used. For this reason, UV emitters which are incorporated into industrial plants must be shielded such that no UV radiation is emitted externally. Despite this protection, safety glasses must be worn at all times when working with UV emitters. During operation, most industrial UV emitters produce a small amount of ozone. This must be removed by suitable extraction, to avoid any danger to personnel working with the equipment.

The complex measures required for UV protection were the impulse for the development of rapidly curing adhesives which do not require UV radiation. Initiators are now available which absorb in the visible region (400–560 nm). Adhesives formulated with these initiators cure under the influence of special blue light emitters.

### 38.7.3 Induction

Induction is a process in which heat is induced in electrically conducting workpieces. When a low-frequency alternating current flows through a coil (= inductor), an alternating magnetic field is produced. This induces eddy currents in ferromagnetic materials and produces magnetic hysteresis losses. The heat is generated in the component itself. The effectiveness, the transferrable energy, and the comparatively accurate temperature control are major advantages over other heating methods.

For adhesive bonding, the induction is used for indirect heating of the adhesive. The inductor must be adapted to the shape and desired temperature profile. Likewise,

**Fig. 19** Saw blade with adhesively bonded cutting elements through induction heating

the frequency has to be adapted to the size and conductivity of the component. The reproducibility of the heating depends on the uniformity of thickness of the adhesive film, which in turn depends on the allowable variation of a component, and requires precise control of the temperature in the sensitive region for adhesive curing.

A saw blade is shown in the Fig. 19. This is used for sawing materials such as marble and granite. It consists of a steel body with sintered diamond cutting segments which are normally brazed onto the saw body. The temperatures which arise during this process cause internal stress in the saw body. After production, the saw body has considerable unevenness and it has to be straightened.

If the cutting segments are bonded rather than brazed, the joints are subjected to a maximum temperature of only 200 °C. There is much lower internal stress in the saw body and no straightening is required after production. The engineering properties, namely, the cutting performance and wear performance are equivalent for the two manufacturing methods.

### 38.8 Conclusions

A large array of auxiliary equipment is available for processing adhesives, regardless of whether that is carried out manually or automatically. To describe all such equipment in detail here would require far more space than is available in this chapter. It has therefore been attempted to describe particular pieces of equipment, such as pumps, which are widely used, covering how they function, areas of use, and also quantitative aspects. It can be stated in summary that the machine processing and the automatic application of adhesives is a highly developed technical discipline.

application of adhesives, and the purpose of use and for the recycling of bonded products after they have been used. This chapter deals with the different aspects of consumer, work, and environmental protection, including health and safety information, related to the use of adhesives in industrial and private areas.

## 39.1 Introduction

The handling of raw materials and products in a responsible way throughout their lifecycle, namely from their manufacture via the usage stage right through to recycling and disposal, is nowadays a generally recognized principle. For many years now, the development and manufacture of adhesives has been carried out following the principle of Responsible Care<sup>®</sup> and the subsequent rules for sustainable development as defined by the International Council of Chemical Associations (Fig. 1) (ICCA 2008). This specifically means that health protection and environmental compatibility considerations are taken into account when developing and manufacturing new adhesives. This has consequences for the composition of the adhesives, the product design, the recommendations for application of the adhesive and the purpose of use, and for the recycling of bonded products after they have been used.

## 39.2 Health Protection

The aim of health protection is to protect people against hazards and exposure. “Work protection” is used to describe protection in commercial and industrial work environments while “consumer protection” refers to private users.

**Fig. 1** ©Industrieverband Klebstoffe e.V., Düsseldorf, Germany

### 39.2.1 Work Protection

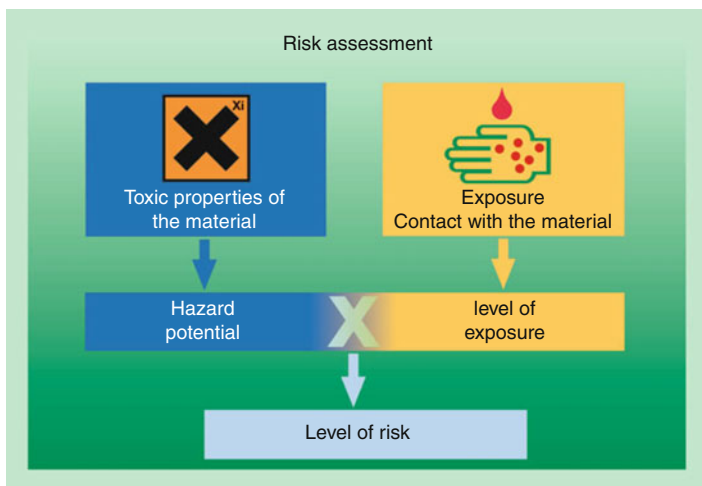

Industrial and commercial users of adhesives require special protection because they work on a daily basis with adhesives, often for many hours a day. In addition to hazards associated with the physical properties of adhesives such as flammability, explosiveness, and burns when using hot melts, it is in particular chemical effects such as toxicity, skin irritation, acid burns, and allergies that have to be avoided. This is achieved by equipping the workplace (workplace guidelines) with air replenishment systems and local extractors, personal protection equipment such as work clothing, gloves, and safety glasses and by ensuring that hygiene regulations are adhered to, for example, thorough washing of the skin before breaks and at the end of work and refraining from eating, drinking, and smoking in the workplace. Safety officers monitor compliance with these safety measures. Personnel who work with adhesives undergo regular training on matters relating to work safety and environmental protection. If special risks are involved, then personnel undergo regular medical examinations.

### 39.2.2 Consumer Protection

Although in a professional work environment possible hazards can be efficiently managed using suitable protective measures, even in situations where there is long-term use, the situation is different for private individuals using adhesives at home where no special protective measures are taken. Different requirements are hence put on these adhesives. This is also so because private users, unlike industrial users, generally have no knowledge of the properties and potential hazards of products. That is why only relatively few of all the known types of adhesives are available to private users, and even then only small amounts are made available in the form of tubes, cartridges, and tins. On the other hand, private users do not use adhesives every day, but rather only occasionally, and even then only in limited quantities and for limited periods of time. As such, the protective measures described for industrial users are generally neither possible nor necessary. It is nevertheless essential that the safety information given on the small packages is observed, as well as basic principles of work hygiene.

### 39.2.3 Health Risks

The area of toxicology is concerned with issues relating to the effects of chemical compounds and mixtures of chemicals. Assessing the health risk is a multistep process. The first step is sound assessment of possible undesirable properties of substances based on recorded data. In the second step, the quantities of material involved and the nature and degree of any possible contact are determined. It is then investigated whether an undesired effect of a material can be caused as a result of this contact. There is no health risk for people if there is no contact with the undesired

**Fig. 2** ©Industrieverband Klebstoffe e.V., Düsseldorf, Germany

material. The risk assessment determines whether and to what extent there is a health risk to people as a result of the relevant hazard potential of the substance and the nature and degree of exposure (Fig. 2). Although the exposure can for example be reduced by automated processing (e.g., robots) or by taking suitable protective measures (e.g., gloves, extraction of vapors, safety glasses, etc.), the hazard potential is a fundamental property of a substance or formulation (mixture of substances). The hazard potential generally decreases when the fraction of hazardous material present is lower. Small amounts of a hazardous substance can often be present without the product having to be accordingly labeled. The physicochemical properties of the substance, the nature and degree of exposure, and the ability of the substance to get into the body determine the relevant amount and the resulting dose that can be taken up by the body. In general, there is no undesired effect below a certain dose. The dose level determines whether and to what degree a substance can harm a person's health. The risk to human health is determined from the hazard potential of the substance and the exposure (opportunity for contact).

#### 39.2.4 Health Protection When Using Adhesives: Examples of Toxicological Assessment

Of the many different types of adhesives, those discussed below are those that are also commonly used in the household:

##### Physically Hardening Adhesives

The active components are mainly solid polymers and resins. For application these must be converted to a liquid form. This can either be carried out by users by means

of heating (hot melts) or can be carried out by adhesive manufacturers by dissolving the components in organic solvents or dispersing the components in water. The dry, fully aired adhesive is generally unreactive and biologically inert. There is hence usually no health hazard. In contrast, there is a potential health hazard from auxiliary components, such as organic solvents, that are present in some of these adhesives. These can make up as much as 80% of the weight of the adhesive product.

### **Hot Melts**

These adhesives contain largely polymers and resins and only small amounts of auxiliary materials. There is virtually never a health hazard. When applying these adhesives manually, there is the risk of burns and users must protect themselves against this. During heating, small amounts of auxiliary materials, contaminants, and cleavage products can be liberated, but these are insignificant when small amounts of adhesive are being processed. In an industrial or commercial environment, an extraction system is recommended due to the larger quantities being used and the longer working times with the adhesives.

### **Solvent Containing Adhesives (e.g., Contact Adhesives)**

In these adhesives, the polymers and resins are dissolved in organic solvents. The hazard potential is determined by the nature of the solvent (e.g., flammability, irritation potential). Due to the high volatility of the solvents, exposure by inhalation of the vapors is the biggest problem. For most solvents, the maximum concentration at the workplace and limiting factors are laid down (workplace limit value). Due to the small amounts of adhesive used by private users, these limit values are generally not reached or are only exceeded for a very short time.

### **Dispersion Adhesives (e.g., PVAc – Polyvinylacetate/Wood Adhesives)**

In the adhesives, the organic solvents are replaced by water and suitable polymers are dispersed in the water. There are hence no potential health hazards from organic solvents. However, water-based adhesives are sensitive to attack by microorganisms (e.g., mold formation). For that reason, dispersion adhesives contain small amounts of preservatives for protection purposes. The potential health hazard is the triggering of allergic skin reactions, for example, allergic reactions triggered by natural polymers such as natural rubber and non-modified colophony resins. The risk of sensitization in nonallergic people is generally extremely low due to the very small amounts of preservatives in the adhesives. Skin contact is here the exposure issue. Depending on the mode of application, skin contact may be unavoidable, as, for example, when using wallpaper pastes. However, here the concentration of preservatives is reduced as a result of mixing with water. As even wearing protective gloves for a long time can lead to skin irritation (e.g., caused by constant sweating), it is worth considering whether the very low risk of direct skin contact causing an allergic reaction justifies wearing protective gloves.

### **Pressure Sensitive Adhesives**

Private users only come into contact with these adhesives in the form of self-adhesive articles such as labels, adhesive tape, etc. As such, these adhesives represent no hazard to private users in practice. Such articles are manufactured industrially using adhesives in the form of solutions, but mostly using dispersions and melts.

### **Chemically Curing Adhesives**

The chemically reactive monomers/oligomers and hardeners and cross-linking agents determine the potential health hazard of these products. Once fully cured, the adhesive polymers are in general nonhazardous. Exposure and risk considerations hence only apply for the time period up until the adhesives have fully cured.

### **Cyanoacrylate Adhesives (Superglues)**

This group of adhesives reacts with water from the surroundings or water on the substrate. As private individuals only usually use small drops when applying the adhesive, the potential health hazard here is that if there is contact with the eyes or splashes of adhesive enter the eye then undesired bonding can take place (can gradually be dissolved using a soap solution). When being used industrially and commercially, possible irritation caused by the cyanoacrylate monomer, thermal effects, and the rapid polymerization reaction have to be taken into consideration. Increasing the humidity prevents irritation of the respiratory tract. Therefore, cyanoacrylate adhesives must be specifically labeled. When carrying out major bonding tasks, not only is it recommended to adjust the humidity of the air but also to wear safety glasses and protective gloves.

### **Silicone Adhesives**

Silicones react with water. Depending on the type of silicone, this reaction releases either acetic acid or alcohols. The acetic acid can be clearly sensed by the nose before any irritation begins. In general, the slowly released amounts are so small that they present no health risk, especially in the case of private users. Old formulations of neutral silicones that release butanone oxime must be labeled, but they are only used nowadays for special applications.

### **Epoxy Resin Adhesives**

Epoxy resins are widely used by hobbyists and in home do-it-yourself applications because of their good bonding properties, for example, for bonding glass, ceramics, or metals. This is particularly so because the supplied twin-nozzle container allows even the smallest quantities to be dispensed and then mixed. Liquid epoxies resins, and also cross-linking agents, irritate the skin and eyes and cause skin hypersensitivity. As such, hobbyists should avoid epoxy resin adhesives contacting the skin. For the industrial application of epoxy resins, safety glasses and suitable gloves must be worn. Epoxy resins having a molecular weight up to 700 are irritating to eyes and skin and they bear the potential risk of causing skin hypersensitivity. Therefore, epoxy resin systems must be labeled accordingly.

### 39.2.5 Adhesive Selection

For the private use of adhesives, there are no legal requirements. The selection of an adhesive is left largely to the experience of users and the recommendations of manufacturers. For commercial users, and in particular for industry, the selection of a suitable adhesive system for a particular application must be based on the technical requirements and the potential health hazard. In a situation where two adhesives are equally suitable, the one providing the lower potential health hazard must be chosen. If using an adhesive that does represent a potential health hazard is unavoidable for technical reasons, the exposure must be limited by taking suitable measures, which may even include automating the process, such that a risk to health is prevented. Safe working with adhesives is guaranteed by observing this regulation and the other regulations described in this section. Adhesive manufacturers provide support here by providing information in the form of technical data sheets and safety data sheets. If necessary, users should contact the adhesive manufacturers directly. As is clear from the iterations in this section, adhesive manufacturers make considerable efforts to protect the health of both private and professional users of their products. It must be mentioned here that from a quantity point of view, only a small number of adhesives have to be classified as hazardous formulations.

Private users complying with the safety instructions given on containers and industrial workers complying with relevant company regulations in their production facilities serve to protect people in accordance with the motto: “prevention is better than cure.”

## 39.3 Environmental Protection

Environmental issues have gained increasing importance over recent decades. The following is an example of a positive contribution to the environment: The car manufacturing industry uses up to 40 kg of adhesive sealants in each vehicle. The main objective of this is to save energy in the form of fuel by means of so-called “lightweight design,” whereby less weight has to be moved over the lifetime of the car and so resources are saved (e.g., 3-l car). On the other hand, the adhesives in this same example could burden the environment if there are residues left over from the application and any cleaning. At the end of the lifecycle of the car, the adhesive that was used must not adversely affect the recycling process and must be disposed of in accordance with regulations. In order to determine the effects on the environment, an environmental assessment is carried out. The expected concentration in the environment is calculated using a model. Simultaneously, the concentration at which no harm is expected to environmental organisms is determined. The calculation models and determination methods are laid down in international standards (European Chemicals Bureau 2003; European Chemicals Agency 2008). An adverse effect on or harm to the environment can be excluded with certainty if the Predicted Environmental Concentration (PEC) is less than the predicted concentration for which no

harm to environmental organisms occurs (Predicted No-Effect Concentration – PNEC), taking into account safety factors.

### 39.3.1 Air

The emission of organic solvents is detrimental to air quality. As such, considerable efforts have been made by the adhesives industry over many years to switch to low-solvent adhesives and where possible to solvent-free adhesive systems. There has been considerable success, and this has also been beneficial for health protection. Today, adhesive bonding is only responsible for less than 3% of all the solvent emissions in Europe. The few large-scale industrial applications operate with solvent-recovery systems. One typical example for a significant reduction of the use of solvent-based adhesives is the construction industry: While, for example, in Germany in 1985 the fraction of solvent-containing adhesives was still about 50%, it is in 2010 less than 10% with a still decreasing tendency. Dispersion adhesives and reactive systems have largely replaced these solvent-containing adhesives (Adhesion KLEBEN and DICHTEN 2010).

### 39.3.2 Water

With dispersion adhesives there is a particular risk of contaminating surface waters. Organic polymers and pre-polymers, although not easy to biodegrade, can be removed in biological treatment plants with the excess sludge. The use of these adhesives in handicraft work, in the home, and for DIY work normally results in only relatively small amounts of adhesive ending up in large amounts of wastewater (communal treatment works). As polymers usually have low toxicity for water organisms and due to the very low concentrations of adhesives in the wastewater, an adverse effect on the treatment plant and adjacent surface waters (outfall) is not expected in this case. In industry, residual adhesive and rinse water must be disposed of in accordance with waste legislation.

### 39.3.3 Soil

When used by private individuals, liquid adhesive residues are usually collected in the hazardous waste collection boxes, but are also often disposed of with the rest of the household waste. The amounts involved here are, however, small. For industrial and commercial users, disposal must be carried out in accordance with the so-called waste code numbers (to be found on the safety data sheets), which determine how the waste is disposed. Adhesive residues are normally disposed of as landfill or incinerated. Regarding the latter, specific contamination of the air by the incineration plants is not expected. The energy used in the manufacture of the adhesives can be partially recovered here.

### 39.3.4 Examples of Assessing the Environmental Impact of Adhesives

#### Production and Industrial Use of Adhesives

In industry, residues of cured adhesives and also non-cross-linked and liquid adhesives occur as waste. The former, as solid materials are either directly passed on as waste for disposal, or are preferably passed on for recycling. In the least favorable environmental scenario, they are disposed of as landfill. They are, however, usually recycled, either via composting or for energy recovery via incineration. Depending on how they have been treated, liquid adhesives are discharged with the wastewater and are either directly passed to a treatment plant or, if necessary, passed to a treatment plant after undergoing a specific pretreatment. There they are biodegraded or removed.

#### Do-It-Yourself/Private Use of Adhesives

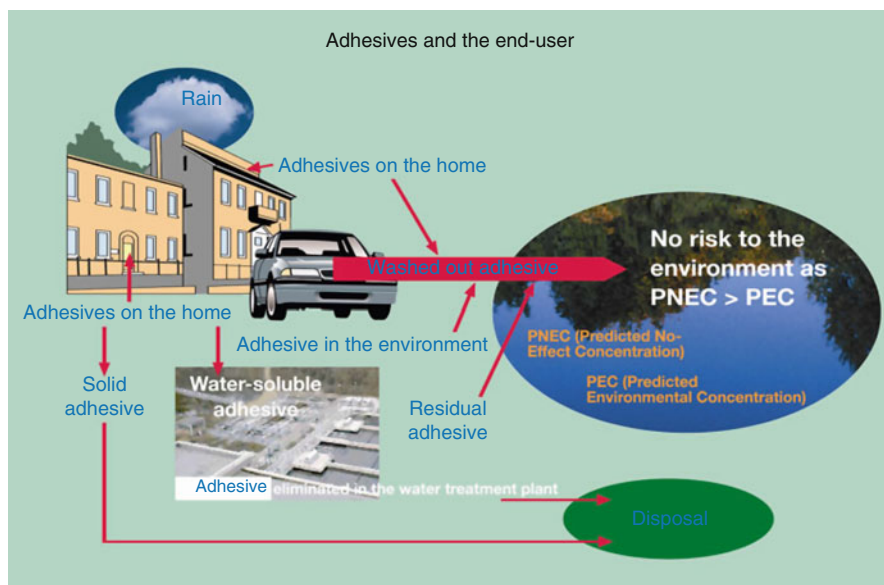

Adhesives used in private household/Do-It-Yourself have to be considered in different groups:

- Solid adhesive waste from the home such as hardened paper or wood glue is usually disposed of with the rest of the household waste.
- Water is usually used to remove water-soluble, hardened adhesives in the home, for example, for removing wallpaper paste. This adhesive-containing water is disposed of with the household wastewater via the water treatment plant. The adhesive components, for example, cellulose derivatives, which are dissolved to varying extents, can easily be eliminated under real environmental conditions, meaning that only very small amounts enter the outfall (river). When composting is used for recycling, cellulose decomposes slowly but thoroughly – as known for plant materials.
- Adhesives used in the home, for example, roofing adhesives, or around the home, for example, for the car, are exposed to processes that can wash out the adhesive, for example, rain. This means that a small amount of adhesive ends up in drain water and then directly enters surface waters.

Considering all the adhesives that are in use, the expected environmental concentration (PEC) is determined. The most unfavorable scenario is assumed in order to ensure that all conceivable possibilities have been taken into account (Fig. 3).

## 39.4 Conclusion

Adhesives as a whole do not represent a major environmental problem. Nevertheless, cured and nonrecyclable residues, as well as excess adhesive from applications are waste materials. These materials not only have to be disposed of, but also represent an unnecessary use of materials and resources. The principle of recyclable design, made possible by having detachable bonded joints, will be important in the future. Besides

**Fig. 3** ©Industrieverband Klebstoffe e.V., Düsseldorf, Germany

technologies for separating bonded materials, a further challenge of bonding technology will be resource-friendly optimization of production and application processes. It will be necessary to incorporate non-removable adhesive into future recycling processes. This will mean that the adhesive to be used for manufacturing a component will have to be customized to the recycling process at the end of the component's lifetime.

## Abstract

Since raw materials for adhesives influence the performance of final adhesive products, the selection, storage, handling, and testing of the raw materials are very important. In this chapter, types of raw materials including basic resins, hardeners, fillers, and functional additives for adhesives are firstly described. In addition, the roles of the materials are also shown. Practices for the quality control of the raw materials consisting of acceptance inspections and testing are also explained. Other tests conducted when adhesive products are shipped are explained too. These tests should be carried out following test standards. The standards for testing raw materials, and standards for materials are also mentioned in this chapter.

## 40.1 Introduction

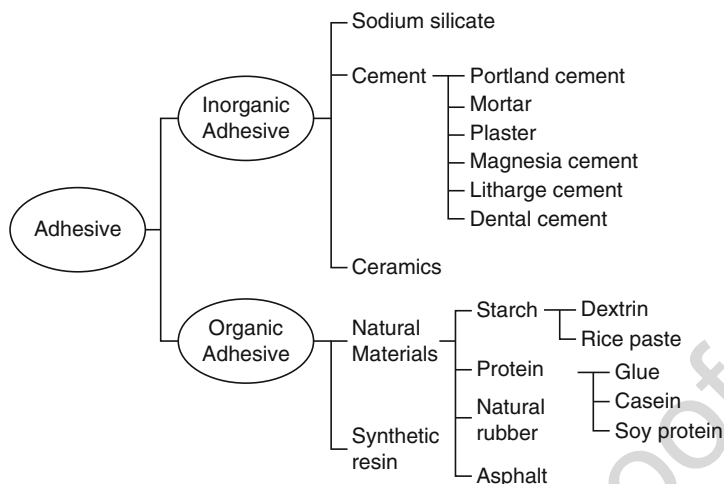

Quality control of products can be done considering only four elements called “4M.” Adhesives are not an exception to that concept. 4M is the abbreviation of “Materials,” “Method,” “Machine,” and “Man.” Managing the four elements, the quality of products can be ensured. Another word, “5M,” which includes “Management” is sometimes used instead of 4M (Ozawa 1987).

What is the definition of “Management” in terms of quality control? Generally speaking, it can be defined as the actual conducts to carry out the whole cycle of “Plan,” “Do,” “Check,” and “Action” (PDCA) for all items. The PDCA cycle is called the Shewhart cycle or Deming cycle (Deming 2000). Note that the management of raw materials is the most important to control the quality of adhesives.

Commercial products of adhesive are varied and the number of raw materials involved in them is almost infinite. The reason to employ so many raw materials is that adhesives need special compositions to meet the different demands or conditions such as adherends, applications, conditions of use, environments, and laws such as regulation concerning the registration, evaluation, authorization, and restriction of chemicals (REACH). Figures 1 and 2 show the main composition of adhesives commercially available. Since adhesives are varied, the raw materials also vary to a great extent. In this chapter, the description is concentrated in synthesized organic adhesives which are commercially available and widely used, because this reduces the number of combinations.

## 40.2 Types and Roles of Raw Materials for Adhesives

An ordinary process of adhesion is performed as shown in Fig. 3 (see Part G). The first step of the process is application of adhesives. Every adhesive must be liquid just before the application. The liquefaction can provide fluidity to the adhesive and help it to enter the micro structure of an adherend surface. The phenomenon is called “wetting.” Methods to induce the liquefaction are as follows:

**Fig. 1** Classification of adhesives by categories of materials

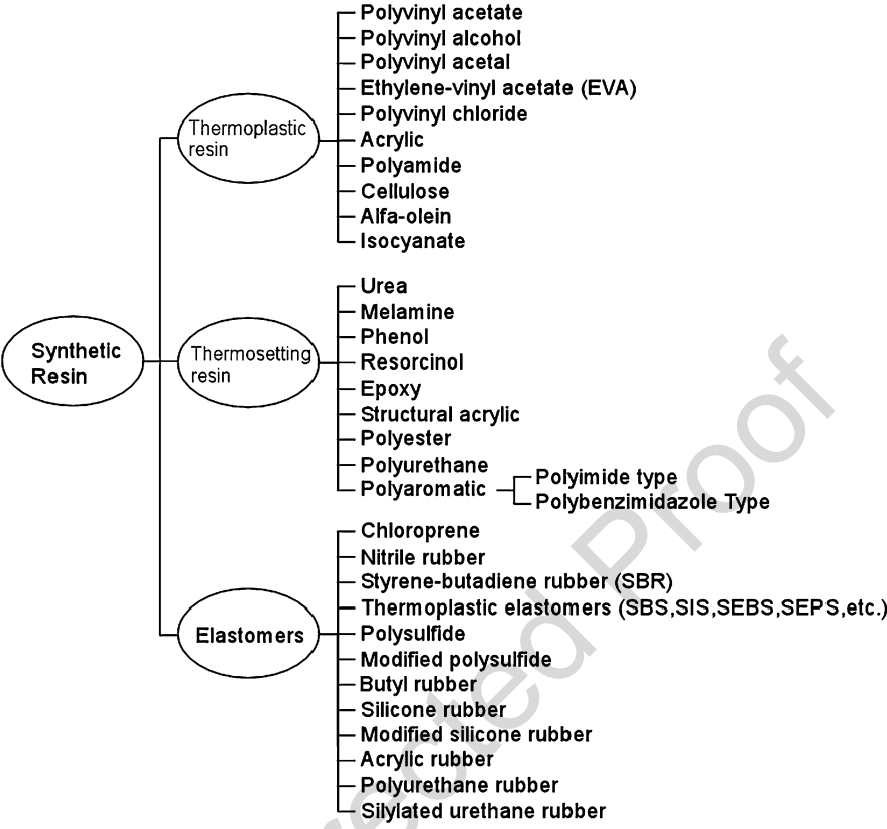

1. Use of solvents such as water or organic solvents
2. Dispersion of micro particles in water, i.e., emulsion adhesives or latex dispersion adhesives
3. Heating, i.e., hot-melt adhesives
4. Use of liquid monomers or oligomers that can be polymerized

Water, solvents, surface-active agents, liquid monomers, or oligomers are the key components for liquefaction of adhesives. The performance of adhesives depends on the mechanical properties of the cured bulk adhesive. To emphasize the performance, many kinds of additives are blended to an adhesive, i.e., tackifiers, plasticizers, antioxidants (age inhibitors), curing agents (vulcanizing agents), adhesion promoters, and fillers. Adhesives consisting of mono component are very rare.

Functional adhesives have to have functions such as flameproofness or conductivity besides the intrinsic function to bond adherends together. Flame retardants or conductive fillers are used for the purpose. They are also the components of the adhesives. More information on composition of adhesives is given in ► [Chap. 13, "Composition of Adhesives."](#)

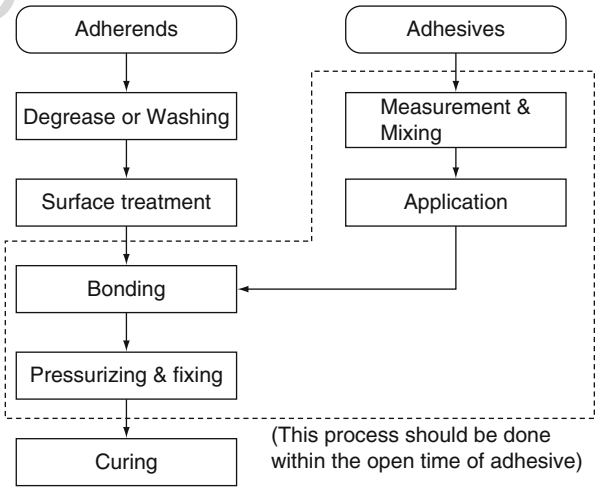

## 40.2.1 Main Components

The main components of adhesives are polymeric materials such as elastomers or synthetic polymers. The main component type for a certain adhesive is decided by the designer considering the type of adherends and use conditions. Control items to

**Fig. 2** Classification of synthetic resins for adhesives

**Fig. 3** Adhesive and adherend preparation in bonding processes

be considered is as follows: solubility parameters, average molecular weights, Mooney viscosity, crystallinity, and existence or nonexistence of functional groups. Materials that can be used as main components of elastomer adhesives are polychloroprene rubbers, nitrile rubbers (butadiene-acrylonitrile copolymer), SBR (styrene-butadiene copolymer), thermoplastic elastomers (SBS, SIS, SEBS, SEPS etc.), butyl rubbers, acrylic rubbers, silicone rubbers, polysulfides, modified polysulfides, modified silicone rubbers, and silyl urethanes.

Materials that can be used as main components of thermoplastic adhesives are vinyl acetate, polyvinyl alcohol, polyvinyl acetal, ethylene-vinyl acetate copolymer (EVA), vinyl chloride, acrylic resin, polyamide, cellulose, alfa-olefin resin, and waterborne isocyanate resin.

Materials that can be used as main components of thermosetting adhesives are urea resin, melamine resin, phenolic resin, resorcinol resin, epoxy resin, structural acrylic resin, polyester, polyurethane, polyimide, polybenzimidazole, etc.

## 40.2.2 Solvents

The role of solvents is to reduce the viscosity of adhesives and to improve fluidity. That can provide the adhesives wettability to create an intimate contact with the surface of adherends. Solvents must be able to dissolve the components of adhesives. Solubility parameter is an index to show the soliditvity of solvents. A solvent can dissolve a high amount of materials whose solubility parameters are close to that of the solvent. Water, alcohols, aromatic hydrocarbons (e.g., toluene and xylene), ketones (e.g., methyl ethyl ketone and cyclohexanone), acetate esters (e.g., ethyl acetate and butyl acetate), n-hexane, cyclohexane, methylene chloride are used due to their solubility, dehydration rate, noncombustibility, and workability. To meet the demands concerning environmental issues, the use of some solvents such as toluene, xylene, ethylbenzene, and styrene is restricted by laws such as the air pollution control law legislated by Ministry of the Environment in Japan (The Ministry of the Environment 1996).

## 40.2.3 Tackifiers

A tackifier is a component to provide initial tackiness to adhesives. The compatibility of the tackifier to the main components is very important to increase the tackiness without degradation of the adhesive mixture. For that purpose, natural resins such as rosin and dammar, modified rosins such as coumarone-indene resin, polymerized rosin, hydrogenated rosin and rosin ester, and polyterpene resin are used. Recently, alkylphenol resins, terpene phenol resins, and xylene resins are out of use because of their hazardous nature inducing sick building syndrome.

#### 40.2.4 Plasticizers

Plasticizers can give flexibility to resins and are often used for vinyl resins. For instance, phthalic esters such as dioctylphthalate (DOP) and dibutyl phthalate (DBP), aliphatic diprotic acid esters, glycol esters, resin acid esters, and phosphoric esters are used as plasticizers. The use of phthalic esters has been decreasing because of environmental regulations.

#### 40.2.5 Fillers

The purposes to mix fillers with adhesives are (1) viscosity control, (2) suppression of resin invasion into porous adherends, and (3) strengthen the cured adhesive layer. Commonly used materials for fillers are minerals such as calcium carbonate, clay, talc, and diatom earth. Cellulose powders and recycled rubber powders are also used for the purpose.

#### 40.2.6 Thickeners

Thickeners are water-soluble polymers used for increasing the viscosity of emulsion, dispersion, and latex adhesives. Typical materials for thickeners are casein, methylcellulose, carboxymethyl cellulose, polyvinyl alcohol, and sodium polyacrylate.

#### 40.2.7 Pigments

Pigments such as titanium white, carbon black, and organic colors are used for coloring adhesives. Mixing of pigments in adhesives can make them less noticeable. In addition, the method has another function in which adhesives mixed with pigments can be visualized by color. Pigments must not react with the other components of an adhesive. Preservation stability of the mixture has to be checked experimentally.

#### 40.2.8 Other Important Components

Antiseptic agents, antiaging agents, antifoam agents, adhesion promoters (e.g., aminosilane coupling agents, alkyltitanate, etc.), or fragrances can be applied to adhesives as necessary.

## 40.2.9 Functional Components

Recent adhesives may include new types of components that can be used as main components or modifiers.

### Silane Coupling Agents

It is widely known that aminosilane coupling agents can be added to adhesives to improve their adhesion strength. Aminosilane coupling agents have organic groups and alkoxy groups that can modify the main resin components of adhesives. Alkoxy groups have compatibility with inorganic materials. They also condense with each other and produce cross-linked structures, which leads to desirable properties such as resistance to climate, acid tolerance, heat resistance, resistance to solvent attack, etc. Aminosilane coupling agents have recently been introduced to many types of resins or elastomers. Special coupling agents suitable for particular materials have also been developed. The methods to apply aminosilane coupling agents to resin or elastomers are as follows (Yanagisawa 2007):

1. Graft reaction
2. Chemical reaction
3. Copolymerization

These methods are shown in Fig. 4.

#### By grafting

#### By chemical reaction

#### By copolymerization

**Fig. 4** Methods to introduce silane coupling agents to molecules

## Functional Acrylic Materials

Oxazoline acrylic polymers have an oxazoline group, which is a kind of cyclic imino ether, as side chains. Ethylenimine acrylic polymers are modified with ethylenimine. Both materials have been used as main components of acrylic adhesives (Noda 2005). Oxazoline acrylic polymers can be applied to paints, coats, adhesives or pressure-sensitive adhesives (PSAs), and textile treating agents as water-base cross-linkers. Applications of oxazoline acrylic polymers are as follows:

1. Water-base cross-linkers: Although carboxyl groups in water-base resins are neutralized by amines or ammonia, oxazoline groups do not react with carboxyl groups and are stable in liquid conditions. When the water-base resin dehydrates, neutralizing agents are evaporated, and the carboxyl groups start to react with the oxazoline groups.
2. Primers for plastics: Oxazoline acrylic polymers have good adhesion compatibility to plastics. The reason seems to be the presence of polarity, affinity, and interaction caused by oxazoline groups that are a kind of cyclic imino ethers. The carboxyl groups in the polymer react with the oxazoline groups and they can also give the polymers good adhesion to plastics.
3. Film laminating adhesives: Although EVA emulsion is often used for film lamination as adhesives, the bonding strength to polyvinyl chloride (PVC) and polyolefin films is not high. The defect can be corrected adding oxazoline acrylic polymers to EVA emulsions having carboxyl groups.

Ethylenimine acrylic polymers have high bond strength to many types of materials because ethylenimine groups are very reactive. The reactions caused by ethylenimine groups can be categorized as (a) polymerization by ring-opening ionic polymerization, (b) introduction of primary amine group in side-chain of acrylic polymers by ring-opening addition of ethylenimine groups to carboxyl groups, and (c) aziridinyl reaction (modification with preservation of aziridinyl groups). The good reactivity of ethylenimine acrylic polymers enables them to be cross-linkers for water-base polymers having carboxyl groups. When the polymers are used as a part of two-part cross-linking systems, use of a double-headed gun is necessary.

## Oxetane Polymers

Oxetane polymers are polymers having oxetane rings that are a kind of four-membered cyclic ether. The ring has high strain and basicity, and the polymer can cause cation ring-opening polymerization, as shown in Fig. 5. The characteristic of oxetane polymers are as follows (Sasaki and Crivello 1992; Crivello and Sasaki 1993a, b; Sasaki et al. 1995; Sasaki 2000):

1. The result of the Ames test is negative even in the condition of low molecular weight monomers.
2. Quick curing to mix to epoxy materials.
3. Relatively high molecular weight of generated polymers.
4. Diversity of synthesis methods because of oxetane ring stability under alkali conditions.
5. Volume shrinkage due to curing is not large and almost equal to epoxy resins.

**Fig. 5** Cationic ring-opening polymerization of cyclic ethers

Such characteristics are suitable for using the material for modifiers of UV curing epoxy adhesives applied to electronic parts.

### Amorphous Polyalphaolefin

Amorphous polyalphaolefins are olefin polymers that are in amorphous condition and have relatively low molecular weights. They are synthesized by copolymerization of propylene alone, propylene and ethylene, or butane-1.

The characteristics of amorphous polyalphaolefins are as follows:

1. Good adhesion compatibility for polyolefins such as polyethylene (PE) and polypropylene (PP).
2. They can be used alone as hot-melt adhesives.
3. Mixture with EVA hot-melt adhesives may be sprayed to adherends.
4. They can be mixed with large amounts of mineral fillers.
5. They can be mixed in asphalt with a good dispersion.
6. Safe and harmless (compatible with the standard: US Food and Drug Administration (FDA) 21CFR.175.105).

**Fig. 6** Deformation mechanism of thermally expandable microcapsules (TEMs)

These characteristics lead to applications such as hot-melt adhesives, modifiers for hot-melt adhesives, modifiers for resins or elastomers, modifiers to prevent corrosion for waxes, and modifiers for asphalts.

### Thermally Expandable Microcapsules

Thermally expandable microcapsules (TEMs) are micro spheres of 10–40  $\mu\text{m}$  in diameter, having thermoplastic shells filled with liquid hydrocarbon of low boiling points. As their temperature rise, the inner pressure increases and the shell is softened. That leads to huge expansion of the sphere up to 20–40 times in volume, as shown in Fig. 6. The TEMs can be applied to dismantlable adhesives, thermally expandable adhesives, or sealants.

### Core-Shell Rubber

Core-shell rubbers have been developed to improve the ductility of epoxy resins without heat resistance reduction. Core-shell technology is a kind of capsulation process in which hydrophobic core resins can be covered with hydrophilic shell resins. There are many combinations of core and shell materials and wide varieties of dimensions, 40–500 nm in diameter, for instance. A method to pre-react liquid carboxylated nitrile butadiene rubber (C-NBR) and an epoxy resin and mix the product into the epoxy resin has been used for long time and it is a typical approach to design structural adhesives recently. Mixture of core-shell rubber is much more effective than those by the C-NBR method.

## 40.2.10 Functional Fillers

### Carbon Nanotubes

Carbon nanotubes are hollow carbon structures as a graphite sheet wound cylindrically. Their diameter is few  $\text{\AA}$  to 100 nm. Since the aspect ratio is very large, the material has a fibrous form. Carbon nanotubes having one graphite layer are called SWCNT (Single-Walled Carbon Nanotube). Other carbon nanotubes are called

MWCT (Multiwalled Carbon Nanotube) (Iijima 1991; Saito 2003; Fan et al. 1999; Nakayama 2002; Akita et al. 2001).

The characteristics of carbon nanotubes are as follows:

1. Chemical stability
2. High electric and thermal conductivity
3. High mechanical properties
4. High electron emission property

The carbon nanotubes are very promising to apply for adhesives as fillers to emphasize the strength and electric or thermal conductivity. Mixing of carbon nanotubes is not easy because of their strong cohesive attraction. Dispersion technology has to be established to obtain good characteristics.

### **Fine Calcium Carbonate**

Fine calcium carbonates, coated with aminosilane coupling agents, have been developed. Their diameter is about 20 nm. The material is promising as fillers to reinforce structural adhesives or elastomer adhesives (Tutui 2006).

### **Micro Balloons**

Micro balloons are convenient to reduce the weight of adhesives because the density of the balloons is very low. Typical micro balloons are 5–300  $\mu\text{m}$  in diameter, and 0.7  $\text{g}/\text{cm}^3$  in density. They have hollow structures comprising of silica (60–65 wt%), alumina (27–33 wt%), and ferric oxide (less than 4 wt%) (Tozaki 2006). The mixture should be carried out so that the micro balloons could not be broken. Since the macro balloons are difficult to be dispersed into resins, they are mixed with solvents and dispersed. After the mixture, the solvents are extracted by evaporation.

---

## **40.3 Quality Control Procedures for Raw Materials**

### **40.3.1 Acceptance of Raw Materials**

Acceptance inspections are necessary when raw materials are received. The name, type, and quantity of a material should be verified. The delivery conditions of raw materials, for instance, chilled transport, are also important in some cases and should be checked. After the acceptance inspections, there are several inspection tests to check the quality of the materials, which should fit the requirements. When these tests are carried out by suppliers of materials, users should check the specification documents indicating the test results. Recently, suppliers tend to contract for these tests. However, tests by users are still important to make sure the quality of their products. Capabilities of users to conduct tests are indispensable to decide the types and sequences of tests, which should be discussed and agreed with the suppliers testing the materials. Types of inspection tests are explained in the following section. Specification documents often include information for workers' health protection

295 such as material safety data sheet (MSDS), which should be always available to the  
296 worker.

297 When a raw material is accepted, the storage term of the material starts. Thus, the  
298 inventory list of a warehouse should be updated. Stored raw materials should be used  
299 “first in, first out.” Too long storage term than the shelf life of a material is  
300 prohibited. On the package of each material, tag labels indicating necessary infor-  
301 mation such as receiving date should be stuck. Inventory managements are important  
302 not only for the performance proof of materials and final products, but also for  
303 accounting managements and chemical material managements for acting in accord-  
304 dance with pollutant release and transfer register (PRTR), which is linked to raw  
305 material purchase, production, and shipping of final products. Nowadays, the  
306 updating of inventory lists can be automatically done with that of the PRTR database  
307 using computers.

### 308 **40.3.2 Inspection for Acceptance**

309 In inspection tests for receiving raw materials, the following properties should be  
310 investigated: chemical equivalent, impurity content rate, molar weight, viscosity,  
311 specific weight (density), color, transparency, conductivity, permittivity, etc. Among  
312 these properties, chemical equivalent, impurity content rate, molar weight, and  
313 viscosity are important.

#### 314 **Chemical Equivalent**

315 For raw materials of reactive adhesives, the chemical equivalent values are very  
316 important to specify the reactivity, and often tested. Epoxy equivalents for epoxy  
317 resins, and functional group equivalents for hardeners are experimentally deter-  
318 mined. Methods to measure the epoxy equivalents are described by industrial  
319 standards as follows: International organization for standardization (ISO) 3001,  
320 Japan industrial standards (JIS) K 7236, and American society for testing and  
321 materials (ASTM) D 1652. For instance, JIS K 7236 indicates the methods using  
322 titration. In this process, an epoxy sample is solved with chloroform, mixed with  
323 acetic acid, tetraethylammonium bromide, and crystal violet solution. The epoxy  
324 sample solution is finally titrated with perchloric acid–acetic acid solution. If auto-  
325 matic titrators can be used, the epoxy sample solution is titrated with perchloric  
326 acid–acetic acid solution by the machines. Functional group equivalents for hard-  
327 eners should also be measured because these are important parameters for adhesive  
328 curing.

#### 329 **Impurity Content Rates**

330 Adhesives for electronic applications are sensitive to impurities. For instance,  
331 inclusion of conductive particles often induces problems of insulation breakdown.  
332 Chlorine inclusion can cause corrosion of metal parts such as electrodes made of  
333 oxygen-free copper foils on flexible circuit boards that can react with chlorine in  
334 adhesives for bonding the foils and the boards, yield dendrites, and lead to insulation

breakdown. Since the phenomena occur at very low density of chlorine, the content rates should be checked by standards such as ISO 21627 and JIS K 7243.

### Molecular Weight

Since main components of adhesives are usually monomers of low molecular weight, the performance of the adhesives is not influenced by the variation of the molecular weight. Thus, it is not important to measure the molecular weights of the components. In contrast, for pressure-sensitive adhesives (PSAs), raw materials such as rubbers and tackifiers have relatively higher molecular weight than those of adhesives, and the variations lead to deviations of the final performances. Therefore, the molecular weights of the raw materials for PSAs are often measured by experimental methods such as end group determination, colligative property measurements, light scattering, ultracentrifugation, viscosity measurements, and gel permeation chromatography (GPC). These methods should be selected properly for objective materials.

### Viscosity

Viscosities of raw materials are very important because they can influence not only the properties of final adhesive products, but also the production process. Methods for measuring viscosities of liquid raw materials are included in the following standards: ISO 2555, ISO 3219, JIS K 7117, and ASTM D1084.

Viscosities of liquids can be described as:

$$\tau = \mu \dot{\gamma} \quad (1)$$

where,  $\tau$ ,  $\mu$ , and  $\dot{\gamma}$  signify shear stress, viscosity, and shear strain rate, respectively. Consider the situation shown in Fig. 7, in which there are two parallel plates of area  $A$  with a separation distance of  $h$ , where the plates translate in relation to each other with a velocity  $v$ . The shearing force  $F_s$  is given by the following equation.

$$F_s = \mu A \frac{v}{h} \quad (2)$$

Although the international system of units (SI unit) for viscosity is Pa·s, cps is also used often for raw materials of adhesives and PSAs. For viscous liquids, Brookfield-

**Fig. 7** Relation between shear force and shearing velocity in viscous fluid

**Fig. 8** Types of viscometers for a viscous fluid

type viscometers or coaxial-cylinder-type viscometers, shown in Fig. 8, are usually used. For higher viscous materials, cone-plane-type viscometers (Fig. 8), Mooney viscometer, and rheometers are used. For example, a Brookfield-type viscometer has a spindle rotating in the liquid with a constant rotational velocity, and the resultant torque is measured. The viscosity of the liquid can be calculated from the torque and calibration results of standard viscous materials commercially available.

For elastomers and rubbers, Mooney viscometers are used, which are documented in standards ISO 289 and JIS K 6300. Brookfield-type viscometers can also be used for elastomers. Elastomers should be dissolved in a solvent in content of 10–20 wt% before measuring with Brookfield-type viscometer.

### **Density (Specific Weight)**

Densities and specific weights are basic material properties and should be measured to check errors of adhesive production. The measurement methods of specific weights are defined by standards ISO1183, JIS K7112, and ASTM D792. Densities are basically equivalent to specific weights, and the selection depends on the nature of the material. Densities are suitable for liquids, and specific weights are for solids. The density of a liquid can be measured with pycnometers or specific gravity cups, whose inner volumes are known. The density is calculated dividing the mass of the liquid by the volume.

Since volumes of solids are quite difficult to measure, specific weights are appropriate for solids (ISO 3675, JIS-K2249). Specific gravity balances are usually used for the measurements. The weights in air and water of a solid are measured using balances. The difference between the weights in air and water is equivalent to the buoyancy indicating the volume of the solid. Dividing the weight of the solid by the buoyancy yields the specific weight. The density of the solid can be calculated multiplying the specific weight and the density of water. The method has a problem

that it cannot be applied to water-soluble materials. In this case, volumes of the materials should be measured by different methods.

For liquids such as solvents, areometers can be used. They are convenient because specific weights of liquids can be measured in the containers.

### 40.3.3 Quality Control of Raw Materials in Storage

Circumstance controls are very important for raw materials in storage. The most influential condition on material degradation is temperature. Air conditioners for warehouses, refrigerators, and freezers should be appropriately selected for the required temperature conditions of raw materials, and used. Although humidity and ultraviolet irradiation are lesser influential than temperature, protection methods have to be taken not only in storage, but also in processing of adhesive products.

For adhesive production, particular amounts of raw materials are extracted by pumps from the containers such as metallic barrels, and transferred to reaction vessels. Some materials such as isocyanate resins are very sensitive to humidity, and solidify when the containers are kept open. For the materials, time limits of opening containers should be specified and kept by workers. Consuming up materials soon after the containers are opened is a good idea. Therefore, proper plans for the production of adhesives can contribute to the quality control of raw materials.

Adhesives for electronic applications are nowadays processed in clean rooms. If containers for raw materials are dirty and contaminated, the cleanliness of the clean rooms may decrease. Therefore, the containers should be stored in clean conditions in order to prevent them from contaminations. More information on storage is given in ► Chap. 36, "Storage of Adhesives."

Education of raw material managers is another point of importance. No manager is the worst. Irresponsible managers are almost the same as no manager. In these situations, the performance of raw materials cannot be proved, and possibilities of defective products increase. Indispensable rules such as keeping materials in proper conditions of storage, and making overdue materials unusable are obeyed strictly by the managers. Disposals of overdue materials may occur due to production plans. Even in the cases, managers must not be blamed.

### 40.3.4 Inspection for Shipment

When adhesives are shipped after the processing, users of raw materials become supplier of products. Inspection should be done to the adhesive products to prove the performances. Specification sheets should be issued for users if required. Sampling tests of industrial adhesives are rare unlike household adhesives. Tests of each production lot are usual.

Inspection tests before shipments of adhesive products are as follows: adhesion strength, tackiness, hardness, viscosity, density, volume shrinkage, thermal expansion, shelf life, pot life, gelation time, water resistance, chemical resistance, weather

resistance, flame retardance, electric conductivity, color, optical properties, amount of volatile organic compounds (VOC) emergence, etc. Some of these tests are the same as those tests for acceptance. Before shipment, strength tests of joints are very important for adhesives in terms of performance proof (see ► Chap. 19, “Failure Strength Tests”). In contrast, for PSAs, tackiness is important (see ► Chap. 15, “Pressure-Sensitive Adhesives (PSAs)”). Other important properties that should be tested are shown below.

### **Shelf Life**

Shelf life is a term during which adhesive can be stored without undesirable physical and chemical changes. The term depends on the storing condition of the adhesive. Thus, the shelf life of an adhesive should be indicated with the storage condition such as temperature, humidity, and light. Since some adhesives are sensitive to oxygen or humidity, the shelf lives of the adhesives should be stored with unopened container during a term, then the viscosities or joint strengths are experimentally measured. The procedure is denoted in test standards such as ASTM D 1337 (see ► Chap. 18, “Thermal Properties of Adhesives”).

### **Pot Life (Working Life)**

Pot life (working life) is the time length in which an adhesive can be applied and used to join after the adhesive comes to an applicable condition. For instance, two-part epoxy adhesives gradually cure and harden after the mixing of the parts, and become too stiff to be applied after their pot lives, decreasing the bond strength. For moisture curable adhesives, the pot lives start when the adhesives are extracted from the containers. Pot lives are determined measuring the viscosities or joint strengths of adhesives with respect to time. The procedures are denoted in some standards, i.e., ISO10364, JIS K 6870, and ASTM D 1338 (see ► Chap. 18, “Thermal Properties of Adhesives”).

### **Curing Shrinkage**

Reactive adhesives such as epoxy and acrylic resins may induce shrinkage stresses that reduce often the bonding strengths. Therefore, the volume shrinkage should be measured by standards such as JIS K6911, in which adhesives are cured in a mold and the dimension of the adhesive is measured to calculate the shrinkage ratio.

### **Curing Rate**

Curing rate is important information for users of adhesives. However, ordinary adhesives cure gradually and sometimes reach to the final strength within a few days. Hence, the time to the final strength is less important than the time when de-molding or handling of the joints can be possible, because the total time of bonding processes highly depends on the de-molding or handling time. In contrast, a too short curing time, which is equivalent to a short pot life, spoils the workability. Therefore, curing rates are very important and should be measured using many specimens such as lap shear joints with respect to time.

### Strength and Hardness

Although the strength of the adhesive in bulk is not so important to be often measured, sometimes it is necessary to verify the specification. For the strength test of adhesives in bulk, dog bone specimens for tension or rectangular specimens for bending are used. In contrast, hardness of adhesives in bulk can be used as an index of curing condition, and is measured in terms of quality control. Hardness measurements include scratch tests and indentation tests, and the latter, such as the Shore test, is often utilized for adhesives in bulk. A Shore hardness tester has a small diamond half sphere equipped at the tip of a hammer, and the hammer hits the surface of a specimen. Hardness is calculated from the height of the hammer rebounding after the collision. A too soft adhesive implies under-cure or mixture of air bubbles, and a too hard adhesive means over curing.

### Glass Transition Temperature

Glass transition temperature ( $T_g$ ) is an important parameter for the quality control of adhesive formulation. The temperature is also related to the maximum usable temperature of adhesives. Adhesives are softened and become viscoelastic around the  $T_g$ . The  $T_g$  of an adhesive can be measured with differential scanning calorimetry (DSC), thermo mechanical analyzer (TMA), and dynamic mechanical analyzer (DMA). The  $T_g$  is calculated from the absorbed or emitted energy measured with DSC, deformation with TMA, and fluctuation of viscoelastic parameters with DMA, although the values from the methods are slightly different. Therefore, the definition of  $T_g$  is quite ambiguous. There is another similar temperature called softening point measured by penetration or bending tests using TMA. This is very close to  $T_g$  in value (see ► Chap. 18, “Thermal Properties of Adhesives”).

### Other Properties

Nowadays, additional functions become important and the performance should be tested. For instance, since the use of Pb solder is nowadays prohibited by the restriction of the use of certain hazardous substances in electrical and electronic equipment (RoHS), conductive adhesives are used instead. For the adhesives, electric conductivity and shear resistance are vital, and their tests, besides other conventional tests, should be conducted. Thus, some adhesives developed in the future may have novel functions that conventional adhesives do not have, and new test methods and standards should be required to check the functions. From the environmental point of view, measurements of volatile organic compound (VOC) emergence and dismantlability of adhesives will become more important in the future (see chapter 58).

---

## 40.4 Material Standards

Since qualities of raw materials influence considerably the performances of adhesive products, the materials should be tested appropriately by test standards depending on the types of materials. The material standards are discussed below.

#### 40.4.1 Main Components

The main components of adhesives are polymers such as elastomers and synthetic resins, and monomers and oligomers for reactive adhesives. As shown in Sect. 3.2, properties that should be tested are chemical equivalent, molecular weight, viscosity, etc. In addition, solubility parameters, crystallinity, and presence of functional groups are also indispensable check points for the design of adhesives.

1. Solubility parameters: Solubility parameters are values indicating the solubility of plastic materials. Materials having similar solubility parameters can be dissolved and adhere to each other very well. Therefore, the value is very convenient to select the main component of an adhesive applied to a particular material. Solubility parameters of ordinary plastic materials may be shown in handbooks (e.g., Handbook of Adhesives edited by Skeist (1990)). Suppliers should be asked about solubility parameters of special plastics.
2. Crystallinity and presence of functional groups: Ordinary polymers except amorphous polymers have crystalline parts. Crystallinity of polymers affects the properties. Polymers of high crystallinity have high cohesive attraction. In contrast, low crystallinity leads to good contact to the adherend surfaces. Therefore, attention should be paid to the crystallinity of polymers used for adhesives. For instance, polychloroprene rubber has several types of low, medium, and high crystallinity, which are shown in the technical data provided by the suppliers. Type selection should be done carefully to design adhesives. The presence of functional groups (e.g., hydroxyl, carboxyl, amino, and epoxy groups) is also important to design adhesives, and the information is also indicated in technical data.

#### 40.4.2 Solvents

Properties that should be controlled for solvents are molecular weight, specific weight (density), boiling temperature, ignition temperature, aqueous solubility, initial boiling point, dry point, sulfur content, bromine index, residue on evaporation, moisture content, etc. Each solvent has a material standard (Table 1) and the properties are controlled by the suppliers.

#### 40.4.3 Tackifiers

Properties controlled for tackifiers are molecular weight, specific weight (density), melting temperature, softening temperature, aqueous solubility, solvent solubility, melt viscosity, burning point, etc. Molecular weights of tackifiers are measured by vapor pressure osmometry (VPO) methods. Melting temperatures and softening temperatures are measured by the method shown in a standard JIS K 2207. The Cleveland method is widely used to measure the burning point of tackifiers.

t.1 **Table 1** Material standard for solvents

t.2	Solvent	ISO	JIS
t.3	n-Hexane (very pure)		JIS K0504
t.4	Mineral spirit		JIS K2201
t.5	Toluene, xylene	ISO 5272,5280	JIS K2435

t.17	1,1,1-Trichloroethane		JIS K 1600

t.18 *ISO* International Organization for Standardization, *JIS* Japan Industrial Standardst.1 **Table 2** Material standard for tackifiers

t.2	Solvent	ISO	JIS
t.3	Dibutyl phthalate (DBP)		JIS K6752
t.4	Diocetyl phthalate (DOP)		JIS K6753
t.5	Di-isodecyl phthalate (DIDP)	ISO 2520, 21, 22	JIS K6750
t.6	Tritolyl phosphate (TCP)		JIS K6752

t.7 *ISO* International Organization for Standardization, *JIS* Japan Industrial Standards543 **40.4.4 Plasticizers**

544 Properties controlled for plasticizers are molecular weight, specific weight, oxidation  
 545 degree, ester number, refraction index, loss on heating, oxidation degree after  
 546 heating, boiling temperature, melting temperature, viscosity, etc. Material standards  
 547 for plasticizers are shown in Table 2.

548 **40.4.5 Fillers**

549 Important characteristics for fillers are low density, uniform dispersibility, workabil-  
 550 ity of cured bulk including fillers, minimum decrease of properties of cured bulk  
 551 (e.g., mechanical properties, resistance for water, chemicals heat, and weather) by  
 552 inclusion of fillers, large maximum content, low cost, etc. Controlled properties are  
 553 average grain size, specific surface area, pH, etc. Since the suppliers usually provide  
 554 experimental reliable data, the users do not test again by themselves.

#### 40.4.6 Thickening Agents

Casein, which is a type of protein included in milk, is used as a thickening agent for adhesives. There are three types of casein: acid casein, lactic casein, and rennet casein, depending on the production process. Acid casein is used for latex adhesives as thickening agents. Since casein is basically insoluble in water, alkali water solutions (e.g., with ammonia, potassium hydrate, sodium hydrate, borax, etc.) are used after water immersion to swell. Quality check of casein is conducted to measure the viscosity of water solution of 1–2%.

Methylcellulose, carboxymethyl cellulose, polyvinyl alcohol, sodium polyacrylic, and polyacrylamide copolymer are also used for thickening agents. The qualities of methylcellulose and carboxymethyl cellulose are checked measuring the viscosity of water solution of 2–5%. For polyvinyl alcohol, viscosity (4% at 20 °C), saponification number, and polymerization degree are indexes of the quality.

#### 40.4.7 Pigments

Color pigments are often mixed in adhesives. Since there are many types of pigments, which can affect the performance of adhesives, thorough discussion between users and suppliers of pigments is indispensable. Standards for pigments are shown in Table 3.

#### 40.4.8 Other Raw Materials

Other raw materials such as antiseptic agent, antiaging agent, antioxidizing agent, antifoam agent, and adhesion promoter are also mixed to adhesives. Tests by users of these materials are very rare. Specifications provided by suppliers should be checked and usable conditions should be kept.

**Table 3** Material standard for pigments

Solvent	ISO	JIS
Titanium oxide (titanium white)	ISO 591	JIS K 5116
Zinc oxide (zinc flower)		JIS K 5102
Carbon black		JIS K 5107
Ferric oxide (colcothar)	ISO 1248	JIS K 5109
First yellow G (Arylide yellow G)		JIS K 5217
Phthalocyanine blue		JIS K 5241

## 40.5 Conclusion

The performance of adhesives depends on the quality of raw materials used for the adhesives. Therefore, it is easy to understand that the quality control of the raw materials is very important. As adhesive manufacturers design and provide adhesives which meet the demand of the market, raw material makers should provide appropriate products to adhesive makers, understanding and considering their needs.

To keep the quality of raw materials, the specifications of materials and their testing methods should be determined and agreed by adhesive makers and raw material makers. Standards of materials and testing methods can be used to decide the specifications. All the purchase and shipping of raw materials should be done following the specifications. For instance, inspection of raw materials are carried out based on their specifications before shipping by raw materials makers, and specification sheets of each product lot are issued. For recent novel raw materials, such as functional fillers for conductivity or flame retardancy, new standards should be established.

Since testing methods are varied, selection of necessary and sufficient tests is important in terms of efficiency and economy. Storage condition of raw materials is also very important to proof the performance of final products. Temperature and humidity of storages or warehouses should be within the range shown in the specification of materials. No material over the shelf life can be used to produce adhesives. First-in first-out sequence is a good manner to manage the inventory of raw materials. Education for workers who treat raw materials is also an effective investment to maintain high quality of adhesive products.

Raw materials for adhesives have to be selected to meet the demands such as high performances, additional functions, and durability including environmental resistance. Traditional techniques to realize the desirable performance is to blend raw materials. Other methods, which have been introduced recently, are as follows:

1. Polymer alloying: This can be applied not only to mutually compatible materials, but also to noncompatible ones using compatibilizing agents.
2. Copolymerization, graft polymerization: They can combine immiscible materials, which leads to hybrid effects and synergies.
3. Pre-reaction: This can introduce sea-island structures in cured adhesive, and useful to reinforce adhesive layers. The technique has been applied to structural adhesives already.
4. IPN (inter penetrate network) structures: Developing of molecular chains penetrating each other can improve the resistance of cured bulk materials due to the stress relaxation. For instance, elastic adhesives have IPN structures comprising an epoxy backbone and modified silicone molecular chains.
5. Nanotechnology: This can be applied to surface modification.
6. Microcapsules. This can be used to realize novel functions such as dismantlability.

These methods are very promising to establish new materials for futures adhesion technology.

The other important requirement for ensuring the quality of raw materials is frequent and close communication between material providers and users. Information-sharing between providers and users is very crucial and indispensable for total quality control of adhesive products.

## Abstract

The processing quality control of adhesively bonded joints in actual production lines is discussed in this chapter. To improve the yield ratio of products, a scientific approach based on both probabilistic design and statistical treatment is indispensable. In addition, control of environmental conditions and materials is also very important. For the purpose, a realistic trial-and-error approach should be done to meet any demands or to solve problems occurring in the production. Investigation of reasons decreasing joint strength is another key point that should be done. The strength decrease occurs often due to mechanical or chemical mismatch of adherends and adhesives. The surface treatment of adherends is important too. Inspection, which can be carried out easily, is desirable in actual production lines.

Process design should be done appropriately to improve the efficiency and the economy of the lines and to increase the yield ratio of products. Parallel processes should be avoided if sequential processes can be adopted. Reduction of operator's tasks is another important issue. The concept of foolproof should be introduced in the process design.

Proper adhesive selection is vitally important, not only for good strength but also for increasing operation efficiency. New types of adhesives have been available to meet the demands to control the process easily. The education and training of operators are also an essential issue. Operators should learn standard procedures to perform their work appropriately. The necessary information should be exchanged properly.

## 41.1 Introduction

It is quite difficult to check visually the adequateness of adhesion bonding after the joining process. Therefore, design of bonded joints, process optimization, and its control are very important. In this chapter, some important aspects are discussed to obtain practically good adhesion in the fabrication lines of products having adhesively bonded joints. The quality control in adhesives production is not treated here. This aspect is, for example, treated in Petrie (2007).

The quality control of adhesively bonded joints in fabrication lines includes control of adhesion processes, appropriate design of joints to ease the process control, and education and direction for works to conduct the manufacturing. Many efforts have been made to improve the quality stabilities (Petrie 2007; Espie 1995; Roberts 1990; DeFrayne 1983; Bandaruk 1962). Due to the invention of new types of adhesives such as acrylics whose strengths are less sensitive to processing conditions than those of conventional adhesives, the quality control can be done more easily and precisely in these days than the previous as shown by Haraga et al. (2009).

Statistical approach is essential to control the quality of adhesively bonded joints in products. Both probabilistic designs of the joints and precision enhancement in each process to increase the yield ratio of useable joints are important. Statistical

approaches, in which the average and standard deviation of joint strengths are obtained and used for joint design or predicting the expected strength range, have been performed in several investigations (Straalen et al. 1998; Stroud et al. 2001; Hadj-Ahmed et al. 2001; Gorbatkina Yu and Ivanova-Mumjieva 2001; Seo and Lim 2005; Vallee et al. 2005a, b, 2006; Arenas et al. 2010). The idea can be applied to actual production processes in industries. Additionally, particular practical methods to improve the yield ratio of usable joints in each stage should be established.

## 41.2 Mathematical Background

Statistical methods are indispensable for ensuring the reliability of adhesively bonded joints. The mathematical background of statistical methods is very briefly explained in this section. See other textbooks (e.g., Montgomery 2008) for more details.

Imagine the case in which there are many samples having their own attributions. For instance, adhesively bonded specimens can be regarded as the samples, and they have strengths as the attributions. The attributions can be often treated with numerical values. A graph, in which the number of samples within a particular range of the numerical value is plotted, as shown in Fig. 1, is called histogram. In this figure, the abscissa axis denotes the range of strength, and the axis of ordinate signifies the number of samples. The summation of the histogram is obviously equal to the total number of the samples.

It is empirically known that a histogram becomes a type of symmetrical shape as shown in Fig. 1 if the sample number is large enough and its attributions are random events such as strength of materials or dimensions of machined parts, for example. If the axis of ordinate is normalized with the total sample number and the attribution range is minimized, the histogram reaches asymptotically a curve called normal distribution or Gaussian distribution as shown in Fig. 2 that is plotted with the function as follows:

**Fig. 1** A schematic illustration of histogram and the shape change with respect to sample members' increase

**Fig. 2** A schematic illustration of normal distribution

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left\{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2\right\} \quad (1)$$

where  $x$ ,  $\mu$ , and  $\sigma$  denote attribution values, average values, and standard deviations of the sample population that can be defined by the following Eqs. 2 and 3:

$$\mu = \frac{1}{n} \sum_{i=1}^n x_i \quad (2)$$

$$\sigma = \sqrt{\frac{1}{n} \sum_{i=1}^n (x_i - \mu)^2} \quad (3)$$

The abscissa axis of normal distribution curves is called random variables, and its ordinate signifies probabilistic density that is equivalent to the existence probability of samples per unit range of the abscissa axis. The existence probability of samples within a particular range ( $a \leq x \leq b$ ) can be calculated with the following Eq. 4. The integration of existence probability through the whole range is obviously equal to 1:

$$P(a \leq x \leq b) = \int_a^b f(x) dx = \int_a^b \frac{1}{\sigma\sqrt{2\pi}} \exp\left\{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2\right\} dx \quad (4)$$

The existence probability of samples within a symmetrical range of  $\pm k$  from the average  $\mu$ , which is denoted as  $P(\mu - k \leq x \leq \mu + k)$ , can be also calculated with the following Eq. 5:

$$P(\mu - k \leq x \leq \mu + k) = \int_{\mu-k}^{\mu+k} \frac{1}{\sigma\sqrt{2\pi}} \exp\left\{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2\right\} dx \quad (5)$$

For instance,  $P(\mu - k \leq x \leq \mu + \infty) = \frac{1}{2}\{1 + P(\mu - k \leq x \leq \mu + k)\}$ , and  $P(\mu - 3\sigma \leq x \leq \mu + 3\sigma) = 0.9973$ . Therefore, 99.73% of samples exist within the range of  $\mu \pm 3\sigma$ . Imagine a situation where the average strength of joint specimens is 20 MPa and the standard deviation is 3 MPa. In this case, 68.26% of the specimens are within the strength range of 17–23 MPa, 95.45% are within 14–26 MPa, and 99.73% are within 11–29 MPa, respectively. In the final case, the ratio of the samples out of the range ( $\mu \pm 3\sigma$ ) is very small because it is 0.27%.

When the reliability of adhesively bonded joints should be considered, joints too weak in strength are out of use. However, too strong joints are not problems. Therefore,  $P(\mu - k \leq x \leq \mu + \infty)$  is more crucial than  $P(\mu - k \leq x \leq \mu + k)$ . The relations between them can be shown as follows:

$$P(\mu - k \leq x \leq \mu + \infty) = \frac{1}{2}\{1 + P(\mu - k \leq x \leq \mu + k)\} \quad (6)$$

Some problems happen when the statistical methods derived above are actually applied to the reliability evaluation of products. At first, all products cannot be inspected. The most usual method is sampling inspection. Thus, it is necessary to predict the average and standard deviation of a population from a small number of samples inspected. This process is called “statistical estimation.” For instance, strength tests of adhesively bonded specimens are adapted to this process because relatively small number of specimens such as five or ten are usually used in order to “estimate” the statistical properties of a large population. The process has been investigated very much. Unfortunately, the method is not versatile because obtaining precise information from few specimens is difficult. Enough number of samples is necessary for determining the precise statistical properties.

### 41.3 Basic Requirements for Highly Durable Adhesion

Highly durable adhesion has to include such capabilities as high strength, low strength scatter, and high resistance to environmental and loading conditions. To realize a highly durable adhesion, an indispensable requirement is cohesive fracture, by which fracture occurs not along the interfaces between the adhesive layer and the adherends but only in the adhesive layer. Table 1 shows the experimental results of acoustic emission (AE) measurement in the case of tensile tests using lap-shear specimens (Haraga 2008). The percentage of the ultimate load corresponding to the first AE occurrence and the total number of AE counts up to fracture are shown. This result implies that interfacial fractures happen at a lower stress than that of cohesive fractures because AE occurs in the case of interfacial fractures much earlier than in

t.1 **Table 1** Percentage of the ultimate load corresponding to the first occurrence of acoustic emission (AE) and total counts of AE until the fracture for different failure conditions (interfacial fracture or cohesive fracture) in adhesively bonded joints

t.2	Fracture condition	Sample no.	Percentage of ultimate load corresponding to the first AE count	Total AE counts until fracture
t.3	Interfacial fracture	1	7%	25
t.4		2	8%	17
t.5		3	31%	117
t.6		Average	15%	53
t.7	Cohesive fracture	1	51%	19
t.8		2	76%	11
t.9		3	100%	1
t.10		Average	76%	10

**Fig. 3** A typical relation between joint strength and cohesive fracture ratio (cohesive fracture area/total adhesion area (C/T)) where the total number of experiments (n) is 1213

140 the case of a cohesive fracture. Since cyclic loads or heating cycles tend to cause  
141 stress concentrations around the edges of interfaces due to the loads applied and the  
142 thermal stresses, they cause interfacial fracture with a low strength and the joints fail  
143 under relatively low loads and short cycles (Haraga 1992).

144 A typical relation between cohesive fracture ratio (cohesive fracture area/total  
145 adhesion area (C/T)) and joint strengths is shown in Fig. 3. In this case, the total  
146 number of experiments (n) is 1213. There is a threshold in joint strength around 40%  
147 of the C/T. Below a C/T of 40%, the number of weak joints increases. Weak joints are

**Fig. 4** Relation between the coefficient of variation CV, the dispersion coefficient D, and the allowable defective ratio (1-R) in strengths of adhesively bonded joints

very rare for a C/T over 40%. A highly durable adhesion can be realized if the C/T of a joint is over 40% just after its production process.

The other index of adhesion durability is the coefficient of variation (CV) that is defined as the standard deviation divided by the average strength. Adhesively bonded joints show a fairly good correlation between the CV and the C/T. A low CV under 0.15 is necessary, and 0.10 is desirable for highly durable adhesion. Interfacial fracture increases the CV. A large CV condition over 0.2 gives unreliable joints and should be avoided (Haraga 2008).

Figure 4 shows the CV and the dispersion coefficient (D) in a case of adhesive joints (Haraga 1992; Teramoto et al. 1993; Nakajima et al. 1997). D is defined as a factor that is multiplied with average joint strength, and this product gives the maximum strength of defectives as shown in Fig. 5, where R is yield ratio of useable joints and 1-R is allowable defective ratio. For instance, when 1-R is 1/100,000 and CV is 0.15, D can be determined as 0.36 with Fig. 4. This case indicates the condition of a sample having a strength lower than 36% of the average joint strength among 100,000 samples. If CV is 0.2 and 1-R is 1/100,000, D becomes 0.15, and this case is obviously not a reliable design. A basic and important rule about reliable design of adhesively bonded joints is the management of C/T under 40% and CV under 0.15.

**Fig. 5** A schematic illustration of the relation between the average bonding strength  $F_\mu$ , the allowable defective ratio  $1-R$ , and the dispersion coefficient  $D$

## 41.4 Important Points for Adhesion Process Control

### 41.4.1 Dimension Allowance of Parts Bonded Adhesively

#### Substrate Deformation

A serious error in the adhesion process is to ignore the dimension allowance of the substrate. Some members are often machined beyond their specified dimension allowance indicated in the design drawing. As shown in Fig. 6, a required flat surface Fig. 6a can be deformed as Fig. 6b or c. The hat cross-sectional member shown in Fig. 7a can be finished in the cross section as Fig. 7b or c due to bad bending forming or can be spring-backed as Fig. 7d or e. Such deformations cause strength deviation due to nonuniform adhesive thickness or bad adhesive spreading or defective goods due to the tilt of the bonded parts.

#### Applied Pressure to Parts in the Bonding Process

Pressure has to be applied to parts during the curing process of adhesives. In this process, excess pressure applied to the members shown in Fig. 7a can induce undesirable deformation as shown in Fig. 7b. Conversely, in the case of Fig. 7c, the member can deform by excess pressure and take the shape shown in Fig. 7a. The deflected members shown in Fig. 7c, d are flattened by pressurization. In such cases, a spring-back force is induced when the applied pressure is released after the

**Fig. 6** Undesirable shape of the bonding surface due to machining

**Fig. 7** Undesirable deformation of hat members due to plastic forming (**a**) no deformation, (**b**) concave deformation in the flange, (**c**) convex deformation in the flange, (**d**) convex deflection, and (**e**) concave deflection

184 bonding process because residual stress occurs due to the permanent deformation.  
185 The spring-back forces act as creep loads to adhesive joints. Creep rupture often  
186 happens not only in the case of weak adhesives such as pressure-sensitive adhesives  
187 at ambient temperature but also in the case of strong adhesives if they are subjected  
188 to high temperatures during a paint-baking process, for instance.

### Environmental Condition Control

Temperature and humidity have to be controlled appropriately during the cure reaction of adhesives. In summer, ambient curing adhesives need a quick operation in bonding process because their gelation time is short. In winter, since gelation time is longer, the time of pressure application is also longer. To avoid the variance of operation and keep the sequence constant, temperature control using air conditioners is highly recommended. Humidity control is also very important, especially when using humidity-cured adhesives or sealants, such as instantaneous adhesives or silicone adhesives. Sometimes, humidity is not “desirable” but rather “indispensable,” and it is necessary to increase humidity when it is very low. On the contrary, in the case of two-part urethane adhesives, the strength decreases due to the foam formation in the adhesive layer, which tends to happen especially in hot-wet conditions, if the operation time from adhesive application to bonding is long, as shown in Fig. 8. Therefore, dehumidification is recommended in such cases. In addition, since polyol components in urethane adhesives tend to absorb water very much, seal-up of adhesive container is also very important.

Dew condensation on the surface of substrates before bonding is another problem. The dews can corrode the surface before bonding and inhibit adhesive tack. Just

**Fig. 8** Strength variation of joints bonded with a two-part ambient curing urethane adhesive with respect to the foam formation conditions, where open time is the time from adhesive application to lapping adherends, in which the substrates are kept in ambient condition

after the start of room heating in winter, cold members may cause dews on their surfaces. Therefore, humidity control is also necessary in this situation.

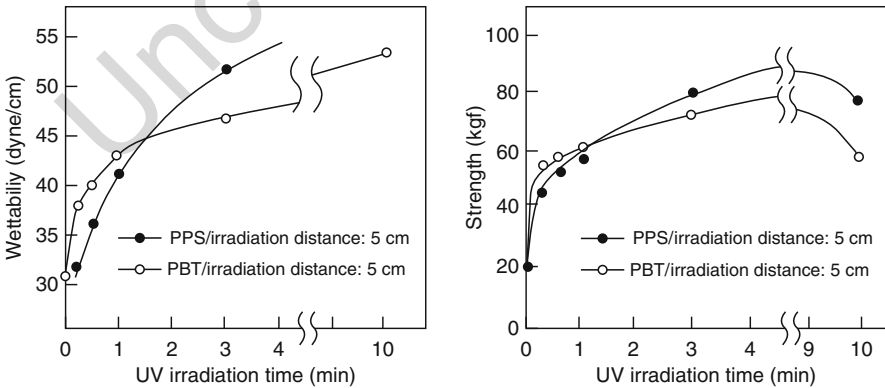

### 41.5 Management and Preparation of the Bonding Surface

#### 41.5.1 Wettability Measurement of the Bonding Surface

The surface condition of substrates before bonding depends on the production lot, the shelf condition, and the storage period. Even if the surface is degreased with solvents or chemicals before bonding, it is not necessarily suitable for adhesion. As a method to evaluate the adhesion adequateness easily, wettability tests can be applied using standard liquids commercially available. It is reasonable to measure the wettability of substrates by random inspection once in each morning and afternoon or every time the production lot changes. Experimentally proved minimum value of wettability for proper adhesion is 36–38 mN/m, where the wettability is denoted as surface tension. The use of parts having poor wettability is never accepted. Action to improve the wettability has to be carried out.

#### 41.5.2 Surface Treatment to Improve Adhesion Adequateness

It is frequent that low wettability surfaces influence badly the production line of the goods. It is desirable to introduce surface treatment processes to low wettability materials such as thermoplastics. For instance, short wavelength UV irradiation with low-pressure mercury lamps and ambient pressure plasma irradiation are popular for the purpose. Even short-term irradiation can improve the wettability of surface very much and the bond strength increases, as shown in Fig. 9.

**Fig. 9** Variations of wettability and strength of polyphenylene sulfide (PPS) and polybutylene terephthalate (PBT) with respect to UV irradiation

**41.5.3 Primer Coating**

To improve adhesion strength, primer coating can be applied on the surface of members. Generally speaking, a thin primer layer is advantageous in adhesion compatibility rather than a thick layer, as shown in Fig. 10. Thicker primer layers decrease bond strength. However, too thin primer layers lead to a problem of spreading defect. Applying primer coating properly with a spray or brush is quite difficult and leads to considerable variation in bond strength. Therefore, the use of low-density solution primers is recommended because a light amount of primer is left on the surface even though an excess of solution is applied.

**41.5.4 Pot Life of Adhesives**

Quick-curing adhesives have short pot lives, which are often shorter than the total time of the bonding process including adhesive mixture, application, joining, and pressurization. Therefore, when the total time is too long, the joint strength decreases, as shown in Fig. 11. Bonding time control is very important in such cases. The control can be done, for instance, using a timer having a ring or light signal capability. The timer has to be turned on when adhesive mixing starts. Operators should finish their work by the ring or light signals indicating the end of time tolerance.

**Fig. 10** Relation between adhesion strength and applied amount of primer coating

**Fig. 11** A typical strength variation of lap-shear joints bonded with a two-part ambient curing modified acrylic adhesive with respect to time from the mixture to the application of the adhesive

**Fig. 12** Verification of adhesive spreading and curing using inspection holes

**41.5.5 Verification of Adhesive Spreading and Curing After the Bonding Process**

It is often requested but not easy to verify the spreading and curing conditions of adhesives in joints after the bonding process. An usual method is to check the amount of spew and its hardness. Another one, which is more sophisticated, is the inspection hole method shown in Fig. 12. In this method, a hole is machined in one adherend to confirm the amount of adhesive and its curing condition. If

enough amount of adhesive is applied and is spread properly along the surface, a spew can be found from the hole, and the curing condition of the adhesive can be checked by pushing the spew. This method is available even when side spews do not form.

#### 41.5.6 Inspection

The performance of structures bonded adhesively is assessed with strength tests of samples selected randomly or dummy samples. If testing machines are not available in factories, alternative test methods that should be easy to carry out are necessary. Unfortunately, such cases are not rare because testing machines are expensive. Figure 13 shows an example: a simple peel test using a manual testing machine of reasonable price, consisting of a roller and a lever (Haraga et al. 2009). The curing situation of adhesive and the C/T are used as the criterion of the test, and C/T should be greater than 40% to pass the inspection. When testing machines are available, the strength of samples can be used as the criterion.

**Fig. 13** Manual testing machine consisting of a peel roller and a handle lever for peel tests of specimens

### 41.5.7 Process Design

#### Optimum Process Layout of Automatic Devices and Manual Operation

Although a fully automatic bonding process including adhesive application and joining of adherends is possible, it is hard to check visually the mixture condition, the applied amount of adhesive, and its application patterns. Imaging technologies are, of course, possible to use recently. However, there are several problems in terms of cost and accuracy so far. A combined process of automation and manual work is very efficient for such situations. For instance, adherend joining can remain a manual operation to check the adhesive condition mentioned above, which is helpful to avoid defects.

#### Adoption of a Sequential Process

An advantage of manual operation is the availability of a sequential process from adhesive mixture to pressurization. This whole process can be carried out continuously by one person. On the other hand, a parallel process is dangerous because the pot life of the adhesive applied to many queuing parts can be attained if the production line stops before the joining process. Since automation needs a parallel process, a waiting system for the adhesive application, which is activated when the following processes consume too much time, has to be installed.

---

## 41.6 Additional Efforts to Ease Process Quality Control

### 41.6.1 Reduction of Operator's Tasks

The quality of products depends not only on the process control but also on the operator's attentiveness. Therefore, the reduction of operator's tasks is very important. Too excess loads are not acceptable. The process should be designed to ease manual works. Refinement of product design is also effective to reduce difficulties in adhesive joining.

### 41.6.2 Foolproof

Mistakes done by operators are another problem. For instance, the adhesive bonding of different parts having similar configurations can cause mistakes. Errors about bonded sides, positions, or alignment of parts must be avoided too. For such cases, it is a good idea to make bumps and dimples (or holes) to facilitate the joining, as shown in Fig. 14. To control the position and the pattern of the combination, side matching, directional alignment, and positioning of parts can be conducted easily.

**Fig. 14** Foolproof method to prevent operators' mistakes of bonding sides, positions, or alignment of parts using bumps or dimples (or holes); (a) without this method, (b) with this method

### 41.6.3 Use of Adhesives with an Easy Process Control

#### Use of Oil Accommodating Adhesives

Surface cleaning of adherends is vitally important for good adhesion, and it influences the performance of the joints. Recently, oil-accommodating adhesives, which can be used directly for oily surface, are available. Two-part acrylic adhesives (SGA) and some types of one-part thermosetting adhesives have this capability. Surface cleaning processes can be omitted, and scattering of bond strength can be reduced using this type of adhesives.

The use of oil-accommodating adhesives has the advantage that steel parts can be stored in oiled condition and degreased before bonding is no longer necessary. The oil prohibits the stains on the surface of the steel parts that can reduce the bond strength. The whole process is also simplified very much.

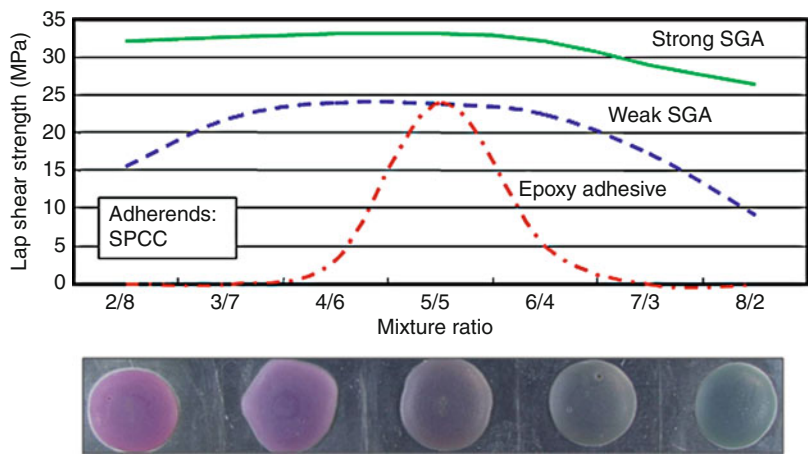

#### Use of Adhesives Tolerant to Wide-Range Mixture Ratios

Two-part ambient-setting acrylic adhesives (SGA) have wider permissible ranges in terms of mixture ratio than two-part epoxy adhesives, as shown in Fig. 15 (Denki Kagaku Kogyo Co., Ltd 2009). Even if the mixture varies, or the adhesive parts are applied individually on each surface, the bonding strength is not so much influenced because of radical polymerization. The use of adhesives insensitive to mixture ratio is convenient to simplify the control of the mixture process.

#### Use of Visually Checkable Adhesives

Mixture ratios of two-part adhesives can be visualized to assign the proper colors to the adhesive parts, as shown in Fig. 15. In actual production lines, sample color tables are helpful for operators to check the mixture ratio.

Innovative adhesives, whose color can be changed with respect to cure progress, are recently available. Figure 16 shows the color change of a two-part ambient-setting acrylic adhesive: NS700 series (Denki Kagaku Kogyo Co., Ltd., Japan) (Tomioka 2010). The colors of the two parts of the adhesive are white and black before mixing. The adhesive becomes green after mixing the two parts. The color

**Fig. 15** Relation between mixture ratio of adhesive parts, lap-shear strength, and variation of adhesive colors (SGA second-generation acrylic adhesive, SPCC cold rolled steel sheet)

**Fig. 16** Colors change depending on the polymerization time in the case of a two-part ambient curing modified acrylic adhesive: NS700 series (Denki Kagaku Kogyo Co., Ltd., Japan)

changes to brown when gelatification starts and to dark brown after full curing. It is possible for operators to check visually the mixture and the curing conditions of adhesives with this method.

### Use of Adhesives Including Spacers

The adhesives shown in Figs. 15 and 16 include plastic fillers as spacers to keep the bond-line thickness constant. The use of such adhesives is very helpful to control the thickness without particular attentiveness.

## **41.7 Education and Training**

### **41.7.1 Operator's Education and Qualification**

Appropriate education for operators is indispensable for a work of good quality in adhesion processes. At first, a process manual book has to be written. Apparatus, materials including adhesives and solvents, procedures, and inspection methods have to be indicated comprehensibly using pictures or photos. Not only the standard working methods and conditions but also the maximum and minimum values of permissible allowance for each condition must be indicated in the procedure description. Determination criteria to pass the inspection should be indicated with specific samples. Prohibited actions have to be indicated explicitly.

Lectures and training for operators should be given using the process manual book. The reason for minimum and maximum criteria must be explained appropriately so that operators can understand them entirely, and there should be no "black box" in the processes.

For operators providing adhesion works at vitally important sites, theory, practice, and examinations are mandatory. The operators passing the examinations can be approved as qualified operators. Only the qualified operators have to be appointed to carry out adhesion processes at important sites.

### **41.7.2 Thorough Exchange of the Information About Process Changeovers**

Processing procedures, methods, and conditions must not be altered by each operator. If any processes shown in the manual book need to be changed to improve the performance, the operator has to inform the manager in advance. The suggestion must be investigated by the manager with the process designer. If the suggestion is worth to be employed, the process can be changed after the authorization of the process and the revision of the process manual book. This rule is indispensable, and all operators must be obligated to comply it.

## **41.8 Conclusion**

For the processing quality control of adhesively bonded joints, scientific approach based on both probabilistic design and statistical treatments is necessary. For decreasing the ratio of defective joints, the coefficient of variation (CV) of the samples should be kept small. The cohesive fracture ratio (C/T) of fractured joint surfaces is vitally important to keep CV small. Since the cohesive fracture ratio decreases often due to mechanical or chemical mismatch of adherends and adhesives, the surface treatment of adherends is important.

Process design should be done appropriately to improve the efficiency and the economy of the lines and to increase the yield ratio of products. The use of sequential

processes, reduction of operator's tasks, and foolproof for workers are also very important and should be introduced in the production process.

The condition of adherend members, adhesives, and process environments are changing continuously with time. Care should be taken to the change and establish flexible adhesion processes and procedures that can meet the change. Therefore, adhesion process should have high adaptivity to the conditional change. The process design should be done as such. The methods shown in this chapter are just typical examples, and other particular efforts must be necessary for each practical process. Reexamination of actual processes in terms of increasing the yield ratio of products having adhesively bonded joints is also essential.

The education and training of operators are effective investments to avoid making defectives and stopping the production line. Inspection of goods is not only the final barrier of shipping defective products but also the first stage of quality control actions.

## Abstract

The objective of any system of nondestructively examining an adhesive joint is to obtain a direct correlation between the strength of the joint (howsoever defined) and some mechanical, physical, or chemical parameter which can readily be measured without causing damage to the joint. Faults may be defined as anything which could adversely affect the short- or long-term strength of a joint. There are two basic areas for examination in properly made joints, the *cohesive* strength of

the polymeric adhesive and the *adhesive* strength of the bond between the polymer and the substrate. In addition, voids, disbonds, and porosities create an additional issue for inspection.

During the production phase, and also in service with critical structures, it is essential to use nondestructive tests to assess the quality and fitness for purpose of the product. The nondestructive test will not measure strength directly but will measure a parameter which can be correlated to strength. It is, therefore, essential that a suitable nondestructive test is chosen and that its results are correctly interpreted. Typical defects found in adhesive joints are described and an indication given of their significance. The limits and likely success of current physical nondestructive tests will be described and future trends outlined.

It is shown that a variety of techniques are available for disbond detection, ultrasonics, and different types of bond tester being the most commonly used. These techniques are very time-consuming, especially if large bond areas are to be tested. Monitoring interfacial properties is much more difficult, and there is currently no reliable test after the joint is made although there are some indications of a possible way forward using high-powered lasers.

---

## 42.1 Introduction

Adhesive bonding offers the designer many advantages, especially in being able to join dissimilar materials without bolts, rivets, etc. (Adams et al. 1997). However, despite its potential advantages, the use of adhesive bonding in safety critical structures has been limited by a lack of adequate nondestructive testing (NDT) procedures: Without such procedures, the reliability of a structure cannot be guaranteed. When using advanced composites, adhesive bonding is often preferred because these materials have low transverse tensile and local bearing strength. The problem comes when it is found to be necessary to define how strong the joint is. While there are certain situations when it is possible to be reasonably confident of the initial strength of a joint if it has been carefully made by a well-established process and there is a record of previous destructive tests, this cannot be guaranteed for the lifetime of the joint. If we add to this the possibility of joints being made incorrectly, we quickly come to the conclusion that there is a need for a technology to determine the strength of a joint without breaking it. This is called nondestructive testing, evaluation, or inspection, usually abbreviated to NDT, NDE, or NDI. Such testing will usually be performed after manufacture or at stages during manufacture. However, in more stringent applications, inspection during service may also be required.

Ideally, a nondestructive test would predict the strength of the bonded joint and its susceptibility to environmental attack. This is very difficult to achieve, partly because a direct measurement of strength cannot be nondestructive, so it is necessary to correlate strength with other properties, such as bond area, interfacial stiffness, etc. Also, the stress distribution in a typical adhesive joint is far from uniform, and so the strength is much more sensitive to the integrity of some areas of the joint than to

**Fig. 1** A simplified schematic diagram showing the various layers in an adhesive joint

others. Measuring bond area, stiffness, and so on will not necessarily give good correlations with strength. Changes in these properties do, however, give an indication that a joint may be defective.

In order to understand the nondestructive evaluation of the strength of an adhesive joint, we need to understand the mechanics, physics, and chemistry which are involved in the production and stressing of such a joint. The details of these factors are given elsewhere in this book, so only a brief description will be given here. A bonded joint generally consists of two adherends or substrates, connected by an adhesive layer. However, it is vital to understand that there are also two surfaces and that adjacent to these is an interphase region such that the adhesive properties do not change abruptly to those of the adherend. These different zones are shown schematically in Fig. 1. The most commonly used form of adhesively bonded joint is in tensile lap shear, as shown schematically in Fig. 2. Many theories have been used to analyze the stresses in bonded joints (see ► [Chaps. 24, “Analytical Approach,”](#) and ► [26, “Numerical Approach: Finite Element Analysis”](#) in this book), but the essence is shown in Figs. 3 and 4. Here, it can be seen that the shear and peel (transverse tensile) stresses are a maximum at the joint ends, while the middle of the joint generally has low stresses. Failure is therefore going to begin at these joint ends and then propagate toward the interior of the joint until total failure occurs. Another important class of adhesively bonded components is in repair patches, particularly for aircraft. It is often cost-effective and convenient to apply a patch rather than to replace an aircraft component, particularly if the need to repair is remote from the source of the component (Pyles 2003; Baker et al. 2009). Since the repair is often

**Fig. 2** Schematic diagram of a single-lap joint bonding adherends of thickness  $t$  and width  $b$  with an overlap  $l$

**Fig. 3** Variation of shear stress with distance along the overlap according to Volkersen's theory

**Fig. 4** Variation of transverse tensile stress (peel) with distance along the overlap according to Goland and Reissner's theory

made in non-factory conditions, it is important to be able to carry out some form of nondestructive inspection before releasing the vehicle back into service.

There exists a wide variety of nondestructive testing techniques for interrogating structures. These range from well-known methods such as ultrasonics and X-rays to a variety of specialist methods such as shearography, tapping, and thermal. However, it must be stressed that many of the techniques used with metallic structures are quite unsuitable for use with bonded joints. Various authors have reviewed the literature on nondestructive testing of bonded joints. The reader is referred to Hagemaijer (1985), Guyott et al. (1986), Adams et al. (1987), the special edition of NDT International which was edited by Adams and Cawley (1988), and recently by

Cawley (2005). Crane and Dillingham (2008) have provided an excellent review of adhesive bonding with composite materials.

The objective of this chapter is to describe the mechanics and physics of the main NDE methods for adhesively bonded joints and to indicate what is possible and not possible.

## 42.2 The Nature of Defects in a Joint

It is instructive at this stage to examine the types of defect which may occur in bonded structures. First, let us consider lap joints in which the bonded area is a few square centimeters or more. Figure 5 illustrates many of the possible defects.

*Porosity* is caused by volatiles and entrained air in the adhesive. The voids may also be due to products of the chemical reaction[s] involved in curing the adhesive. Porosity is therefore present in most bond lines to some extent. *Adhesive cracks* are due to problems with curing (cure and/or thermal shrinkage) or to large applied stresses, either one-off or repeated (fatigue). Local areas of *poor cure* are due to incorrect mixing of the adhesive system. Larger areas, possibly extending through the whole bond line, are either due to incorrect mixing, incorrect formulation, or insufficient thermal exposure. Sometimes, poor cure is self-correcting with time in that the chemical reaction continues, albeit slowly. Voids are often due to air becoming trapped by the pattern of laying the adhesive or to insufficient adhesive being applied. Voids can also be caused by relative movement of the adherends

**Fig. 5** An illustration of the various defects which might be present in an adhesive bond line

**Fig. 6** Void in adhesive bond line most probably caused by moving the joint before the adhesive had reached a sufficient state of cure

during the curing process. Large voids cannot be caused by volatiles, unless something is very wrong with the adhesive system. Figure 6 shows what can happen in a tubular joint when the adherends are moved before the adhesive has reached a stage in its cure cycle when it has hardened sufficiently. The voids offer a path for the ingress of water or other fluids and fatigue crack initiation (see ► [Chap. 33, “Fatigue Load Conditions”](#) in this book). *Surface unbonds* are an alternative form of void, often caused when adhesive is applied to one adherend only and unevenly. The most dangerous form of these can occur where the adhesive and adherend are in contact, but there is no significant bond strength between them. Such defects may be caused by poor surface preparation, failure to remove the manufacturer’s backing film completely, a loose substrate, and so on. Such bonds are called *zero-volume unbonds* or *kissing bonds*. While the latter term is commonly used today, it implies there is a bond, whereas, in fact, there may be no bond at all, or only a very weak one. Jeenjitkaew et al. (2010) and Marty et al. (2004) have given an excellent description of the causes and morphology of kissing bonds. Galy et al. (2017) and Jeenjitkaew and Guild (2017) feature among various authors who have tried to make realistic kissing bonds and then to devise methods to test them. *The main problem is to be able to make these joints so that they are representative of true structures. Only then can the process of testing them move forward.*

The presence of defects in lap joints is more indicative of poor joint manufacture than of impending failure, especially for short-term loading. Over the long term, defects may allow faster ingress of water or aggressive substances or provide sites for fatigue crack nucleation. It still, therefore, remains necessary to look for these defects. Karachalios et al. (2013) have shown that the strength of lap joints may or may not be affected significantly by large voids in the interior of a lap joint. This is because fracture initiation in the adhesive occurs due to the failure strains in many

**Fig. 7** Variation of failure load with defective area for single-lap joints bonded with AV119 adhesive showing how the lap-shear strength is a function of adherend type and remaining bond area (From Karachalios et al. 2013)

**Fig. 8** A sketch of honeycomb bonded to a skin and showing the fillet (From Adams et al. 1997)

adhesives being much less than the yield strains of structural steel or aluminum. However, if high-strength alloys are used with modern rubber-toughened epoxies, the lap joint strength is more or less proportional to the bonded area. This is shown in Fig. 7.

The other major form of joint used with structural adhesives is the T joint used in bonding honeycomb to the skins as shown in Fig. 8. The skin and core are bonded by a large number of these lightly stressed joints. It is essential that the adhesive forms a generous fillet, as shown in Fig. 9a, and not the apparently more economical but weaker joint shown in Fig. 9b. Some years ago, the author tried to stiffen an

**Fig. 9** Good and bad bonds between honeycomb and skin  
(From Adams et al. 1997)

aluminum alloy honeycomb core by filling with a polyurethane foam. This was then scraped down to the level of the honeycomb and the bond made. Unfortunately, the foam prevented the formation of the fillet, and the joint failed at a low load. With bonded honeycomb structure, the major defects consist of a lack of attachment between the core and the skin. This may be due to several causes such as locally crushed honeycomb (Fig. 10a), skin defects (Fig. 10b), or lack of adhesive (Fig. 10c). In themselves, none of these defects may reduce the short-term joint strength. However, as for the lap joint, they may show poor preparation and may provide sites for fatigue crack propagation.

## 42.3 Tests Carried Out Before Bonding

In order to make a successful adhesive joint, it is vitally important that the surfaces to be bonded should be properly prepared. Usually, this means clean, chemically active, and sufficiently strong. We therefore need surface inspection tests to ensure that the surfaces do not contain excessive amounts of water vapor, hydrocarbons, or other contaminants. Today, there exist many powerful laboratory tools for assessing surface properties. However, these are rarely used in manufacturing environments since they are slow and expensive.

A simple test involves the wettability of the surface, by measuring the contact angle. A full discussion of surface preparation and wettability is given in Part B in this book. If the surface is clean, it is readily wetted, and a drop of water will spread

**Fig. 10** Possible defects with honeycomb core and skin system (From Adams et al. 1997)

over a large area. However, if it is contaminated, the water will remain as droplets. A useful procedure with carbon-reinforced or glass fiber-reinforced plastics is to abrade the surface with a fine “wet and dry” carborundum paper until a thin film of water can be spread over it. A more quantifiable test involves measuring the spread of a liquid drop of constant volume through a transparent gauge placed over the drop or by looking at the “contact angle” between the drop and the surface. Commercial products are also available which will indicate the suitability of the surface for bonding by showing as colored. These self-indicating primers also contain substances to enhance the bond between the surface and the adhesive. The main problem is the uncertain life expectancy and stability of these primers.

The Fokker Contamination Tester, described by Bijlmer (1978), uses an oscillating probe to measure the electron emission energy. This varies greatly with the degree of surface contamination and can even be used to detect residues from alkaline cleaning operations.

None of these methods is totally satisfactory, and the best means of ensuring that a “good” surface exists prior to bonding is carefully to control the processes leading to its preparation, having previously established “good practice.” Maintaining good control over the manufacturing process will increase the probability of achieving a defect-free joint, and this is particularly important in the case of adhesive strength for which no satisfactory nondestructive testing method currently exists (Schliekelmann 1972; Kim and Sutliff 1978).

Crane and Dillingham (2008) claim that the tape peel test (in which a PSA tape is pressed on to a surface and then peeled off) offers an approach that is potentially inexpensive which could be implemented in a fast-paced production environment. Unfortunately, there is insufficient data at this time on the wide range of possible contaminants and the possible levels of concentration for this approach to be applied without further testing. However, it does offer an approach to providing the NDE engineer an important tool to access the adhesion potential of a composite surface before the consolidation of a component.

## 42.4 Testing After Bonding and During Service

By far the majority of nondestructive testing (NDT) techniques associated with adhesive bonds are applied after the joint has been made and are usually carried out at the manufacturing location or during service. Most techniques are void detectors, and, although it is claimed that the cohesive strength of the adhesive is being assessed, this is unlikely to be the case.

### 42.4.1 Ultrasonics (Pulsed)

The monitoring of ultrasonic echoes forms one of the most widely used methods of nondestructive testing for bonded joints and composites. The method is commonly used for the detection of disbands, voids, and porosity.

An incident pulse of ultrasound will be reflected and transmitted (assuming normal incidence and hence no refraction) at each interface of the joint. The amplitudes of the reflected ( $R$ ) and transmitted ( $T$ ) pulses for a unit amplitude incident signal are dependent on the acoustic impedances of the materials on either side of the interface and are given by

$$R = \frac{Z_2 - Z_1}{Z_1 + Z_2} \quad (1)$$

$$T = \frac{2Z_2}{Z_1 + Z_2} \quad (2)$$

where  $Z$  is the acoustic impedance given by  $\rho c$ ,  $\rho$  is the density, and  $c$  is the speed of sound in the material under examination. Subscripts 1 and 2 denote the materials on the incident and remote sides of the interface, respectively.

If a defect is assumed to contain air or any other low-density substance, it will have a very low acoustic impedance relative to the adhesive or adherend. A pulse incident at the defect is almost totally reflected, leaving negligible energy to be transmitted through the defect. Measurement of the reflected or transmitted energy may therefore be used to indicate the presence of a defect. The simple ray model of a pulse of ultrasound being specularly reflected at a defect is valid when the defect

**Fig. 11** Schematic of ultrasonic pulse in through-transmission mode (From Adams et al. 1997)

diameter is about one wavelength or larger. Porosity typically comprises pores which are orders of magnitude smaller than the wavelength. Therefore, porosity does not give simple specular reflection but scatters energy in all directions, thus attenuating the propagating pulse.

Various techniques based on ultrasonics are used in connection with adhesive joints. Essentially, a small piezoelectric crystal is pulsed repetitively, causing it to radiate high-frequency sound waves at the natural frequency of the crystal. Normally, these brief wave trains (about five cycles long, at 1–20 MHz and repeated say 1,000 times/s) traverse the joint and can be detected, either by using the same crystal or by using a separate receiver (Fig. 11). By interrogating the change which has taken place in the wave train, it is possible to deduce various characteristics of the structure through which it has traveled. The probes have to be correctly aligned and care must be taken so that the pulse will not be reflected or diffracted by curvatures in the surface. If the adhesive contains imperfections such as roughness, cracks, or porosities, the waves will be scattered, and less will be detected by the receiver. If there is a void, the wave can be partially or totally reflected, again reducing what is transmitted. Fine detail can be revealed, if at all, only by using focused or otherwise concentrated “beams” and intelligent analysis.

In ultrasonic inspection, there are two basic techniques which are commonly used, through transmission and pulse echo. The *through-transmission* technique monitors the amplitude of an ultrasonic pulse transmitted through the joint. The amplitude can be reduced effectively to zero when a disbond larger than the beam width is present, smaller amplitude reductions being seen in the case of porosities, microcrackings, disbonds, and voids whose plan area is smaller than the beam width.

**Fig. 12** Water-jet probe  
(From Guyott et al. 1986)

The technique uses separate transmitting and receiving transducers, positioned on either side of the structure to be tested. Alignment of one transducer with the other is vitally important and can present difficulties when large components are tested. Alignment of the transducer axis perpendicular to the surface to be tested, however, is not as critical as with other techniques. Through transmission is often used for the production inspection of large structures such as aircraft fuselage and wing sections, coupling generally being achieved with water jets, such as shown schematically in Fig. 12. The method is also particularly suited to the inspection of honeycomb structures. Using a pulse-echo technique (see below), only the bonding of the top face to the core can be tested reliably, whereas using through transmission, both top and bottom bonds between skins and core can be inspected in a single test. However, through transmission is not generally suitable for in-service inspection since access to both sides of the structure is often difficult or impossible and the attenuation and reflections even in “good” structure can be sufficiently large to render the technique of little value. Also, while it gives an indication that a defect exists, no information about its depth within the structure can be obtained. The *pulse-echo* technique generally uses a single transducer as both the transmitter and receiver. Provided the ultrasonic pulses generated by the transducer are short enough, the individual echoes from each interface can be resolved, their position and amplitude being used to detect the presence of a defect. A large fraction of the pulse will be reflected at a defect owing to its large reflection coefficient; echoes from features behind the defect will also be reduced or disappear.

It is also possible to use a single transducer in a “double through-transmission” configuration. This is achieved by placing a reflector plate beneath the structure in an immersion tank as shown in Fig. 13 and monitoring the echo from the reflector plate.

**Fig. 13** Water bath used for ultrasonic C-scan inspection  
(From Adams et al. 1997)

As in through transmission, this signal is almost completely attenuated by disbands larger than the beam, smaller amplitude reductions being produced by voids, porosities, and smaller disbands. In all pulse-echo testings, alignment of the transducer axis perpendicular to the surface of the structure or reflector plate is important if the reflected signal is to be received back at the transducer. Sometimes, a second receiver probe is used instead of the reflector, the two probes being linked by a yoke. This is often necessary with honeycomb structures since the returning signal is very weak and is swamped by the much more powerful reflected signals. The probe is traversed automatically over the structure, and the amplitude of the signal associated with transmission through the structure is indicated on an *X-Y* or similar recorder. The *X* and *Y* coordinates correspond to the position on the surface, while some other parameter, such as gray scales or false color, is used to indicate quality. Because of the inconvenience of immersing the whole component or specimen, special water-jet probes can be used on large (aerospace) structures. Again, probe alignment is a serious problem.

Good coupling between the transducers and the structure is essential and can be achieved by pressing them together with a film of glycerine or some similar coupling agent between them. Liquid couplants have the disadvantage of affecting the surface if this is in any way absorbent. Alternatives include laser-induced and monitored ultrasonics (Monchalín 1993) and air-coupled probes (Farlow and Hayward 1994; Schindel and Hutchins 1995). Other non-contacting ultrasonic transducers include electromagnetic acoustic transducers (EMATs) (Thompson 1990). Another method is to use a rubber wheel (Drinkwater and Cawley 1994) which can be rolled over the surface. The mechanical characteristics of the rubber are carefully chosen for maximum impedance matching and minimum attenuation.

Several methods of displaying ultrasonic reflections are available, the most common being *A*- and *C*-scans. The simplest presentation is an *A*-scan which shows the amplitude of the signal as a function of time (or distance, if a value for the velocity of sound in the medium is known), as shown in Figs. 14 and 15. In manual testing, an *A*-scan is obtained at each test point and is interpreted by the operator.

If the amplitude of the through-transmitted signal (or of a particular echo in pulse-echo testing) is monitored at each point on the surface of the test piece, a *C*-scan can be produced. Measurements at each point are taken using a scanning mechanism, which produces a plan of the defect positions but gives no information on their depth. The example of Fig. 16 shows a *C*-scan of an adhesive joint sample roughly 100 mm square that had been subjected to environmental attack. Large edge

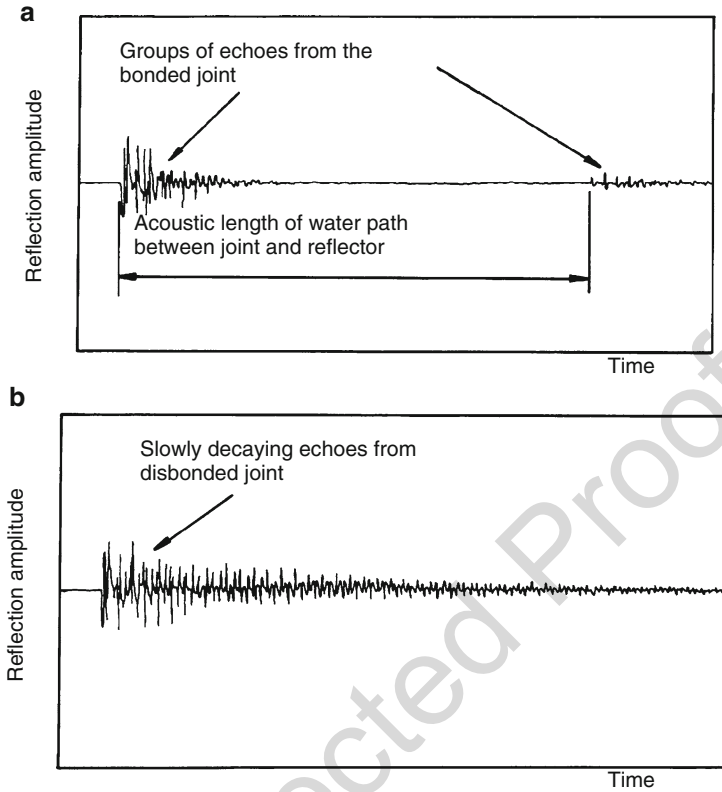

**Fig. 14** Schematic of A-scan from a good joint (From Guyott et al. 1986)

disbonds can clearly be seen, together with groups of small disbonds remote from the edges. Corrosion of the aluminum on one side of the sample that was unbonded is also evident. The automatic scanning mechanisms required to produce *C*-scans usually employ immersion or water-jet coupling, whereas *A*-scan devices often use the contact technique. Portable scanning frames to facilitate *C*-scans on site are also available commercially.

Other ultrasonic techniques which show promise are oblique incidence waves (Pilarski et al. 1990) and Lamb waves (Bork and Challis 1995). Rose and coworkers (1995, 1996; Puthillath and Rose 2010; Rose and Ditri 1992) have used guided ultrasonic waves to detect defects in adhesively bonded joints. Gowini and Moussa (2016) used surface acoustic waves to investigate the change in surface acoustic wave (SAW) phase velocity due to the change in adhesion of a thin film using an aluminum nitride (AlN)/silicon (Si) SAW sensor. They showed that as the adhesion of the film weakens on the surface of the AlN/Si SAW sensor, the velocity dispersion profiles fluctuate since as the adhesion of the layer improves the stress transmitted increases and the wave is more confined in the film layer. Gauthier et al. (2017) Used Lamb waves and showed that modes could be very sensitive to the nature of the interface, that is to say to the level of adhesion, if properly selected.

#### 42.4.2 Sonic and Ultrasonic Vibrations

In the through-thickness direction, an adhesively bonded joint can be regarded as an oscillating system. In its simplest form, the system consists of two masses separated by a spring [the adhesive]. Any variation from a given standard might be thought to indicate the presence of a defect. Unfortunately, the system is more complex than

**Fig. 15** A-scans from (a) good and (b) disbonded joints (From Guyott et al. 1986)

this. For instance, a reduced stiffness of the adhesive layer might be due to porosity, non-optimum cure, cracks, or simply a thicker layer than usual. On the other hand, if the joint was in a panel which was consistently produced by using a film adhesive to control the bond-line thickness, then any variation in frequency would indicate a defect of some sort, although it would not be easy to ascertain of what kind.

Sonic vibration techniques, using frequencies of 1–30 kHz, measure the local stiffness of the structure. Disbonds reduce the local stiffness as measured perpendicular to the surface. Usually, only disbonds or voids can be found, the minimum detectable size depending on the size and depth of the defect. Although the detectable defect size is larger than that obtained using ultrasonic techniques, the tests are often more convenient since they do not require a couplant between the transducer and the test structure.

Commercially available mechanical impedance measuring instruments generally take measurements at a single preset frequency. The impedance is highest over good areas and lowest over disbonded areas. The test becomes unreliable when the structure itself becomes more flexible as the impedance of a defective zone can be higher or lower than that of a good zone, depending on the frequency (Cawley 1984,

**Fig. 16** C-scan of joint after environmental attack showing large edge disbonds and smaller disbonds remote from edges (From Vine et al. 2001)

1988). One advantage of this type of test is that, instead of using a couplant, a dry point contact is used between the transducer and structure. This dry contact has a finite stiffness (Lange and Teumin 1971) which must be kept as high as possible, to maximize the sensitivity of the technique.

A different principle is used in ultrasonic resonance testing. Here, thickness vibrations are induced in the adherend/adhesive/adherend sandwich in which the two adherends are considered to act as rigid masses, while the adhesive is an almost massless spring. If the type and thickness of the metal sheets are constant, then the resonant frequency is a function of the thickness and bulk modulus of the adhesive.

By injecting short pulses of broadband ultrasound (0.5–15 MHz) into a bonded panel and using modern digital techniques to obtain a frequency spectrum in “real time” of the structural response, it is possible to observe differences between good and bad structures. Lloyd and Brown (1978) showed that certain phenomena, such as water absorption, can be readily detected by this method.

A general preview of vibration techniques for testing composites and adhesives is given by Cawley and Adams (1987).

#### 42.4.3 Spectroscopic Methods

Ultrasonic spectroscopy or the measurement of the through-thickness vibration characteristics of an adhesive joint can be used for the nondestructive testing of

the cohesive properties of the adhesive layer (Cawley and Hodson 1988). The modulus of the adhesive can be determined from measurement of the through-thickness natural frequencies if the thickness of the adhesive layer is known. The Fokker Bond Test Mk II (Schliekelmann 1975), which uses a spectroscopic measurement, is the only commercially available instrument which claims to indicate the cohesive properties of the adhesive in a joint. Frequency and amplitude changes in the first two modes of through-thickness vibration of a system comprising the transducer and the joint are measured. These parameters depend on both the adherend and the bond-line thicknesses as well as the material properties. The range of frequencies over which the instrument operates is typically between 0.3 and 1.0 MHz. Small voids and disbonds at different depths in a multilayer joint can be detected reliably. However, prediction of the cohesive strength of the adhesive is questionable (Guyott et al. 1987) since the frequency shifts, resulting from a change in cohesive properties or bond-line thicknesses, are small and of a similar magnitude to each other. Thus, to obtain a true measure of the cohesive properties with this instrument, the bond-line thickness must be kept constant (or be measured separately). Roth and Giurgiutiu (2017) used piezoelectric wafer active sensors which were permanently bonded to the aircraft structure. Electromechanical impedance spectroscopy, a local vibration method, was used to detect disbonds from the changes in the mechanical impedance of the structure surrounding the disbond. The main problem with this method is the need to bond the sensors in a sufficient number of places to provide a realistic NDE method.

#### 42.4.4 Other Acoustic Methods

Tapping the structure with a hammer or coin is one of the oldest methods of nondestructive inspection. This is essentially a subjective method, and there has been considerable uncertainty about the physical principles involved. When a structure is struck with a hammer or coin, the impact depends on the local impedance of the structure and the hammer used. The local change in structural stiffness produced by a defect changes the nature of the impact. This is indicated by the force-time history of the impact on the structure which can be measured by incorporating a force transducer in the hammer. Impacts on good and disbanded areas of an adhesively bonded structure are shown in Fig. 17. Characteristically, the impact on the sound structure has a higher peak force and a shorter duration than that on the damaged area. Thus, a measure of either peak force or duration can be used to locate defects. Since the method uses only measurements of impact force, no transducers need to be attached to the structure, thus avoiding the coupling and alignment problems which arise with ultrasonic techniques (Cawley and Adams 1988, 1989). The sensitivity and reliability can be increased by further processing the force-time histories such as by taking Fourier transforms of the signal to present the data in the frequency domain (force vs. frequency). Hart-Smith and Thrall (1985) recommend the coin-tap test since it is unable to find flaws that are so small that they can be ignored anyway!

**Fig. 17** Tapping with an instrumented hammer over a good and a disbonded joint

#### 42.4.5 Acoustic Emission

Application of stress to a material will eventually lead to microscopic fracture or slip (Curtis 1982). This is usually associated with a local release of energy which propagates as a stress wave. The wave has a high-frequency content and is referred to as “acoustic emission” [or stress wave emission] which can be detected either by a high-frequency microphone or by a piezoelectric transducer. Unfortunately, it is necessary to stress the joint to a high proportion of its failing load in order to generate sufficient emissions, and there is doubt whether this is practical in most cases. It is therefore not recommended for general use although there are occasions where it may be effective.

#### 42.4.6 Thermal Methods

By heating one surface of a bonded sandwich structure and observing the temperature rise of the opposite face, areas of debond, which resist the transfer of heat, show as cool areas. Alternatively, if the heated face is scanned, debonds will show as hot areas.

The temperature rise on the heated surface is governed by the amount of energy deposited and the speed of application, combined with the thermal properties of the surface material. If the thermal pulse is short enough, the ensuing diffusion process is totally controlled by the material itself. The contrast observed at either surface due to the presence of defects depends on the defect size, its depth from the observed surface, the initial surface temperature rise, and the thermal properties of the material. While these parameters change from one specimen to another, the testing technique is always to record the temperature variation of either surface directly after the thermal transient has been applied. Temperature differences caused by the presence of defects may be seen over timescales ranging from sub-millisecond to

several seconds, depending on the material properties and thickness. The useful information is often obtained within 500 ms, so it is necessary to use a system which can acquire many sequential images in this time window.

The equipment required to perform transient thermography falls into two categories: the transient heat source and the thermal imaging/analysis system. The heat pulse must have a sufficiently fast rise time to provide a rapid temperature rise since it is the steepness of the temperature gradient which provides the contrast between defective and non-defective areas. In materials of high thermal diffusivity [the ratio of thermal conductivity to mass density] such as metals and carbon composites, this rapid temperature rise can conveniently be provided by discharging several kilojoules of energy from a bank of capacitors through xenon flashtubes which are directed at the area of interest. For poor thermal conductors such as glass fiber composites, the rate of heating produced by hot-air blowers is frequently adequate. Temperature sensing is normally done with a scanning infrared camera. Heat pulses or moving heat sources were used by Reynolds (1988). Temperature-sensitive paints of liquid crystals and thermoluminescent coatings can also be used. High-power lasers can be used, but care must be taken to avoid causing damage to the surface.

Major improvements in thermal imaging equipment have been made in recent years. Early work on the method used a thermal imaging camera whose output was recorded on a video tape, the analysis being performed on the recorded image using slow-motion replay and freeze-frame facilities. (The technique was once called pulse video thermography (Hobbs et al. 1991).) Now the images are stored digitally, and automatic processing routines are available (Shepard 1997).

In general, the sensitivity of the method is reduced as the depth of the defect from the surface monitored by the thermal imaging camera is increased. The sensitivity is best expressed as the defect diameter/depth ratio required for the defect to be detectable. This sensitivity is material specific and must be determined experimentally using specially fabricated test plates containing flat-bottomed holes of different diameters and depths. Typical values of the ratio of minimum detectable defect diameter to defect depth are 2–4 for metals (Hobbs et al. 1994). The performance in carbon fiber composite may be somewhat poorer than this because the composite has higher conductivity in the plane of the fibers than in the through-thickness direction. The heat therefore tends to diffuse parallel to the surface, rather than through the thickness, and so is less affected by the presence of disbands or delaminations that run parallel to the surface. However, there is a wide variety of sensitivities reported in the literature on carbon fiber composites (Hobbs et al. 1994). In general, the best results are obtained if the maximum possible amount of energy is deposited on the surface of the structure, though care must be taken to avoid thermal damage.

Conventional X-ray techniques are of little use on metal-to-metal bonded joints since the polymeric adhesive is much less dense than the adherends. Metallic fillers (Segal and Kenig 1989) can be used to enhance the contrast and show tapering or voids. However, the density of fiber-reinforced plastics adherends is of a similar order to the adhesive and so X-rays can be used, by choosing a suitable energy and flux. For honeycomb-cored panels, X-rays are used for checking the position of the

core and whether it has been locally crushed or otherwise damaged and to monitor the position of water ingress.

A thermal neutron source can also be used (Michaloudaki et al. 2005) since neutrons are absorbed or scattered by hydrogenous materials such as hydrocarbons. Unfortunately, such sources are typically nuclear reactors and accelerators, and so are neither cheap nor readily available!

Tighe et al. (2016) interrogated carbon fiber-reinforced plastic (CFRP) single-lap joints to compare the detection of different defect types using pulsed phase thermography (PPT). A PTFE insert, of the type widely used to simulate defects in composite materials, was added to the bond line of the joint. Liquid layer kissing defects were simulated using silicon grease. PPT clearly identified the PTFE insert but not the silicon grease contamination. PPT identified the silicon grease defect when the joint was loaded, probably because loading opens the defect and produces a gap that provides sufficient thermal contrast for detection.

#### 42.4.7 Optical Holography

By using holographic interferometry, it is possible to measure surface displacements to less than 0.5  $\mu\text{m}$ . Load is applied to a structure by vibration, vacuum cup, pressure, or heat. Defects show as local perturbations in the holographic interferogram (Rao et al. 1990). The technique has found application with sandwich structures but not lap or similar joints.

#### 42.4.8 Visual

Hart-Smith and Thrall (1985) recommend a visual inspection of the adhesive fillet and suggest it is the most effective of all inspection techniques for bonded joints. The state of the fillet is a good indication of the state of the adhesive at the end of the joint. A porous fillet indicates too high a heat-up rate or the presence of moisture in the joint. A lack of fillet indicates a lack of pressure and may indicate internal voids. Just as the water-break test is an indicator of the adherend surface, the contact angle of the cured adhesive at the end of the fillet, formed when the adhesive was liquid, indicates if surface contamination is present.

---

### 42.5 Future Developments

The major problem with nondestructively assessing the strength of adhesively bonded joints remains the so-called kissing bond, in which there is continuity, but little or no strength. Many years ago, the author tried to generate a high-intensity tensile stress pulse which would fracture a kissing bond. Using mechanical impact, it proved impossible to achieve a sufficiently short-duration pulse which could be reflected as a tensile pulse in a thin adhesive joint. Gupta and coworkers (1990;

Gupta and Yuan 1993; Yuan and Gupta 1993, 1998) used high-intensity lasers to create tensile shock waves which could fracture weak bonds between a coating and a substrate. Bossi and coworkers at Boeing (Bossi et al. 2002, 2004, 2009, 2011) also tried to generate high-intensity, short-duration stress pulses to fracture these kissing bonds in adhesively bonded joints. After experimenting with flash electron beams, they settled on high-intensity lasers which gave pulses of a few hundred nanosecond duration. With joints made using carbon fiber-reinforced plastic (CFRP) adherends, they were able to distinguish bond quality on surfaces created with different peel ply preparations such as polyester and nylon fabric and surfaces prepared with contamination using a silicone release agent. When examined with conventional ultrasonics, these joints appeared to be identical. The technique developed by Bossi et al. is to use a laser-induced pulse to fracture a weak kissing bond and then to use conventional ultrasonics to detect this fracture. They have developed the technique for application to real aircraft structures. Monchalin 2007 has also worked on this method. The problem is to fracture a weak bond while not fracturing an otherwise good bond and to leave it in such a state so that it can be seen using conventional ultrasonics. The technique is interesting and seems to offer a way forward.

---

## 42.6 Conclusions

The types of defect encountered in adhesive joints and the nondestructive testing techniques available to detect them have been reviewed. Several techniques are available for disbond detection, the most commonly used being ultrasonics and different types of bond tester. These techniques are very time-consuming if large bond areas are to be tested; so there is increasing interest in rapid scanning methods such as transient thermography. The detection of poor cohesive properties is more difficult but can be achieved with ultrasonic or dielectric measurements. Monitoring interfacial properties is much more difficult, and there is currently no reliable test after the joint has been made. The high-intensity laser method is the only possible technique at the moment, but this needs a lot of development before it might become commercially acceptable.

Finally, we still need to correlate measurable defects with actual strength in the way in which joints are used, that is, in the tensile lap-shear mode where the main stresses are at the joint ends. Since the middle of the joint is relatively lowly loaded, detection of voids in the middle may indicate poor production and a possible leakage path, but it may not necessarily indicate a weak joint.

## Abstract

Fracture observation is one of the key ways to understand the behavior of bonded assemblies. The plural science of bonded assemblies includes three main areas such as polymer sciences, physical chemistry of surfaces and interfaces, and mechanics. Solving the equation of adhesion needs intersection of all these aspects. Moreover, this multi-physics science is also a multi-scale one. Understanding surface fracture deals with all these aspects. This chapter presents three types of measurement systems: microscopy, compositional analysis/material identification, and mechanical observations. A table sums up an exhaustive list of the major observation devices and precise references of works that use these types of methods. Then, the main methods are detailed with macroscopic and mesoscopic observations, microscopic observation, physicochemical analysis, and mechanical observations.

## 43.1 Introduction

One can wonder why people are so interested on the failure mode of bonded assemblies. One reason is probably the need for manufacturers and users in various industrial fields to trust in this technology of multi-material assemblies. Users are very often interested in having cohesive failures in the adhesive, mainly for a reason that is not so objective. The idea is linked to the need to have predictable failures. So, cohesive failure means that physical phenomena happen in the “material” of the adhesive. It seems to be easier to predict it than with the contribution of the interfaces. However, sometimes these failures occur at the interface with interesting strength, etc. So, how can we understand these fractures?

### 43.1.1 Structural Bonding, a Plural Science

By definition, a bonded structure is composed of two substrates connected together by a bonding agent called the adhesive. This bond defines two interfaces connecting each other the substrates to the adhesive. The assembly made of the adhesive and the

**Fig. 1** Structure of an adhesive joint made of two interfaces and the adhesive

**Fig. 2** Structural bonding, a plural science

two interfaces constitutes an adhesive joint. Figure 1 presents a very schematic view of this structure. The analysis of this structure, therefore, requires understanding the behavior of each constituent: adhesive, interfaces, and substrates. Each of these elements, by its essence, contributes to influencing the response of such a structure subjected to mechanical loading.

### 43.1.2 The Need for a Plural Science to Solve the Equation of Bonding

Structural bonding is a plural science. Representing it, in a schematic way, is not easy as the domains linked to structural bonding interpenetrate. Figure 2 presents the problem to solve for finding an acceptable solution for the behavior of a bonded structure. The solution is defined in the center (in white). This area is the overlap of three strong scientific domains: the science of polymers (1), the physico-chemistry of surfaces and interfaces (2), and mechanics (3). Understanding and being able to predict the behavior of a bonded structure mean being able to cover and interact with

these three areas. This plurality makes difficult, but nevertheless very interesting, the problematic of structural bonding.

### **Area of Polymers Science (1)**

Adhesives are for the most part polymers. Polymers constitute a class of materials in their own. Because these materials possess dissipative processes, they are very useful for bonded assemblies. They are generally characterized by high breakage energies.

### **Area of Physico-chemistry of Surfaces and Interfaces (2)**

The notion of interface defines the boundaries of a domain. Indeed, the field of application of the “science of polymers” is limited because of the presence of the two substrates. These polymer/substrate boundaries provide an interface that needs to be understood. An adhesive is not only a polymer, but it is also a material with an adhesive capacity. Understanding of the phenomena of adhesion requires analysis on several scales. Several concepts from the molecular scale up to the macroscopic scale are thus studied. Total adhesion is generally analyzed by decomposition into mechanical adhesion, physical adhesion, and chemical adhesion. Mechanical adhesion incorporates the notions of wetting, mechanical anchoring, and diffusion/interdiffusion. Physical adhesion is concerned with the different forces that interact at short and long distances (van der Waals, electrostatics, etc.). Finally, chemical adhesion is concerned with covalent bonds. Numerous references highlight the complexity of these phenomena and theories on adhesion.

### **Area of Mechanics (3)**

The last domain proposed to solve the equation of bonding is mechanics. The problems proposed by the industry must meet a specification. This document specifies under which conditions and under which constraints the bonded assembly must resist: durability, environment, stress rates, temperatures, fracture loads, etc. The difficulty of this field is, therefore, to be able to propose means of characterization and prediction of the mechanical strength of the assembly.

## **43.1.3 Interactions Between These Areas**

The solution of the structural bonding problem requires a very wide range of skills which are difficult to dissociate from one to another. Thus, in order to show these interactions, Fig. 2 defines three subdomains marked “A, B, and C,” highlighting these interactions between the “science of polymers,” the “physico-chemistry of surfaces and interfaces,” and “mechanics.” The intersection of these interactions constitutes an approach for solving the problem of structural bonding. Initially, several decades ago, these interactions were weak. Today, these areas are increasingly interacting. The best marker of this evolution is the organization of congresses around adhesive bonding which often revolve around two parallel sessions, one physico-chemistry and the other rather mechanical.

**Fig. 3** Representation of a polymer-metal interphase (Coulaud 2007)

**43.1.4 What About the Role of Interfaces**

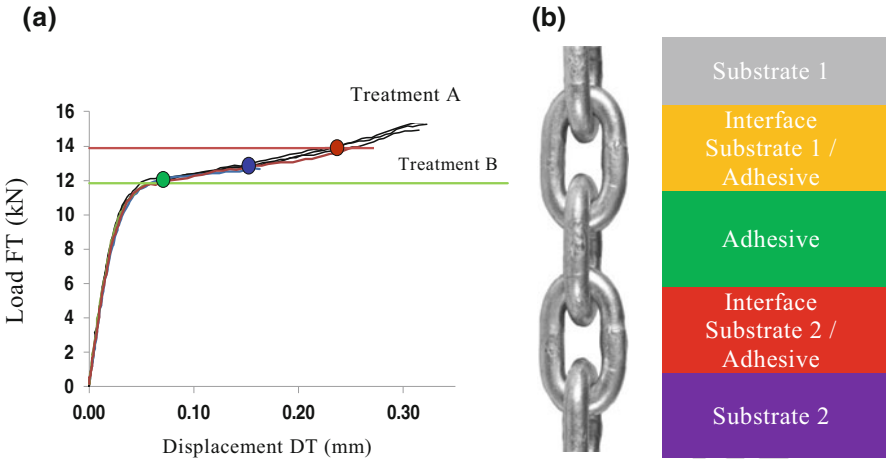

The analysis of the failure modes of bonded assemblies differs from the “classical” analyses of materials by the eternal question, what is the role of the interfaces?

**Example of Structure: Polymer/Metal Interface**

The interphase is a geometric boundary that defines the transition between the adhesive and the polymer. This zone is characterized by numerous physical, chemical, and mechanical phenomena. Figure 3 presents a sectional view of this bonding zone (Coulaud 2007). The structure is characterized by numerous layers from the substrate (1) to the polymer (6): the surface layer of the substrate (2), a layer resulting from surface treatments (3), a contamination layer (H<sub>2</sub>O, CO<sub>2</sub>, etc.), and a layer of polymer modified by the substrate (5). This structure is specific to the nature of the materials used (substrate and polymer) as well as to the manufacturing process. It is therefore necessary to question its influence on the macroscopic behavior observed.

**Example of a Macroscopic Behavior**

Figure 4 shows the influence of interfaces on the macroscopic behavior of adhesives (Arnaud 2014). For Hysol<sup>®</sup>-EA9309.3NA adhesive, modified Arcan shear tests were performed. Two treatments were compared. The first is an unclogged sulfur anodizing treatment. The second treatment comprises corundum abrasion 220 followed by an anti-stick treatment. The same curing cycle was applied to the adhesive. For treatment A, the maximum load reached is close to 16 kN, and the maximum displacement at break is approximately 0.3 mm. The observed behavior is nonlinear and identical for the three tests performed. For the specimen with anti-adhesion, the nonlinear behavior followed is the same. For the second, load and displacement at failure are considerably lower. Moreover, for the three tests carried out, the displacements at break (visible with the green, blue, and brown dots) are dispersed. Given the plasticity of the adhesive, the fracture loads are similar. For all six tests, the failure is adhesive. This example clearly highlights the contribution of interfaces to the response of a bonded joint. Figure 4b shows the multilayer structure of an adhesive joint: the adhesive, the two interfaces, and the substrates. Vallat (2013) symbolizes the contribution of this structure as a chain composed of five

**Fig. 4** Macroscopic role of interfaces on the behavior of an adhesive in an assembly: (a) demonstration of the influence of surface treatment on modified Arcan shear tests (Arnaud 2014) and (b) multilayer structure of a bonded joint (Vallat 2013)

links. Each link is an important element. It is the failure of one of these links, placed in series, which generates the failure of the whole assembly.

### 43.1.5 The Importance of Multi-scale and Multi-physics Observations

As a consequence of the structure of bonded assemblies itself, to understand fracture, it is necessary to use multi-scale and multi-physics observations. In this chapter, most of these methods are presented.

### 43.1.6 The Importance of Observation on the Understanding of the Physics of Failure

#### Structural Adhesives Are Sources of Defects

The manufacturing process generates intrinsic defects during the production of the bonding. Adams characterizes these defects (see ► Chap. 42, “Nondestructive Testing”). Figure 5 presents the various defects observed. They may be bound to the surface preparation with areas having adhesion defects, with or without kiss bonding. These defects can be related to macroscopic porosities: absence of adhesive or to microscopic porosities. They can also be linked to the polymerization process: cross-linking defects, cracks generated during shrinkage, and cross-linking gradient. As a consequence, the modes of failure are a manifestation of different physics which can be observed in the fracture surfaces.

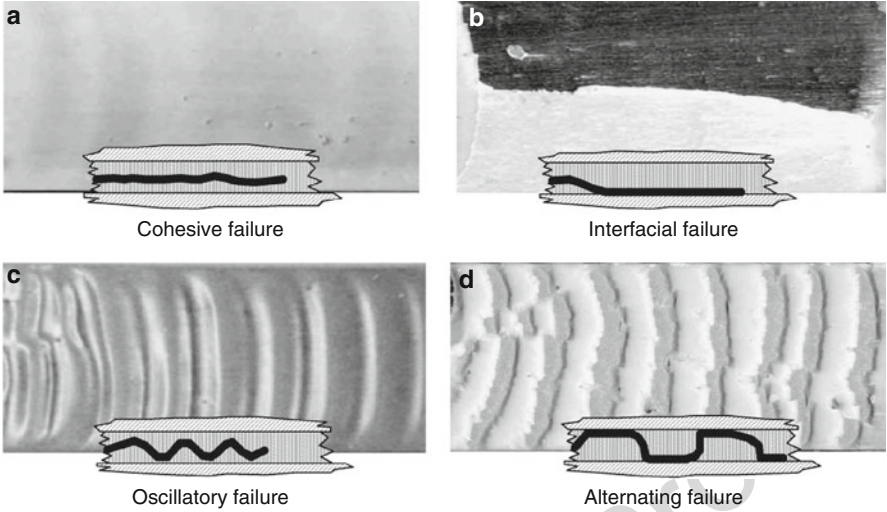

**Fig. 5** Various defects which might be present in an adhesive bond line (Adams see ► Chap. 42, “Nondestructive Testing”)

**Fig. 6** Tensile tests on bulk samples: (a) Dog-bone samples, (b) Air bubbles in the section (Arnaud 2014)

### Example of an Application: Dog-Bone Tensile Specimen

Dog-bone tensile specimens are classical tests to characterize the mechanical properties: Young’s modulus and Poisson’s ratio. Arnaud et al. (2015) carried out these tests. Figure 6 presents the stress-strain curves. A linear behavior is firstly observed and then a nonlinear one. Tests were performed with a crosshead speed of 0.5 mm/min. Though special care was considered to manufacture the specimens, all the fractures occurred near a porosity observed in Fig. 6b. This is a very simple example, but it highlights the need to well understand physics to explain the behavior observed. This analysis starts with the observation of the fracture surface. This chapter is dedicated to the different means to observe fracture in adhesive bonds. The main message that must be understood by the reader is the fact that observation setups are closely related to the comprehension of the physics observed.

**Fig. 7** Different locus of failure and crack trajectories observed in mode I testing of adhesively bonded double cantilever beam (DCB) specimens. (a) Cohesive failure, (b) Interfacial failure, (c) Oscillatory failure, (d) Alternating failure. (Chen and Dillard 2001)

## 43.2 The Difficulty of Identifying an Adhesive or Cohesive Failure

### 43.2.1 Presentation of the Different Modes of Failure

Chen et Dillard (2001) presented in their work different kinds of failures for adhesively bonded assemblies. Four types can be distinguished (Fig. 7): failure in the adhesive, also called cohesive failure or failure at the interface between the adhesive and the substrate. These modes are commonly observed and very easy to determine. Two types of failure called oscillatory and alternating failures also exist as described in Fig. 7c, d.

### 43.2.2 Subjectivity of the Analysis

Figure 8 presents two specimens after failure. The test considered was a modified Thick-Adherend Shear Test that applied shear loadings to these interfaces (Cognard et al. 2011a). Two surface treatments were used: mechanical preparation with abrasion followed by acetone degrease and chemical treatment. With the first surface treatment, the failure is fully adhesive. With the second one, the failure is mainly cohesive (around 90% cohesive). Therefore, determining the role of the interface on the strength at failure seems to be quite easy. Figure 9 shows failure

**Fig. 8** Influence of the surface preparation on the failure mode for an epoxy adhesive: (a) results with a mechanical preparation and (b) results with a chemical one (Cognard et al. 2011a)

**Fig. 9** Failures in single-lap joints with steel substrates: (a) fully adhesive failure, (b) 50% cohesive failure, (c) mixed mode adhesive-cohesive failure (Legendre et al. 2016)

surfaces for single-lap shear tests with hard steel sheet metal substrates with a zinc coating (Legendre et al. 2016). The failure is adhesive (Fig. 9a) and mixed-mode adhesive/cohesive in Fig. 9b. The main question that can be asked is about the surface described in Fig. 9c. How is the cohesive failure defined? If there are blue areas on both sides of the joint, it is easy to determine a cohesive failure. However, looking close to the interface, a “white” zone can be observed: a close adhesive failure zone. It seems that in this zone the interface transmitted the kinematic deformation of the substrate to the adhesive and after that broke. Research is still under way to determine whether this area can be defined as cohesive or not. It depends today on the country and on the industrial field where it is considered. One element in discussion is the fact that it is possible to predict or not a reliable strength at failure with this type of fracture surface.

### 43.2.3 A Multitude of Experimental Setups to Try to Understand the Failure of Bonded Assemblies

The purpose of this chapter is not to give a detailed and exhaustive list of methods of analysis but to propose multi-scale and multi-physical analysis methods to analyze the failure of bonded assemblies. Thus, the following table gives a non-exhaustive list of characterization setups used in the three domains of bonded assemblies described above. Three types of analyses can be considered despite some recovery.

- Microscopy techniques are used to mainly observe at different scales surfaces and adhesives from the millimeter (macroscopic observation) to the nanometer. These observations were in the past realized in two dimensions. Nowadays the third dimension can be more easily considered thanks to confocal microscopy or X-ray micro-tomography systems.
- The second domain is used to analyze the composition and the identification of the material. These ones are mainly physicochemical analysis based on thermal and spectroscopy applications.
- The third domain is based on the comprehension of the deformation of the bonded assemblies to understand fracture. It is mainly linked to kinematic observations in order to define the localization of the mechanical failure process.

Table 1 presents these three domains. References of recent works are listed for each analysis. Only certain methods are described later in this chapter more precisely.

## 43.3 Macroscopic and Mesoscopic Optical Observations

### 43.3.1 Failure Surfaces

#### Within the Adhesive

The load path influences the failure mode within the adhesive. Créac'hcadec et al. (2014) characterized the behavior of a thick flexible adhesive (Sikaflex-265) under different monotonic tensile/compression-shear loads, using a modified Arcan fixture, which was designed to limit stress concentrations in order to define an experimental methodology enabling structural adhesives to be characterized up to failure. The results allow defining the load and displacement envelopes characterizing the adhesive to failure under multiaxial loading conditions.

For the different tests, cohesive failures were observed around the median plane of the adhesive (Fig. 10). These fracture surfaces underline the good quality of the cohesion between Sikaflex<sup>®</sup>-265 and ABS substrates using Sika<sup>®</sup>Primer-206 G+P. It seems that a specific fracture pattern characterizes each test configuration. The load direction seems to determine the topography of the fracture pattern. For tensile tests, fracture surfaces are smooth and have a fault in the center of the surface as well

**Fig. 10** Fracture patterns of the adhesive in bonded assemblies for tensile/compression-shear tests: (a) tensile test, (b) shear test, (c) traction-shear test, (d) compression-shear test (Créac’hcadec et al. 2014)

as a V-shaped line at one of the ends of the sample (Fig. 10a). The analysis of the patterns represented in Fig. 10b shows clearly rhombus shapes. Small streaks are also observed associated with a failure at different levels in the adhesive thickness when loaded under shear. Under tensile-shear loads (Fig.10c), the failure mode is quite similar to the case of tensile loadings; the tensile part of the load seems to govern the failure mode. Moreover the tangential displacement at failure is lower

under tensile-shear loads than under shear loads. Fracture patterns under compression-shear (Fig. 10d) show a rough surface where streaks are more pronounced and denser than during the shear loading situation. The fracture path is not straight and very irregular as the adhesive has been ripped out locally associated with the compression part of the load.

### Adhesive/Cohesive Mixed-Mode Failure Surface

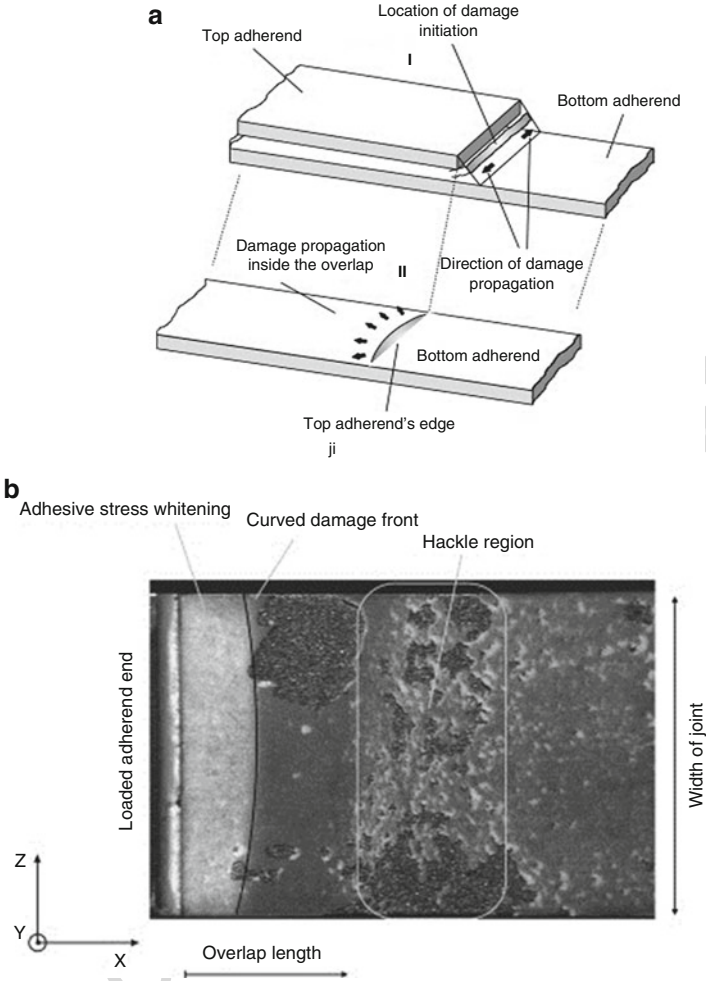

The load path also affects the type of failure, i.e., adhesive failure close to the interface or cohesive failure in the adhesive. Arnaud et al. (2015) made similar modified Arcan tests for a bicomponent epoxy adhesive. The main part of the work was to identify the influence of the water aging of bonded assemblies. The fracture surfaces shown in Fig. 11 present the initial mode of failure without aging. They observed that in tension, the failure was mainly cohesive for the unaged state. Then, it became partially cohesive during aging. But at the last aging time, it was again fully cohesive. This evolution seems to indicate that the interface was slightly affected by humid aging in tension. However, it was not clear enough to conclude on a real interfacial degradation. In the other loading directions, the failure is mainly adhesive and does not reveal any evolution during aging (Fig. 11b–d).

## 43.3.2 The Importance of Local Geometry on Adhesive Joint Failure

One way to understand fracture surface is to know where the fracture initiated. A lot of works were made to understand the contribution of the free edges of bonded assemblies. These zones are mainly the reasons of failure in adhesive joints. Karachalios et al. (2013) explained the failure process of single-lap shear tests with the localization of damage initiation at the extremity of the substrate in the middle of the test specimen. The failure process then develops on each side of bonded joint to finally reach to interface (Fig. 12a). This analysis was obtained thanks to the fracture surface observed (Fig. 12b). This study was carried out with ductile substrates and adhesives.

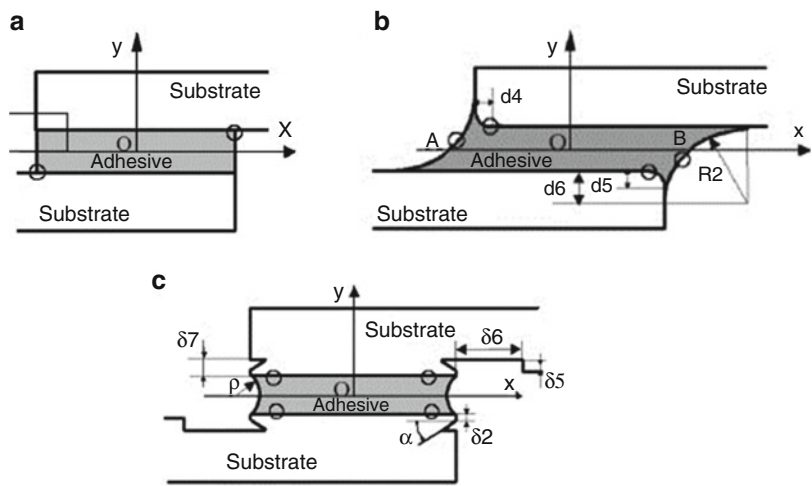

**Fig. 11** Fracture profiles of the modified Arcan test during seawater aging; results are presented for the initial fracture surfaces (Arnaud et al. 2015): (a) tensile test, (b) shear test, (c) traction-shear test, (d) compression-shear test

**Fig. 12** Failure mechanism in single-lap shear test: (a) Description of failure mechanisms for ductile adhesives, (b) failure pattern of a 60 mm overlap with AV 119 adhesive (Karachalios et al. 2013)

Understanding the contribution of the free edge is very important. To analyze these geometries, finite element methods are very useful and used. Cognard et al. (2011b) analyzed the influence of some geometrical parameters on the stress concentrations in the case of the single-lap joints (Fig. 13). The stress concentrations can contribute to fracture initiation in the adhesive joints and thus can lead to an incorrect analysis of the adhesive behavior. Therefore, understanding the stress distribution in an adhesive joint can lead to improvements in adhesively bonded assemblies. This study was accomplished using finite element simulations under elastic assumption using refined meshes and using a pressure-dependent model, which accurately describe the elastic limit of the adhesive. It has been shown that geometries used

**Fig. 13** Influence of local geometry on the strength at failure (“o” zone of maximal equivalent stress in the adhesive under elastic assumption): (a) straight geometry, (b) geometry with a chamfer, (c) geometry with beaks (Cognard et al. 2011b)

in various studies in order to reduce the influence of edge effects can generate quite large stress gradients close to the adhesive-free edges.

Specific geometries can significantly limit the influence of edge effects .The use of substrates with beaks and a cleaning of the free edges of the adhesive allow a large reduction in the stress state close to the free edges of the adhesive and thus allow an optimization of the maximum transmitted load in single-lap joints. The numerical results underline that the overlap length and the adhesive thickness also have an influence on the stress distribution in the joint. Moreover, it has been shown that significant evolution of the stress can exist throughout the thickness of the adhesive; therefore, simplified methods that roughly analyze the average stress state through the joint can overestimate the maximal transmitted load of single lap joints. Thus, refined analyses of the stress distribution in the adhesive are necessary to obtain precise design of adhesively bonded assemblies. To sum up, it is necessary to take special care to the local geometry: the principle proposed (Fig 14a) and how it is manufactured (Fig. 14b–d).

### 43.4 Microscopic Optical Observations

#### 43.4.1 One-Dimension Roughness

Mechanical adhesion is mainly explained by the surface topology. Thanks to a rugosimeter Arnaud (2014) determined the parameters of a one-dimension roughness, parameters which favor in particular the mechanical attachment, in order to be able to reuse them during future coating applications. Thus samples of aluminum

**Fig. 14** Geometry of the free edge of modified Arcan test specimen to reduce the edge effects with beaks: (a) definition of the local geometry (Cognard 2008), (b) cross view for an adhesive thickness of  $2e = 0.1$  mm, (c) cross view for an adhesive thickness of  $2e = 0.2$  mm, (d) cross view for an adhesive thickness of  $2e = 1$  mm (Cognard et al. 2010)

**Fig. 15** Analysis of a substrate with a rugosimeter: (a) measuring device and (b) roughness profile generated after passing the rugosimeter along a line (Arnaud 2014)

2017 were studied, in the form of bars of 10 mm thickness and surface  
10 × 100 mm<sup>2</sup>. A roughness profile was obtained by passing the roughness tester  
on a straight line of the substrate (Fig. 15b). For better precision, it was necessary to  
measure several lines. The results are given in Table 2. The mean gap, defined as the  
arithmetic mean of the absolute values of the distances between peaks and troughs,  
noted Ra, and the total gap, defined as the most important distance between the  
highest peak and the deepest trough, noted Rt, measured were, respectively,  
0.455 µm and 3.46 µm. These two parameters are the most influential in terms of  
roughness.

### 43.4.2 Scanning Electron Microscopy

The scanning electron microscope is a tool able to observe surfaces from 10 to  
0.1 µm. Figure 16a presents an example of a scanning electron microscope (SEM)  
study of an Arcan aluminum-adhesive-aluminum-modified assembly. An overall  
view of the adhesive shows the presence of fillers or porosities in the adhesive.

t.1 **Table 2** Roughness parameters for an untreated substrate (Arnaud 2014)

t.2	Line	L1	L2	L3	L4	L5	L6	Mean value	Standard deviation
t.3	Ra (μm)	0.489	0.546	0.491	0.395	0.427	0.383	0.455	0.064
t.4	Rt (μm)	3.86	3.99	3.89	2.8	2.65	3.54	3.46	0.587

**Fig. 16** Scanning electron microscopy of an aluminum-epoxy-bonded assembly: (a) overview, (b), (c) zooms of some details (Arnaud 2014)

329 Two different patterns are distinguished, surrounded in Fig. 16a. A zoom is made on  
330 these details in Fig. 16b, c. Thanks to these observations, we are able to confirm the  
331 presence of charges in the adhesive and to measure them. The diameter of these  
332 beads announced by the supplier is 0.13 mm, which seems consistent with the  
333 observations of microscopy. Scanning electron microscopy is generally completed  
334 with addition measurement systems like energy-dispersive X-ray spectroscopy; one  
335 would be able to distinguish a void from a sphere, for example. A list of these  
336 systems is detailed in Table 1.

**Fig. 17** TEM micrograph of the interphase: evidence of structural defects (Beuguel et al. 2017)

More detailed information can be obtained. This is the case of the work of Beuguel et al. (2017). They observed decohesion between a polypropylene matrix and a polyamide nodule. Figure 17 was obtained with a higher resolution thanks to a transmission electron microscope.

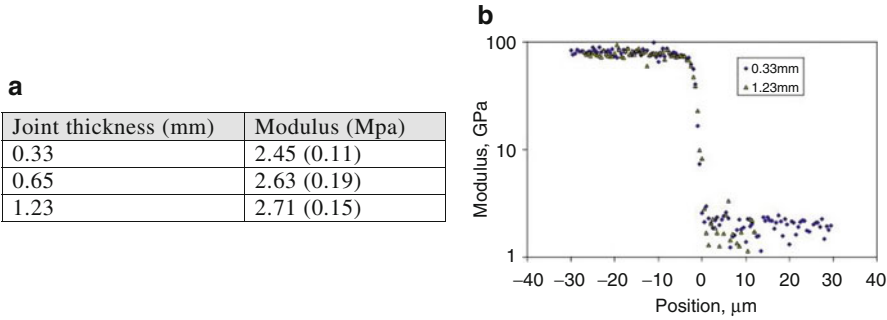

#### 43.4.3 Nanoindentation

The discontinuity between two elements, the substrate and the adhesive or the matrix and the nodules, is a source of questions. Mechanicians are very interested in having local information on the mechanical properties. Is it an interface? Is it an interphase? What happens in this discontinuity? The use of nanoindentation provides local variations in the Young's modulus. The principle is based on a load applied very locally thanks to a pyramid. The process of indentation is measured with a load-displacement curve. The posttreatment gives then the reaction of the material indented. Davies et al. (2009) used this technique trying to approach a variation of the Young's modulus between an aluminum substrate and an epoxy adhesive along the geometric interface. In Fig. 18b zero defines the origin of this interface. For a positive abscissa, the values are defined for the adhesive. For a negative abscissa, this is the substrate that is measured. Several measurements were made for three adhesive thicknesses: 0.33 mm, 0.65 mm, and 1.23 mm. They conclude that if an interaction between the substrate and the adhesive exists for the materials considered, this zone is very thin around two microns of thickness.

#### 43.4.4 Atomic Force Microscopy

The atomic force microscopy is able to provide information up to 10 nm. The measurement principle is based on the flexion of a beam which is moved over a

**Fig. 18** Nanoindentation of an epoxy adhesive: **(a)** measured Young’s modulus values, mean (standard deviation) of 10 values for each sample, measured at mid-thickness by nanoindentation; **(b)** across aluminum/adhesive interface, two joint thicknesses (Davies et al. 2009)

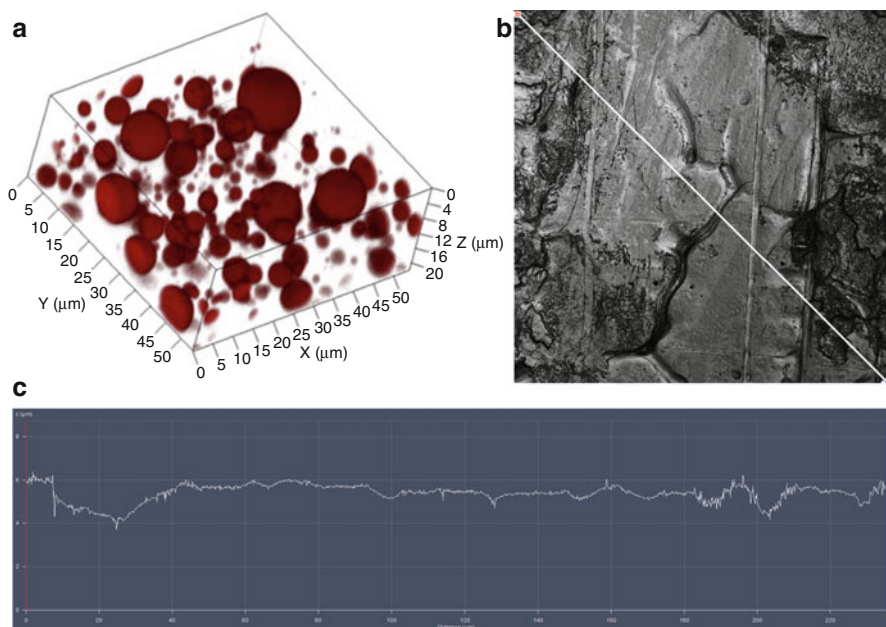

**Fig. 19** AFM measurements (Critchlow et al. 2006): **(a)** AFM image of hand-polished nickel tooling ( $5 \times 5 \mu\text{m}$  area). Vertical scale 60 nm; **(b)** AFM image of abraded nickel tooling, vertical scale approximately 0.3  $\mu\text{m}$

surface. The interaction between the tips of the beam induces a deflection of the beam which is measured. This interaction permits to define the topology of the measured surface. This is the first mean to use AFM. The second principle is based on the recording of the load necessary to deflect the beam. Thanks to this load measured, it is possible to obtain a map defining the local mechanical properties of the surface. The measurement process is quite long but gives a lot of information for small surfaces. Figure 19 gives results coming from the work of Critchlow et al. (2006). They analyzed the difference between hand-polished and abraded surfaces.

#### 43.4.5 Confocal Microscopy

The confocal microscope is an optical microscope able to measure information on a surface with a small depth of field. As a consequence, the volume studied has a maximal depth of 350–400  $\mu\text{m}$ . To observe structures through this volume, the

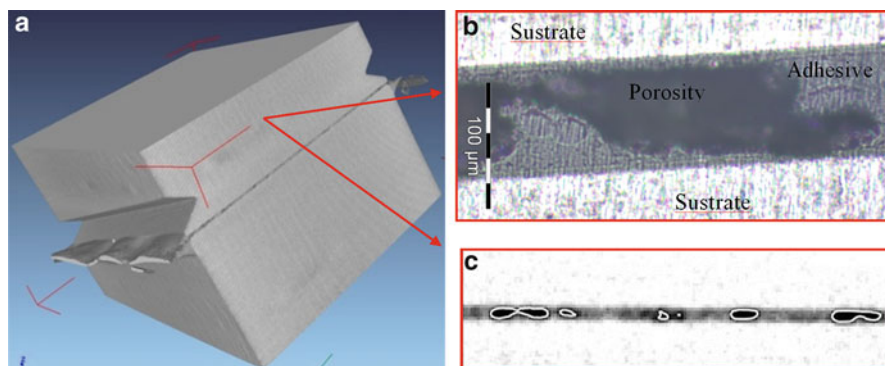

**Fig. 20** Confocal microscopy: (a) confocal micrograph of PP/PA6 blend: 3D observation of nodular morphology (Beuguel et al. 2017), (b) 3D measures of a zinc coating (Legendre et al. 2016), c roughness profile obtained along the *white cross line* (b)

material should be translucent. Beuguel et al. (2017) used this technique to observe the nodular morphology of a PP/PA6. Figure 20a defines the volume studied. The nodules are in red. It is possible to observe the variation of their dimensions, their distribution in a 3D space. Legendre et al. (2016) also used this technique to have a 3D topology of a steel sheet surface with a zinc coating. As previously shown in this chapter for the one-dimension roughness, it is possible to extract from this geometry the profile of the surface along a line (Fig. 20b, c).

#### 43.4.6 X-Ray Microtomography

In recent years, the development of measurement techniques has evolved toward three dimensions. The microtomography principle is based on the X-ray method. A specimen is lighted with an X-ray source. The image obtained is recorded thanks to a two-dimension screen placed behind the specimen. To obtain the third dimension, the specimen is placed on a rotary vertical axis. Between each measurement, a step of rotation is imposed. All these steps describe a complete turn. The whole images are then post-treated to build a three-dimension volume. Maurice (2012) used this technique to measure the voids in an aeronautical adhesive film. In this industrial field, the process imposes to use a pressure chamber, i.e., an autoclave, to reduce

**Fig. 21** Microtomography analysis of an aeronautical adhesive: (a) 3D tomography measurement, (b) SEM cross view, (c) measurement of porosity by microtomography (Maurice 2012)

porosity in the assembly. It is slightly dependent on the pressure and temperature cycles. Figure 21 presents these results. Large voids were observed. The size of these defects is relatively important: their height is similar in scale to the adhesive thickness, and their length can be two or three times larger. Microtomography observation, performed on a sample of about 10 mm height, width, and length, confirmed this observation, and numerical post-processing of the results using myVGL™ software enables the void ratio to be measured as, at least, 20% in volume.

## 43.5 Physicochemical Analysis

### 43.5.1 Scanning Electron Microscopy with Energy-Dispersive X-Ray Spectroscopy

To understand X-ray spectroscopy, it is firstly necessary to understand the term spectroscopy. It can be defined as an experimental study to decompose in a succession of elementary data a complex and physical phenomenon. The set of these elementary data is called the spectrum. The data can be an energy, a wavelength, a frequency, etc.

An energy-dispersive X-ray spectroscopy gives information about the chemical composition of the analyzed material. The impact of the electron beam on the sample produces X-rays which are characteristic of the elements present on the sample. Figure 22 shows an analysis of the particles described in red in Fig. 16. The lines of the spectrum are specific for an atom. Figure 22 defines lines for carbon (C), oxygen (O), aluminum (Al), silicon (Si), and gold (Au). Carbon (C) and oxygen (O) are detectable. They correspond to the polymer material detected by the EDX beam behind the bead. The fillers are therefore glass beads, and very little porosity is detectable. The gold comes from the coating made before the analysis to make the samples conductive (Arnaud 2014).

**Fig. 22** EDX analysis of two particles in an adhesive joint in red (Fig. 16) (Arnaud 2014)

The EDX spectroscopy is often coupled with a SEM in order to have the distribution of the atom in a representative surface. Arnaud (2014) studied with this method a coating based on molybdenum disulfide  $\text{MoS}_2$  (Fig. 23). Sulfur and molybdenum are present in good atomic mass ratio (Fig. 23c). In addition to the aluminum 2017, alloy made of aluminum and copper, there are elements of silicon, magnesium, oxygen, and carbon which must constitute the remainder of the coating. The EDX analysis in Fig. 23 confirms that sulfur (e) and molybdenum (f) are located in the same places and are very complementary to aluminum (d), constituting the majority of the coating. The position of the silicon appears to be an inclusion or pollution. The random position of the other species, carbon (b), oxygen (c), and magnesium (d) suggests their presence in the coating at lower amounts, which is confirmed by the percentages by mass.

In this context, it is necessary to make an important remark about fracture analysis. Pollution of the broken specimen must be fought. Particular attention should be given to samples just after their failure. Thanks to the progress of the analysis methods and the increase of their sensitivity, it is now possible to observe and detect very little particles. These particles can come from the test specimen but also from a contamination of the environment. In order not to be orientated in a wrong way, no pollution of the test samples must be satisfied.

### 43.5.2 Scanning Electron Microscopy with Raman Spectroscopy

When a well-known monochromatic ray light is applied to a material, the reflected signal is out of phase due to an exchange of energy between the ray light and the environment. This effect is called the Raman effect. The spectroscopy analysis of the reflected light gives information on the material itself. It is then possible to identify

**Fig. 23** SEM observations of an aluminum 2017 substrate treated with a molybdenum disulfide coating: (a) zoom  $\times 100$ , (b) zoom  $\times 1,000$ , (c) EDX study of the composition of the zone with zoom  $\times 1,000$ , (d) aluminum, (e) sulfur, (f) molybdenum (Arnaud 2014)

molecules, chemical bonds, their proportions, and their structure. The method used by Raman analysis produces better spatial resolution than the attenuated total reflectance-Fourier transform infrared (ATR-FTIR) spectroscopy technique and makes it possible to analyze smaller samples.

Davies et al. (2009) tried to identify modification of the interface between an epoxy adhesive and an aluminum substrate. Across the interface (Fig. 24a), they observed local spectra (Fig. 24b). These spectra allow local variations in molecular species to be detected. Analysis of these results in terms of molecular groups is

**Fig. 24** (a) Optical view of the cross section analyzed by Raman scattering (100× objective lens in *white* light). Substrates (*white*) at *top* and *bottom* of photo. Each *black circle* corresponds to a Raman spectrum recorded, in the adhesive, (b) three Raman spectra along the cross section (Davies et al. 2009)

446 complicated, as this was a formulated commercial adhesive. The spectra (Fig. 24b)  
 447 point out the chemical bonds: C=C, C-O, C-H, CH-OH, and C<sub>6</sub>H<sub>6</sub>-H. Each Raman  
 448 shift is representative of a chemical bond. The analysis was completed in their work  
 449 with other analysis methods. It was the crossing of all the method used that can  
 450 propose scientific structured results. More information can be found in their work  
 451 (Davies et al.).

### 452 43.5.3 X-Ray Photoelectron Spectroscopy

453 Whereas X-ray Raman spectroscopy applies monochromatic ray light on a surface,  
 454 photoelectron spectroscopy applies an X-ray. The depth impacted by the X-ray  
 455 radiation is up to 5 nm. It enables to analyze the chemical composition and the  
 456 chemical bonds of the surface. For example, Kadiyala et al. (2016) analyzed joint

**Fig. 25** (a) XPS survey of neat and fractured joint surfaces of PI; (b) The C1s core-level XPS spectra for joint surfaces fractured at 25 °C (Kadiyala et al. 2016)

interface fractures of a thermoplastic semicrystalline polyimide for different temperatures: 25 °C, 150 °C, and 225 °C. As Fig. 25b points out, the type of chemical bonds and their quantities can be identified.

#### 43.5.4 Differential Scanning Calorimetry

The curing process of an adhesive is analyzed by solving the energy equation (Devaux et al. 2015):

$$\rho C_p \frac{\partial T}{\partial t} = \nabla(\lambda \nabla T) + \phi_r, \quad \text{with } \phi_r = \rho \Delta H_r \frac{\partial \alpha}{\partial t}$$

where  $\rho$  is the density of the adhesive,  $C_p$  the specific heat,  $\lambda$  the conductivity of the adhesive,  $T$  the temperature,  $H_r$  the total heat of the polymerization reaction, and  $\alpha$  the degree of cure.  $\phi_r$  is the heat flux produced by the polymerization reaction.

Two main phenomena are involved during adhesive curing: polymerization and cross-linking. There is a competition between these two events during the curing process. For a bicomponent epoxy adhesive, the uncured resin is mixed with a hardener according to a ratio recommended by the manufacturer in order to initiate the curing process. The chemical reaction within the mixture proceeds, and polymer chains cross-link to each other. As a result, molecular weight increases, causing an increase in viscosity. The cross-linking is an exothermic reaction; thus, the formation of the polymer network generates heat which results in a temperature increase. The molecular weight continues to increase until the gel time. It is the time for which the adhesive transforms from a liquid phase to a solid phase. This transition is also called the gel point. From this point, the molecular weight increases until forming a fully cross-linked polymer network. As a consequence, it is necessary to have reliable

information on the curing process. The differential scanning calorimetry can provide such information.

### Kinetic Analysis

As an example, Devaux et al. (2015) studied Hysol EA-9321 adhesive from Henkel, a two-component thixotropic, solvent-free epoxy-based resin. The adhesive is prepared using a mixing ratio of 2:1 by weight of the respective constituents (resin and hardener). According to the manufacturer's data sheets, a specimen cured during 1 h at 82 °C is completely cured (curing degree  $\alpha = 1$ ), and the glass transition temperature of specimens cured during 5–7 days at 25 °C is 88 °C.

The heat released during the cure reaction was detected by using a heat-flux differential scanning calorimeter connected to a thermal analyzer. This calorimeter is made of two steel pans. One of these is empty, and the other one contains sample weighting between 5 and 10 mg.

At first, dynamic and isothermal scans were carried to determine kinetic parameters of each one. Then, both kinds of scans were conducted to simulate few steps curing cycles.

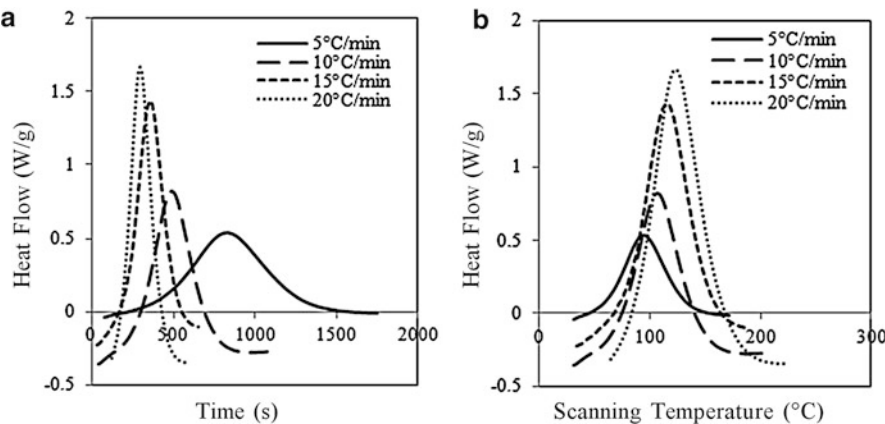

Dynamic scans were carried out in the temperature range of 25–200 °C at constant heating rates of 5, 10, 15, and 20 °C/min. Isothermal scans were run at temperatures ranging from 25 to 100 °C. Equilibrium at the target isothermal temperature was reached in the sample holder with a rate of 20 °C/min. This rate was chosen sufficiently fast to prevent the reaction between resin and hardener before the start of isothermal scan. Coupled scans were made in the same way as previously, i.e., a dynamic scan was conducted until the required isothermal temperature, and then a second dynamic scan was conducted until the second required isothermal temperature.

For each scan, a second heating run on the same sample under the same conditions was carried in order to define the baseline along which the curve heat flow versus time is integrated.

The DSC curves in dynamic analysis are shown in Fig. 26. The shape of the exotherm was heating dependent. The value of the total heat released was determined by integrating heat flow versus time under the exotherm along a straight baseline. This heat of reaction,  $\Delta H_T$ , was independent of the heating rate (Table 3).

Figure 27 shows the heat flow released versus time for isothermal scans. The maximum heat flow is reached faster for high curing temperatures, due to the acceleration of the reaction between resin and hardener. Table 4 presents the heat of reaction released during isothermal scanning.  $\Delta H_{ISO}$  is calculated by integrating the area under the heat flow versus time curves along a straight baseline, defined as previously.

The curing degree,  $\alpha$ , is based on isothermal and dynamic scans and is calculated as  $\Delta H_t / \Delta H_T$ ;  $\Delta H_t$  is the heat of reaction released during isothermal scan at time  $t$  and  $\Delta H_T$  the total enthalpy of reaction calculated during dynamic scans. In this way, intermediate curing states of the adhesive as a function of time over isothermal temperatures were determined.

**Fig. 26** Dynamic scanning: heat flow at different heating rates as function of (a) time and (b) temperature (Devaux et al. 2015)

t.1 **Table 3** Total heat of reaction at different heating rates (Devaux et al. 2015)

**Fig. 28** DSC results: influence of the accelerated aging on an epoxy adhesive (Arnaud 2014)

**Analysis of the Glass Transition Temperature (Tg)**

The evolution of Tg provides information on the physical phenomena affecting the polymer studied. Thus, Arnaud (2014) studied the evolution of an accelerating aging under temperature and seawater absorption. Figure 28 presents the evolution of the heat flow versus temperature for a rate of 10 °C/min. Four types of specimens were tested. The reference submitted to a cold curing cycle. The Tg measured was 55 °C defined by the inflection point on Fig. 28 (“reference curve”). A second specimen was cold cured and post-cured at 40 °C during 1 month. Tg increased to 71 °C (Fig. 28; “to the woven” curve). It was fully cured like the study presented by Devaux et al. (2015). The third curve defines a cold-cured adhesive and aged in seawater at a temperature of 40 °C (Fig. 28; “seawater” curve). The Tg obtained increased to 63 °C indicating the post-cured of the adhesive during aging. A fourth specimen was cold cured aged in seawater at a temperature of 40 °C and dried in an oven at 40 °C during 1 month (Fig. 28; “seawater + drying” curve). The Tg obtained was 70 °C. This specimen points out the reversible phenomenon of the seawater aging. The evolution of the Tg measured by DSC gives information on the physical phenomena.

**Fig. 29** TGA analysis (Zhao et al. 2016)

### 43.5.5 Thermogravimetric Analysis

The thermogravimetric analysis consists on measuring with precision the weight of a specimen submitted to a thermal loading under a controlled atmosphere with air, azote, oxygen, etc. The measured variations transcribe the chemical reactions that occurred. The principle is similar to a measured combustion. At the end, residues are generally analyzed to quantify nonorganic charges. To explain this method, it is possible to quote the work made by Zhao et al. (2016). They analyzed with thermogravimetric analysis the composition of an adhesive made of two components: epoxy and a flame retardant named bisphenol-A bridged penta(anilino) cyclotriphosphazene (BPA-BPP). The results are plotted in Fig. 29. The evolution of weight was described regarding the temperature under nitrogen atmosphere. Different compositions were studied, starting with the BPA-BPP and the epoxy themselves. The weight of BPA-BPP started to decrease around 250 °C. At 700 °C, the residual weight was 60%. It means that there were residual nonorganic components. For the epoxy analysis, two main variations occurred (Fig. 29b) around 400 °C and 600 °C. Each peak corresponds to a chemical reaction. Then they studied the mixture.

### 43.5.6 Attenuated Total Reflectance-Fourier Transform Infrared (ATR-FTIR) Spectroscopy Technique

As the previous spectroscopies presented before, the attenuated total reflectance-Fourier transform infrared (ATR-FTIR) spectroscopy technique is based on the infrared light on the material. The returned signal is then measured. The difference is linked to the properties of the material. Each peak measured is specific to a chemical bond. It is also possible to define their quantities. Gorassini et al. (2016)

**Fig. 30** ATR-FTIR spectra of cellophane, backing side of unaged (a) and artificially aged (b) tape C (Gorassini et al. 2016)

studied the composition of an old pressure-sensitive adhesive, used to assemble pages in very old books, in order to recover and understand the initial chemical properties of the adhesive and their modifications due to aging. Three adhesive were tested: a cellophane available in literature and a commercial adhesive unaged and aged. They confirmed that the adhesive used was mainly made of cellulose acetate (Fig. 30).

## 43.6 Mechanical Observations

The following points are not often defined as a “post-fracture analysis” because these measurements are generally carried out in the laboratory during an instrumented test. However, it is very important for mechanical engineers to establish the relation between the loads applied, the deformations of the bonded assemblies, and their fracture surfaces. As the experimental methods need posttreatment after the test, they can be defined as “post-fracture analysis.” Moreover, these methods can bring a lot of information to understand the fracture of adhesives.

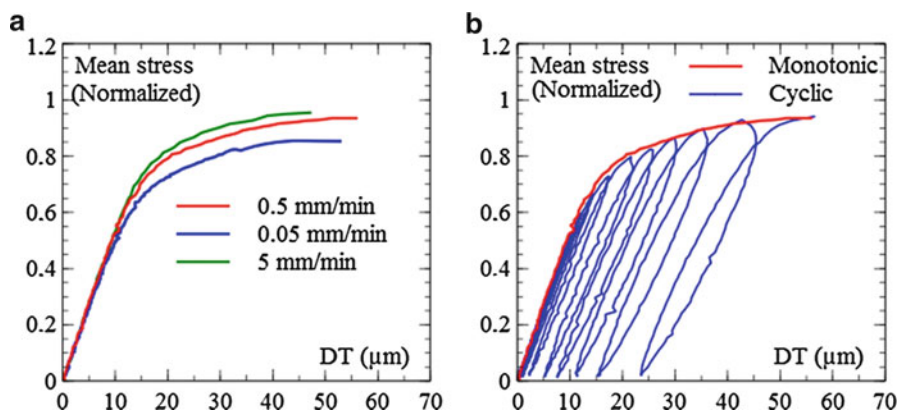

### 43.6.1 3D Digital Image Correlation

3D digital image correlation systems are able to measure the displacement of a surface in three dimensions (Cognard et al. 2005; Créac'hcadec et al. 2008; Maurice 2012). It is made of a pair of cameras and a lighting system that take pictures at a defined time rate. The frames are then recording with different signals like the tensile

**Fig. 31** 3D digital image correlation system: (a) Modified Arcan experimental device, (b) image recorded and post-analyzed with the relative displacement of both sides of the adhesive joint in the out of plane y-direction DN, (c) tensile load, relative displacement DN curve (Maurice 2012).

load of the test machine. Figure 31 presents an example of a modified Arcan test measured with this type of system. Figure 31b presents a post-treated frame with the adhesive joint area analyzed composed of the adhesive and two aluminum substrates. The correlation system provides a kinematic field for the entire picture. Here the relative displacement of both sides of the adhesive in the y-direction is plotted. The resolution of this system is around 1/100 pixels. It depends on the scale factor to convert it in millimeters. As a result, Fig. 31c plots a load-displacement curve in blue. It is then possible to develop law behavior to explain such observations (Cr  ac  hadeac 2008). Most of all, Maurice (2012) improved the posttreatment

**Fig. 32** Influence of strain rate and behavior under cyclic loads of bonded assembly under shear loads: (a) strain rate effect and (b) behavior under cyclic loads (Maurice 2012)

method to explain the cleavage along the x-direction that can be observed if the alignment of the Arcan device is not well done. This technique is very interesting to understand the type of fracture. It is then possible to measure different phenomenon behaviors of the adhesive joints, like strain rate effect or cyclic behaviors (Fig. 32). For fatigue test, an improvement is necessary to have real-time measurements (Créac'hacdec et al. 2015). This method is very interesting and can be used for local measurements. Davies et al. (2009) pointed out the linear evolution of the shear strain for a thick epoxy adhesive. No specific behavior close to the interface was observed (Fig. 33).

### 43.6.2 Digital Volume Correlation

The digital image correlation gives information on the surface of an observed specimen. The next question is then what happens in the material. That's the reason why digital volume correlation is developing a lot. The principle is similar to the microtomography principle described before. However, a 3D reconstruction is made for each step of loading like the 3D image correlation system. It is then possible to have in three dimensions the evolution of the strains versus loading path. Boufert et al. (2017) studied the microstructure of a core and observed with a resolution of 12 μm. The volume is defined in Fig. 34a. They applied a load thanks to the indentation sphere (Fig. 34b). They post-treated their recorded frame and were able to plot a stress field (Fig. 34c). This method is very useful to have information in the assembly. This is not very developed in the adhesive field, but in the coming years, it will probably bring to the adhesion community very important data.

**Fig. 33** 2D digital image correlation for a pure shear deformation of a thick epoxy adhesive joint (Davies et al. 2009)

**Fig. 34** Digital volume correlation: (a) 3D rendering of the microstructure of the core material studied herein and observed at a resolution of  $12\text{ }\mu\text{m}$ . The size of the volume is  $4.8 \times 4.8 \times 3.2\text{ mm}^3$ ; (b) section of the microstructure with the indenter (in white) that applied the load, (c) stress field extracted from the DVC measurements (Bouterf et al. 2017)

**Fig. 35** Ultrasonic images (C-scans) of a sample in immersion in Harrison solution: (a) without clear coat after 331 h (b) with clear coat after 315 h of immersion in Harrison solution. *White scale bars: 5 mm. The arrows mark the initial defects (holes of 0.5 mm diameter)* (Oehler et al. 2012)

### 43.6.3 Ultrasonic Testing

Nondestructive tests are very interesting to bring information on adhesion. This is the case for ultrasonic tests. The principle is described in the chapter dedicated to NDT methods (see ► Chap. 42, “Nondestructive Testing”). An ultrasonic wave is generated to a surface. The return signal is measured. The difference is linked to the material itself. Oehler et al. (2012) worked on decohesion of an interface subjected to an immersion in Harrison solution. A hole with a diameter of 0.5 mm was made in the coating. A good coating and a bad one were tested. Decohesion was observed with ultrasonic scans (Fig. 35) for the clear coat.

This method was used by Maurice (2012) for composite single-lap shear tests (Fig. 36). Tests were performed with a tensile testing machine. The test was stopped at different load levels. Ultrasonic measurements were performed at each step of loading. The overlap was observed. At the corner, a fracture initiated linked to the edge effects and then propagated to the center. This is particularly visible in Fig. 36b. After this propagation, the fracture of the whole specimen occurred.

## 43.7 Conclusions

Solving the equation of adhesion needs information coming from multi-physics and multi-scale analysis.

1. Fracture analyses are a huge source of information. This information comes from various supports: microscopy, compositional analysis/material identifications, and mechanical observations.
2. Each means of analysis should not be taken separately. It is the intersection of these different types of analysis that constructs the failure understanding.

**Fig. 36** US scan for a composite single-lap shear test sample: (a) geometry of the specimen, (b) example of US scans obtained at different loads for different specimens; the scale goes from 0.3 (red) to 4 dB (blue) of signal loss (Maurice 2012)

3. In this chapter, the mainly experimental devices are presented, but this list is not exhaustive.
4. The development of measurement methods is increasing with precision and sensitivity. The today's means are certainly not those of tomorrow's ones.
5. Having a good picture or a good spectrum needs good operators to prepare the sample, not to pollute them, to master the observation device, etc.
6. Moreover, good pictures are not synonymous of good interpretations. To have a good explanation, it is necessary to have a long experience, especially in these observation techniques. The failure comprehension is then the intersection of specialists of each domain area.
7. Scientists or industrials that work on adhesion should be able to interact with all these domains. This is not so simple due to the initial training of each one.

**Acknowledgements** This work was realized using different results coming from PhD theses I had the pleasure to supervise. So I really want to thank N. Arnaud, O. Devaux, J. Legendre, J. Maurice, for the work they performed. I also want to thanks the different research collaborators (industrials and academic) for their help and their financial support. I also want to thank Philippe Elies and Gérard Sinquin (Université de Bretagne Occidentale) for the measurements they performed in the Pimm-DRX technology platform: Imaging, Microscopy and x-ray diffraction.

## Abstract

This chapter focuses on experience with adhesively bonded joints in aircraft structures. It covers their analysis (emphasizing the inherent nonuniformity of adhesive bond stresses), their design, some common pitfalls in past and current practices (the worst of which is the continued myth that adhesive bond load transfer is distributed uniformly over the bond area, so that all that is needed to

make stronger joints is more bond area), and the critical need for ensuring that the glue is stuck (not by after-the-fact monitoring, which is all but impossible and therefore unreliable, but by proper specifications and quality control during manufacture). It covers the load redistribution around defects and damage, showing that not all damage causes an immediate loss of strength (even though repairs may be necessary to protect against subsequent environmental degradation). It emphasizes a little-appreciated point that the adhesive bond, itself, must never be designed to be the weak link in the chain of strength, so that it cannot act as an instantly catastrophic fuse; the weak link must be in an adherend outside the joint for bonded designs to be reliable. This chapter also includes a discussion of the choice of appropriate bonding tool concept and the great benefits from sometimes using nontraditional tools. The key issue is shown to be that the governing tolerance is not that for the parts, or the tool, but for the thickness of the bond line. The real critical tolerance is on the order of 0.025 mm (0.001 in.), not  $\pm 0.4$ –0.8 mm (0.016–0.032 in.). This requires a far more thorough coordination between design of the parts and the bond tool than has customarily been applied in the past. It is made abundantly clear that tighter and tighter tolerances on the parts and tools are not the way to go. One must rely on a drape-to-fit manufacturing philosophy, the benefits from which are shown to be enormous. The issue of inspection is discussed because a failure to understand what can work and what needs to be checked has led to far reaching adverse consequences. Misplaced faith in after-the-fact inspections is shown to have replaced the proper emphasis on proper process control during manufacture. It is shown to be impossible to restore 100% of bonded-joint strength after it has been manufactured incorrectly (or manufactured “correctly” in accordance with process specifications that simply do not work). And the futile search for the Holy Grail of being able to monitor degradation of bond strength during service has led to a ban on using this technology, in some instances, even when there is no other alternative approach that works. This chapter concludes with examples of the successful widespread application of adhesively bonded joints in aircraft primary structure.

---

## 44.1 Introduction

There are two basic classes of adhesive bonding in aeronautical structures. One is structural bonding, with epoxy, phenolic, or acrylic adhesives, that transfers load between members. The second is sealants that protect against corrosion at interfaces. The stiffnesses of these classes of polymers differ greatly, but the two basic needs are remarkably similar. The first is that the adhesive or sealant will stay stuck for the life of the structure, in all service and storage environments, while the second is that the adhesive will not fail even when the surrounding structure has been broken.

Given that the mechanical properties of these polymers are orders of magnitude lower than those of the adherends they bond together, this second requirement may seem difficult to achieve. Nevertheless, it has been possible by distributing the load

transfer as a shear load over a sufficiently large area and the use of sufficient steps for bonded joints between thick highly loaded adherends. The key is to protect the adhesive from direct or induced peel loads while using the shear capability of the adhesive to transfer the loads. This requires efficient joint designs, which are easily established for thin structures but which become progressively more complicated for thicker structures. The details of the joints are described here and in other chapters in the volume.

Ensuring that the adhesive or sealant is stuck properly in the first place, and that it continues to adhere for the life of the structure, is actually the more challenging of the two needs because it is so misunderstood by far too many of those involved in this industry and others. The science of adhesion is vital to the success of bonded joints, but its importance is largely unrecognized today. The greatest difficulty in this regard is that success is completely dependent on correct surface preparation and processing, which cannot be verified by any of the standard nondestructive post-inspections. Worse, while the correct techniques are known, many of the process specifications of past, and even current, applications of adhesive bonding violate these requirements. They continue to be used because the inappropriate methods do not always result in instantaneous separations between the components, so not everyone involved acknowledges that there is a problem. This doubt is reinforced because most of the inspection methods can detect only physical gaps between the members, not whether or not they are actually bonded together. The procurement system makes it difficult for military services to allocate costs that would be incurred to update repair manuals for products that are long out of production but still in service. There is also a concern, in a litigious society, that any change in specifications would cast doubt on the integrity of every part made under the older procedures, regardless of whether or not such concerns could be justified. Sadly, the consequence of not implementing improvements promptly has been a reluctance to apply the technology as widely as it ought to be because of the bad reputation created by every group of in-service failures.

The bonding processes themselves are actually remarkably tolerant of quite wide deviations from nominal requirements, but when the specifications are inappropriate, or simply not followed, the consequences are very widespread. Worse, defects in mechanically fastened structures tend to be local, and 100% of the design strength can be restored by drilling out and replacing defective fasteners or even a few discrete parts. But processing errors in bonded and composite structures, once made, create situations in which no repair short of complete disassembly and remanufacture can restore 100% of the design strength and durability. It is not possible to inspect quality into bonded and composite structures afterward; they need to be made correctly in the first place. The cultural changes needed to ensure this are actually the greatest of all the obstacles to the more widespread use of bonded structures. Conversely, the durability of those bonded structures that were made appropriately is legendary, in regard to both fatigue and corrosion. The incentives for widespread use of bonded aerospace structures remain tremendous.

This chapter is presented from the perspective of what actually happens, rather than what should happen, in the hope that it will encourage improvements to be

made throughout the industry and regulatory authorities. Without these, it is unlikely that the full benefits of this technology will ever be attained because of the bad image created by the occasional lapses in quality and highly publicized consequences. Even so, it should be noted that, with the only exception of the well-known Aloha 737 incident in 1988, the kind of surface preparation and processing problems described here have resulted only in additional costs, which have inhibited the application of this technology, rather than created circumstances that made safety a concern. The contents of this chapter focus on what over 30 years of experience has been identified as the key issues that need to be understood in creating reliable bonded structures – issues that are rarely even mentioned in standard treatises on the subject, such as why it is imperative to not design to nominal loads but to ensure that the bonded joints will never be the weak link in the structure.

This chapter addresses the following topics: Adhesive Characteristics Needed for Design and Analysis; Surface Preparation; Design of Adhesively Bonded Joints; Additional Considerations for the Design and Analysis of Adhesively Bonded Joints in Fiber–Polymer Composite Structures; Design Features Ensuring Durability of Bonded Joints; Load Redistribution Around Flaws and Porosity; Effects of Thermal Mismatch Between Adherends on Strength of Bonded Joints; Inspection, Testing, and Quality Control; Concerns About the Misplaced Emphasis of the Quality-Control Inspections for Bonded and Composite Structures; Bonded Repairs; Other Industry-Specific Factors; and Examples of Use of Adhesive Bonding in Aircraft Structures.

---

## 44.2 Adhesive Characteristics Required for Design and Analysis

At the macro level, at which most bonded-joint analyses are made, the mechanical data needed are complete stress–strain curves in shear for a range in temperatures covering the operating environment. Typical structural adhesives are stronger and more brittle at low temperatures and weaker and more ductile at high temperatures than at room temperature, as shown in Fig. 1.

Despite these great differences in bulk individual mechanical properties, the strength of structural joints (in which the adhesive strains are far from uniform) is far less sensitive to the test temperature than that of short-overlap test coupons (in which the adhesive strains are close to uniform, which is why they are used to generate the stress–strain curves). (This is explained in more detail below, in terms of elastic–plastic adhesive models (Hart-Smith 1973a, 1974).)

The nonlinear behavior shown in Fig. 1 is not the result of plastic deformation akin to that for ductile metals. It can best be understood in the context of the strain invariants that eventually resulted in the development of the strain-invariant failure theory (SIFT) failure model for fiber–polymer composites. This had its foundation in earlier such analyses developed by Gosse (see Gosse and Christensen 2001) for the failure of homogeneous polymers, including adhesives constrained between much stiffer adherends. There are only two possible failure mechanisms available for any solid homogeneous material. One is dilatation which, in the context of adhesively

**Fig. 1** Adhesive stress–strain curves in shear, as a function of temperature

bonded joints, is associated with the induced peel stresses at the ends of the bonded overlap. The other is distortion, which is the dominant behavior of the adhesive layer away from the ends. According to the SIFT model, there is absolutely no interaction between these two mechanisms, which is why it is permissible to prepare separate analysis methods for shear-load transfer in bonded joints and for premature failures by peel. Peel failures represent a failure of the adhesive layer to utilize its full shear-transfer capability.

The value of the first strain invariant, the sum of three orthogonal strain components,

$$J_1 = \epsilon_1 + \epsilon_2 + \epsilon_3, \quad (1)$$

cannot be measured on any pure (neat) adhesive test coupon because failure by distortion according to the other (von Mises shear strain) invariant,

$$\gamma_{VMcrit} = \sqrt{\frac{1}{2} [(\epsilon'_1 - \epsilon'_2)^2 + (\epsilon'_2 - \epsilon'_3)^2 + (\epsilon'_3 - \epsilon'_1)^2]}, \quad (2)$$

(where the prime denotes principal values) occurs before the dilatational limit had been reached. Failure of polymers by dilatation (increase in volume) occurs only in a constrained environment, as between two circular rods bonded at their ends and pulled apart, as shown in Fig. 2 (or between the adherends in bonded joints). Transverse constraints, perpendicular to the load, are needed to prevent the natural Poisson contractions which, if they occurred, would decrease the dilatational strains in the adhesive.

The strain-invariant polymer failure model (SIFT) permits the superposition of separate analyses for shear and induced peel loads. There is no interaction between

**Fig. 2** Butt-jointed test coupon to measure  $J_1$  strain invariant for adhesives

the two failure mechanisms. While the need for this has been minimized through sound design practice (gentle tapering of the ends of the adherends to minimize the induced peel stresses, as explained later), the new model puts this technique on a secure scientific foundation and also accommodates any applied transverse shear loads.

At the microlevel, initial damage in bonded joints is defined by whichever of the two strain invariants reaches its critical value first. At the ends of the overlap in a badly designed bonded joint or test coupon, the dilatational  $J_1$  failure mechanism would always occur first. There are no significant peel stresses in the interior of the joint, so the distortional invariant will be exceeded first. The visual consequences of this failure may seem to be one of dilatation because the first indication is the formation of a series of hackles formed at roughly  $45^\circ$  from the adherends being bonded together, as shown in Fig. 3. (Exactly the same model applies for in-plane-shear failures in the matrix between parallel fibers in composite laminates.) These are, in reality, failures by distortion, which result in tensile fractures perpendicular to the highest principal stress.

Once hackles start to form, the adhesive layer is no longer a continuum but a series of parallel ligaments being bent elastically. There is no precise model for progressive damage to adhesive layers as more and more shear strain is applied, but a constant-stress model has served as a very useful model. This is explained in Fig. 4, based on the notion that damage starts at the knee in the stress-strain curve and that there should be some limit on how much can be tolerated, like the 2% offset definition of design ultimate load for mechanically fastened joints in ductile members. The tail end of the stress-strain curve is reserved for load redistribution around bond flaws and damage, as discussed later. It is recommended here that the knee in

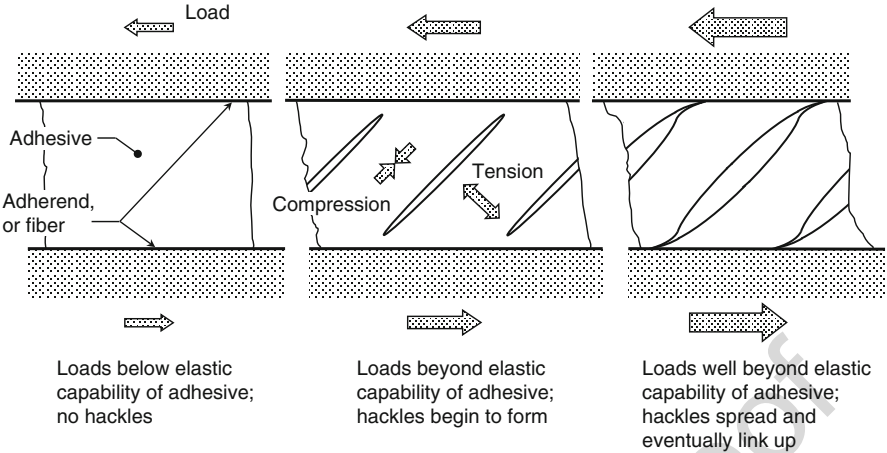

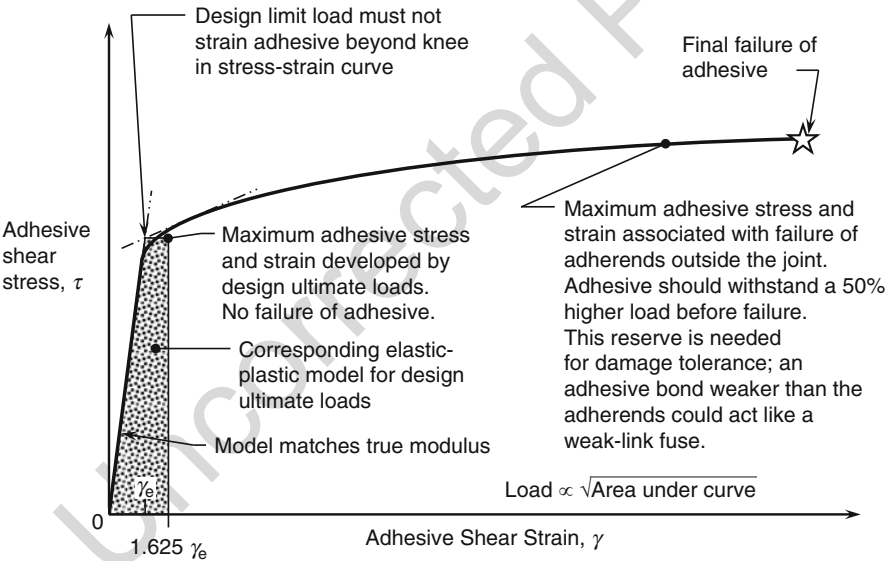

Fig. 3 Formation of hackles in adhesively bonded joints

Note that design process must account for nonlinear adhesive behavior, but a precise stress-strain curve is not mandatory. An approximation, based on a similar adhesive, will usually suffice.

Fig. 4 Relations between knee in stress–strain curve and design limit and ultimate loads

the stress–strain curve be defined to be the design limit load, for each environment (but it should be acknowledged that the bonded structures and composite repair facility for the Royal Australian Air Force, in Amberley, Queensland, have successfully set the design limit strain at twice that value). What is now clear is that the

original notion (Hart-Smith 1973a, 1974) of designing to ultimate design load at the very end of the stress–strain curve is no longer appropriate.

In the event that the adhesive is so brittle, in a particular environment, that there is insufficient “nonlinear” behavior to satisfy the conditions described in Fig. 4, design ultimate strength is established at the end of the short stress–strain curve in shear, and design limit load is then set at two thirds of that load. These conditions are more frequently encountered in deep space than in atmospheric flight conditions. Brittle adhesives are used on aircraft primarily in high-temperature applications as in the vicinity of engines. In such environments, even brittle adhesives are quite ductile.

The stress–strain curves of adhesive layers under a close-to-uniform state of deformation, as in Fig. 1, are customarily measured on a thick-adherend test coupon using very sensitive displacement extensometers, developed by Krieger (1988), as shown in Fig. 5. Each aluminum adherend is typically 9.5 mm (0.375 in.) or 12.7 mm (0.5 in.) thick to enforce a close-to-uniform shear strain in the adhesive.

Most adhesives are still characterized by the average shear stress measured on standard lap-shear test coupons (ASTM D-1002) in a variety of environments. This can be misleading in the context of joint design since this so-called adhesive shear strength varies with the adherend material, their thickness usually 1.3 mm (0.063 in.), and with the length of the overlap, as described by Hart-Smith (1993). Such coupons should never be used for anything other than quality-control tests, for which their complex mixture of variable shear and peel stresses makes them very useful.

**Fig. 5** Thick-adherend adhesive test coupon and instrumentation (Printed with permission of American Cyanamid Corporation)

Some researchers have also measured what they perceive to be fracture mechanics properties under up to three modes, the first being crack opening and the second shear, thinking that these properties could form the basis of bonded-joint design. The author has yet to see any successful joint designed using these properties and will not discuss them further. No such value can be related to the long overlap needed to ensure the minimum shear strain in the middle of the overlap, where the adhesive is not critical and is low enough to prevent the accumulation of creep damage to the bond line. Worse, if the bonded joint is critical under peel-stress (Mode I) loads at the ends of the overlap, it should be redesigned to make the adherends thinner there, so that the crack-opening mode is no longer critical. It makes little sense to accurately establish the low strength of a badly designed bonded joint when it is so simple to modify the design to achieve a far higher strength, for which the adhesive is not critical in peel – one in which the merits of the adhesive's shear strength are allowed to dominate.

---

### 44.3 Surface Preparation

Proper preparation of surfaces to be bonded is the most critical step in creating durable bonded joints. This is best known for bonded aluminum structures because of the publicity given to the USAF-funded Primary Adhesively Bonded Structures Technology (PABST)-bonded fuselage demonstrator, performed at the Douglas Aircraft Company in Long Beach, California, in response to almost 10 years of widespread in-service disbonds associated with the first generation of 180 °C (250 °F)-cured epoxy adhesives in combination with etched, rather than anodized, surfaces. All earlier bonded aircraft structures (done mainly by de Havillands in England and Fokker in Holland) had been trouble-free because they used phenolic adhesives over chromic acid-anodized surfaces. In the 1940s and 1950s, the pioneers in this field, such as de Bruyne (1957) and Schliekelmann (1983), had studied potential durability issues very thoroughly before they undertook production bonding. Unfortunately, their diligence created the illusion that no bonded structures would ever have durability problems, so when others later changed materials and processes for bonding to simplify the manufacturing of bonded structures, they omitted to conduct the same kind of thorough durability testing and relied on short-term static tests alone, with disastrous consequences. Whole fleets of aircraft built to US bonding specifications during the late 1960s and early 1970s had all their bonded structures remanufactured. Some tried to do only local repairs, to no avail, as indicated by Hart-Smith and Davis (1996), in which it was shown that nearly half of all bonded repairs were to the same structures that had already been repaired for the same global processing errors. The disbonds would not occur until water was absorbed into the adhesive layer, which took time, but was inevitable. Local repairs are useful for impact damage to a properly bonded structure, in which none of the surrounding structure is likely to disbond, but they are unsuitable for global processing errors, as shown in Fig. 6.

Exterior and internal views of the same bonded honeycomb panel, after a second failure (Large Dark gray Area), showing innumerable small holes drilled to inject resin after the first failure, to make it impossible to detect those disbonds, and the shiny resin-free inner skin surface to which the injected adhesive (two irregular light gray areas) had clearly never bonded.

**Fig. 6** The futility of local bonded repairs to global interfacial failures

**Fig. 7** Representation of pores in anodized aluminum surface prepared for bonding (Thrall Jr. and Shannon (1985), Chap. 4; Marceau, Boeing)

270 All of this should have come to an end in the middle of the 1970s when  
271 phosphoric acid anodizing and optimized etch processes were established, particu-  
272 larly since Bethune at Boeing developed the simple wedge-crack test, ASTM  
273 D-3762 (Marceau et al. 1977), that made it easy to distinguish between properly  
274 and improperly prepared bonding surfaces. The properly prepared surfaces had a  
275 stable oxide coating, with many pores that the primer could penetrate, as shown in  
276 Fig. 7.

It should be noted that, while the test procedure is very reliable, it is rendered ineffective if the “permissible” extent of interfacial disbond growth during the 1 h-long test is set so high that it fails to reject unacceptable surface treatments. The tests reported by Thrall Jr. and Shannon (1985) show that the limit should have been set at no greater than 3.2 mm (0.125 in.), which is consistent with the very large number of PABST tests that never showed more than 1.6 mm (0.063 in.) of growth. Yet the limit set for the ASTM standard was 19 mm (0.75 in.) which, according to the tests reported by Thrall Jr. and Shannon (1985), would result in more than 95% of all of their bonded structures having been “acceptable,” no matter how bad they actually were.

It is also worth noting that a key element of the PABST bonding processes was the use of a phenolic-based primer, BR-127. And it is particularly significant that the first generation of 180 °C (250 °F)-cured epoxy adhesives that absorbed water so fast, and were associated with the many earlier in-service bond failures, were later found to perform just as reliably on the improved surface treatments as the second generation of such adhesives that were far more resistant to water absorption.

Sadly, even 20 years later, the author was to see local repairs being made to large engine cowls using the same obsolete surface preparations as had caused the failures that were being repaired. When he pointed out the inevitability of further failures to the rest of the panel, in the not too distant future, it was explained to him that the use of the better newer materials and processes in the repairs would violate the aircraft’s type certificate. It was illegal to not repair it in any way other than to make it conform to the original structure when it was built! This attitude was not confined to commercial aircraft. Repairs to helicopter blades continued to be made using paste adhesives over sandpaper-abraded aluminum surfaces. In this case, the explanation provided was that the model concerned had been out of production for over 20 years, so there was no mechanism to update the technical orders governing its maintenance and repair. In these cases, and many others, the futility of the obsolete repairs was well understood, even by those performing them. Is it not time to put an end to such practices? Surely the interests of aviation are better served by reliable surface treatments for bonding than by perpetuating other techniques that are known to be unreliable. Interestingly, the same organization that provided the service data cited by Hart-Smith and Davis (1996) has since found that they suffered not a single failure on 3,000 bonded composite patches they applied over grit-blasted/silane aluminum surfaces. The financial incentives to mandating the use of only reliable surface treatments are well established.

Other metal alloys, such as steel and titanium, also need appropriate surface treatments for bonded applications. The surface treatments for various metals are described in other chapters.

For bonded and co-bonded fibrous composite structures, the need for proper surface treatment is far less known. The absence of reliable after-the-fact inspection techniques that besets metal bonding is exacerbated by the failure to include any durability tests as part of the quality assurance program for the production of bonded composite structures. Just as with the adhesive bonding of metallic structures, the lap-shear test coupon alone has been found to be insufficient to ensure the durability

of any bonded joints. At best it can ensure only that the adhesive was cured properly (adequately cross-linked) – not that the adhesive is actually stuck. The reason for this inexcusable omission would seem to be that corrosion has been seen in conjunction with the failed bonded aluminum structures and that fiber–polymer composites cannot corrode. Whatever the cause, the need for the surfaces being bonded to have a higher energy level (be more active) than the surface of the adhesive is just as great for bonding polymers as for bonding metal alloys. Most of the surface treatments for composite surfaces to be bonded ensure precisely the opposite – that the surface will be totally inert. Some peel plies have even been coated with a silicone release agent to ensure that the peel plies can be stripped off without the slightest damage to the underlying substrate (Hart-Smith et al. 1996). This is not to imply that the problems with bonded composite aeronautical structures are as widespread as they were with bonded metallic structures. Rather, the problem is one of not knowing because there is no way of finding out before the parts separate in service. Worse, since there is no mandated durability test for bonded composite structures equivalent to the wedge-crack test, at the time of manufacture, such structures continue to be produced with no means of ensuring that they will not fall apart at some later date.

Of all the specified surface treatments for bonded composite joints, only low-pressure grit blasting has an unblemished service record. The reason why it has not been standardized on is inexplicable since none of the other techniques can be applied for bonded repairs, so there is no way of any manufacturer or operator avoiding having to master this technique. One cannot put a peel ply back on a structure and peel it off a second time.

Another critical issue with bonding of composite structures is pre-bond moisture, which can exist in a multiplicity of forms, each with its own distinct adverse consequences. Moisture absorbed in cured laminates and driven to the surface by the heat of the bond cycle prevents any adhesion from occurring without creating detectable symptoms. Such water lowers the energy level of the substrate, as described by Mahoney (1988), and can lead to the condition illustrated in Fig. 8, in which a complete area failed to bond but was not detected. Figure 8 shows a perfect replica of the original peel ply, known to be free of silicone, on both sides of the adhesive layer. There was no sign of adhesion at all. Yet this and many similar panels had passed all quality-control lap-shear test coupons and 100% ultrasonic inspection at the time of manufacture. It is known that these parts had been cured many months before they were bonded in another part of the country; they were not dried in an oven before bonding. Clearly, they should have been.

Moisture absorbed by the adhesive before it is cured has the effect of creating a weak porous bond. Moisture condensed on the surface of uncured adhesive films taken out of the freezer and unwrapped before it had thawed out also collects at the interface and prevents the glue from sticking. Sometimes, even when the need to properly dry laminates before bonding has been recognized and specified, it has not always been enforced at the facilities of remote suppliers. Yet the need to do so continues to be demonstrated conclusively, along with the benefits from doing so, as reported by Myhre et al. (1982).

10X

Note clear imprint at left of *other* peel ply in skin underneath adhesive layer, to which the adhesive also failed to bond.

**Fig. 8** Peel ply imprint *left* by failure of adhesive to bond to a composite surface

Peel plies continue to be the most frequently specified surface preparations for bonding fiber-polymer composites. But they are not always reliable. Worse, there have been cases in which silicone was transferred from bagging film used in consolidation cycles. There is a tendency to underrate the importance of the so-called consumable products, like bagging film, breather, peel plies, etc., which are stripped off cured or staged parts and discarded after the cure. Some specifications even leave the selection of these materials entirely up to suppliers, with no restrictions. That is wrong! All surfaces that come in contact with the final composite part in both its uncured and cured states need to be controlled just as tightly as the prepreg itself. After all, most of them are cured together in an intimate contact. It is a standard practice to isolate tool-preparation rooms in which release agents are applied from any bonding or composite clean room. Workers there wear clean white gloves. Every article that comes in contact with uncured adhesives or composite materials, or surfaces to be bonded, needs to be treated as a potential source of contamination or a nonbond, no matter how insignificant the article seems to be. Not all procedures are as strict as this, but the loopholes in the paperwork need to be closed. There is one specific polyester peel ply that several organizations within Boeing prefer that is made on dedicated machines to eliminate contamination. This is the only peel ply permitted to be used for the 777 horizontal and vertical tails and on all subsequent production. Even so, the most stringent of tests are required to ensure the absence of silicone on each roll before it is allowed into the factory. Their prior experiences and current research sponsored by the Federal Aviation Administration (FAA) (see Bardis 2001) both confirmed the need for such care. The author would still prefer to also see the universal acceptance of something equivalent to the wedge-crack test for metal bonding – a sustained peel load in a hostile (hot/wet) environment to confirm the absence of all other mechanisms for creating inert bonding surfaces, as well. Any such lapse in quality will affect the entire structure. It is not difficult to detect the conditions that lead to global processing errors before they

occur, provided that one looks, and nothing can be done about them if they are not detected until after the part is built.

#### 44.4 Design of Adhesively Bonded Joints

The design and analysis procedures cited in this chapter were developed by the author under three government-sponsored R&D contracts over a period of years. The first was for NASA Langley during the period 1970–1973 (Hart-Smith 1973b, c, d, e), in which the elastic–plastic adhesive model was introduced and the first of the A4E series of Fortran computer codes was derived. The second increment of work was for the USAF at WPAFB, during and following the PABST bonded fuselage contract, from 1976 to 1983. Three new computer codes, A4EI, A4EJ, and A4EK, were produced and the effects of flaws and variable bond layers were covered (Hart-Smith 1982a, b, 1984a, b). There were many publications from the first two contracts. The third, also for the USAF, concerned bonded composite patches over cracks and corrosion damage in metallic structures, from 1997 to 2003 (Hart-Smith 2001). Not all of the analyses from the most recent contract have yet appeared in print.

The design of double-lap and single-lap bonded joints between nominally uniformly thick adherends is straightforward. The design of the 100% full-load transfer bonded joints with no fail-safe rivets for the pressurized PABST bonded fuselage, Thrall Jr. and Shannon (1985), was reduced to a single table of overlap versus skin thickness, supplemented by a requirement to gently taper the ends of the overlaps locally for the thicker skins to prevent premature-induced peel failures. It is crucial to note that the overlaps are universal in the sense that they are independent of the magnitude of any applied loads. This enables the design of the bonded joints to be completed before the internal loads in a structure have been established. The key to this design method is explained in Fig. 9, for double-lap joints, in which the overlap is established as the sum of the elastic trough needed to ensure that the minimum adhesive shear stress is so low as to prevent creep from occurring there under even sustained loads and the “plastic” load-transfer zones needed to transmit the full strength of the adherends outside the joint.

As first presented, this method is conservative in the sense that no credit is taken for the small increment of load transferred through the elastic trough. When designing patches in confined areas, the width of the plastic zones could be reduced by a length  $2/\lambda$  to compensate for this effect. All of the tests during the PABST program to validate the method were at the slightly longer overlaps.

Figure 10 presents the actual sizes used for the PABST fuselage, as a function of basic skin thickness.

The splice plates should be made half as thick as the skins, for maximum theoretical efficiency, to make each end of the bonded overlap equally efficient. However, early tests of such joints showed a propensity for fatigue failures in the splice plate, where the skins butted together, rather than in the skins, which had a nominally equal stress. Consequently, the splice plates were made one gauge thicker. The overlaps in this table can be approximated by a simple design rule, that the

Fig. 9 Design procedure for double-lap bonded joints

Central sheet thickness $t_i$ (in.)	0.040	0.050	0.063	0.071	0.080	0.090	0.100	0.125

<sup>3</sup>For nominal adhesive thickness  $\eta = 0.005$  in. For other thicknesses, modify strengths in ratio  $\sqrt{\eta/0.005}$ .

(Unit Conversion Factors: 1.0 in. = 25.4 mm, 1,000 lb/in. = 175 kN/mm)

Fig. 10 Standard design overlaps for double-lap bonded joints between aluminum adherends

overlap be 30 times the thickness of the central adherend (skin). If there is a substantial stiffness imbalance between the adherends, the load transfer through the bond will be intensified at one end, with respect to the other, resulting in decreased shear strengths.

Figure 10 includes a comparison between the theoretical bond strengths if the adhesive was strained to the very end of the stress-strain curve in shear and the strength of the 2024-T3 skins. For the thinnest skins, the bond has three times the strength of the skins, while for the thickest skins in the table, the ratio has fallen to about 1.5:1. This is why, for still thicker skins, it would be necessary to resort to splice designs with one or more steps in the overlap, to restore the margin in the bond strength. The need for this excess strength is described in a later section of load redistribution around flaws and defects. It should be noted, however, that the bond will fail by creep if an applied load sufficient to yield the aluminum adherends is maintained indefinitely. The higher bond lengths can be achieved only for loads that are quickly applied and removed.

The information in Fig. 10 needed to be supplemented only by the design modifications in Fig. 11, whereby the ends of the overlap of the thicker adherends were tapered down to a maximum tip thickness of 0.75 mm (0.030 in.), to minimize induced peel stresses in the adhesive. (The corresponding tip thickness for fiber-polymer composite adherends is only 0.50 mm [0.020 in.] because of interlaminar weaknesses.) If this local tapering was omitted for the thicker adherends, the adhesive would fail under induced peel stresses long before its shear strength could be attained.

The design of single-lap bonded joints is even simpler because the most critical location for any long-overlap bonded joint is in the adherends at one or both ends of

**Fig. 11** Tapering at ends of bonded overlap, to restrict induced peel stresses

the adherends, as the result of combined membrane and bending stresses. These are minimized by increasing the overlap, as explained by Hart-Smith (1973c, 1978). Analyses for the PABST bonded fuselage established a design overlap-to-thickness ratio of 80:1. (This can be reduced to 60:1 for single-lap joints that are stabilized against bending of the adherends, as by being part of a sandwich panel.) Tapering of the ends of the overlap to alleviate induced peel stresses is still necessary using the proportions shown in Fig. 11. The bending moment at one end of the overlap is intensified greatly whenever one adherend is stiffer (thicker) than the other. It is not possible to make single-lap or single-strap (flush) bonded joints with a strength greater than the adherends outside the bonded overlap, so they tend to be used only for thinner more lightly loaded structures.

The analyses referred above are essentially exact but can be applied only to bonded joints between adherends of uniform thickness. A new approximate method was developed during the composite repair of aircraft structure (CRAS) R&D contract that covers tapered adherends as well. The method, explained by Hart-Smith (2001/2002), relies on the knowledge that the adhesive stresses will be extremely low everywhere except in the immediate vicinity of changes to or interruptions in the thickness of the adherends. It starts with a closed-form analysis in which it is assumed that all the members are fused rigidly together over the entire overlap. The load sharing between the overlapped members can also account for residual stresses caused by thermal dissimilarities between adherends, as between composite patches and cracked metallic structures and between bonded titanium stepped plates at the ends and sides and the composite skins to which they are bonded. This level of analysis will predict local spikes of instantaneous load transfer at every discontinuity in load path. The second step in the analysis, also by closed form, distributes those spikes as plastic load-transfer zones of finite width, assuming locally uniform adherend thicknesses that match the real local thicknesses. If the plastic zone needed to transfer each load spike is less than the characteristic length  $1/\lambda$  defining the elastic load-transfer length, where  $\lambda$  is the exponent of the elastic stress distribution (see Fig. 9), the load spike is replaced by an elastic load distribution with an integral matching the calculated spike. This simple method was shown to be exactly equivalent to the precise solutions in the event that the adherends really were of uniform thickness.

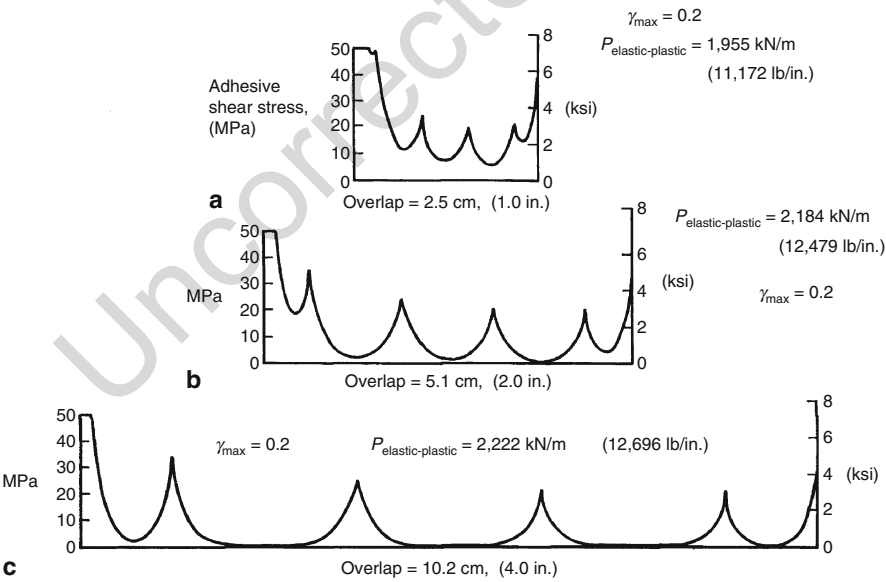

Bonded joints between thicker adherends than covered by Fig. 10 need stepped-lap joint designs, as in Fig. 12, for the higher loads associated with thicker members.

Instead of an increment of load transferred at each end of the bonded overlap, there is an increment of load transferred at each end of each step in such a joint. The addition of more steps requires an increase in the bonded area, but it is important to note that an increase in bond area without any increase in the number of steps is ineffective, as explained in Fig. 13. For bonded composite joints, the strength is predicted to keep increasing all the way to a single ply per step.

Each step in a stepped-lap bonded joint is characterized by exactly the same governing differential equations as govern simple overlaps between uniformly thick adherends.

**Fig. 12** Stepped-lap bonded joints for thicker adherends (AIAA Astronautics and Aeronautics)

Note: All cross sections identical and all step lengths proportional

**Fig. 13** Insensitivity of joint strength to bond area without an increase in the number of steps

There have, for decades, now, been reliable analytical tools available for the design and analysis of adhesively bonded joints. Even so, there is still far too much reliance on the oversimplified model whereby the bond strength is assumed to be the product of some fictitious uniform adhesive “allowable” shear stress and the bond area. If more joint strength was needed, all one had to do, according to this procedure, was to increase the bonded area. Bonded joints do not obey such rules. Such a formula is valid today only in the context of short-overlap test coupons in which the goal is to create as closely as possible a uniform state of stress and strain in the adhesive. In the context of structural bonded joints, such a model ceased to be applicable by the end of the First World War, when airframes stopped being made from wood and fabric. That was the last time that the glue was stronger than the materials being bonded together, so that almost any design would work if the scarf angle was low enough.

The most reliable of the mechanics-based bonded-joint models are of closed form because of the locally very high stress and strain gradients, and the need for iteration to cover material nonlinearities makes finite-element solutions difficult. The finite-element models need to be converged with respect to grid size because accuracy of such analyses is not guaranteed. This problem has been exacerbated in the realm of fiber–polymer composites by the patently false simplifying assumption that the fiber and resin constituents can be homogenized into a single “equivalent” anisotropic solid. A by-product of this error is the myth of singularities at the edges of composite panels, at every change in fiber direction, which has spawned a whole field of study. The singularities vanish the instant that the notion of zero-thickness interfaces is discarded. Yet some researchers have devoted their entire career to the study of such mathematically created conditions that do not exist in physical reality. One needs to be very careful in interpreting finite-element analyses of bonded joints. Conversely, it was only through the use of properly converged finite-element models of discrete fibers in a block of resin that Gosse (1999, private communication) was able to finally validate his concept of dilatation as the primary failure mechanism for constrained polymers in bonded joints and composite laminates. There were no singularities, and the correct answer was unchanged when the mesh size was doubled or halved.

---

#### **44.5 Additional Considerations for the Design and Analysis of Adhesively Bonded Joints in Fiber–Polymer Composite Structures**

When boron–epoxy and carbon–epoxy composites were first introduced into aerospace structures, the only form of prepreg available was unidirectional tape. This imposed on the design of stepped-lap bonded joints some restrictions that were covered by empirical design rules. Those people involved in designing such joints, at that time, all knew not to put a layer of 90° fibers adjacent to the metal step plate and designed their laminate lay-up sequence and step heights accordingly. Consequently,

interlaminar failures in the composite could be avoided and the failure forced into through-the-thickness breaking of either the composite or metallic adherends. This was meant to occur outside the bonded overlap, but it was rapidly learned from test that the thin end step of the (usually) titanium step plate would fatigue off if that step was too long. This meant that, as far as the adhesive was concerned, it was necessary only to show that it had an integrated shear strength greater than the strength of the weaker adherend. Peel stresses were eliminated automatically because the end step in the composite was always too thin to allow them to develop to a significant level. So the A4EG and later A4EI stepped-lap bonded-joint analysis codes made no provision for interlaminar failures in the composite adherends.

Later, when carbon-fiber reinforcement was made available in the form of woven fabrics, it slowly became apparent that laminates could fail interlaminarly adjacent to, but not in, the adhesive layer. In retrospect, it probably took too long for the causes to sink in. Half of the surface of a woven fabric is covered by tows of  $90^\circ$  fibers. The application of a transverse shear force would cause cracks to run up through those bundles until they were arrested by the first  $0^\circ$  fibers they encountered, as explained in Fig. 14.

If these initial cracks progressed any further, it would be in the form of delaminations parallel to the adhesive layer, as shown.

These two codes could not provide such a check since there were no places to enter the interlaminar strengths. Initially, that would not have mattered since there was no way to measure the interlaminar shear strength of an all- $90^\circ$  laminate, either, so there was no reference data to compare against. The standard shear stress test coupon was for an all- $0^\circ$  laminate, although tests were also run on  $0/90^\circ$  cloth laminates and those containing  $\pm 45^\circ$  layers. But these were not standard properties and were not catalogued at the time. When the need for these data did become apparent, the McDonnell Aircraft Company engineers performed a very large

**Fig. 14** Interlaminar cracking through bundles of  $90^\circ$ . Fibers adjacent to a bond line acted on by a  $0^\circ$  load

number of tests on uniform adherends, not stepped-lap joints, to characterize the interlaminar failures as a function of laminate fiber pattern and adherend thickness. They then proceeded to use the A4EI code in reverse to establish fake adhesive properties which would match the measured interlaminar failure strengths using tables to document the adhesive “properties” to be used. This worked, but it was complicated badly by the presence of induced peel stresses at the ends of the overlap that caused their own set of interlaminar failures. These were governed by a different power law in regard to the adherend thickness from that governing the shear-load transfer, as explained earlier.

Eventually, the author realized that what was needed was a revision to the A4EI codes to allow separate checks to be made for adhesive shear failures and interlaminar shear failures using two sets of properties that did not need to be fiddled. There also needed to be a peel-stress cutoff because the codes were being improperly used to analyze uniformly thick adherends as well as stepped-lap joints. The peel failures, if they occurred, would do so in the manner of Fig. 15; they would always precede the shear failures, undercutting it, unless they were excluded by the use of thin adherend tip thicknesses.

The coding for the interlaminar shear effect has been completed, but not yet distributed. However, that for premature peel failures has not been. The author still feels that the correct response to induced peel failures is to reduce the adherend tip thickness, rather than accepting an unnecessary decrease in shear-load transfer capability. Also, until recently, the theory with which to analyze the shear and peel failures in the resin was not available. Some people believed that there had to be an interaction between the shear and peel stresses. With the advent of the SIFT failure model (Hart-Smith 2010) for fiber–polymer composites, it is now possible to analyze the stresses and strains in the resin, including those from residual thermal stresses resulting from curing the laminate at a temperature much higher than its operating temperature. It is now clear that the distortion and dilatation failures in the resin are separate and unrelated, so there is no interaction between shear and peel. The SIFT model characterizes strength in terms of two characteristic invariants for each

**Fig. 15** Induced peel-stress failures in composite laminates with excessive tip thicknesses

constituent (fibers and resin), so it also overcomes the problem of measuring the reference strengths to be inserted into the code for checking against. These invariants do not vary with the nature of the loads, so a test under one set of loads can be converted into a strength under all other sets of loads (unless there is a change in failure mode or in the constituent that is failing). There is now hope for a greatly improved analysis capability of the strength of both stepped and uniform bonded joints.

Unfortunately, more work remains to be done. The original codes were written in Fortran IV; the author is not fluent in the later versions, and there has been no funding available to pay someone who is. Even so, the author knows of one organization where his revised listing of the code enabled them to get an operational version accounting for the shear effects. But they have yet to master the SIFT model, so they must still rely on the McDonnell empirical test data for the reference properties. Finite-element modeling techniques, using ply-by-ply models for the laminates, have been able to characterize the effect of the fiber direction adjacent to the bond on the load-transfer distribution; very little goes through the softer 90° layers. Unfortunately, they are even weaker than they are softer, so the problem of premature failure remains. Accounting for nonlinear adhesive behavior is not easy with finite elements, either.

Even though the analysis codes associated with these extensions of the A4EI codes are not widely available yet, it is considered important to explain these additional phenomena, for which the understanding is complete. Without this explanation, there will continue to be confusion over measured test failures that the old theory cannot explain which brings with it a level of conservatism in design so severe as to unnecessarily restrict the use of bonded composite structures.

---

## 44.6 Design Features Ensuring Durability of Bonded Joints

Durability in bonded joints requires both that the bonded interfaces are stable (the glue stays stuck) and that the adhesive is not failed by the combination of mechanical loads and residual thermal stresses caused by dissimilar adherends. The first issue has nothing to do with the geometry of any bonded joint, although joints fail faster under peel-dominated loads than under shear loads. There are two limits associated with durability that are influenced by the geometry of the joint. The first of these is the peak shear and peel stresses at the ends of each overlap. This is obvious and well understood. The other is to limit the strain level near the middle of the overlap, even in the most severe environment. This is the little understood requirement represented by setting the minimum stress level at or less than 10% of the maximum, which defines the overlap needed to prevent any creep from accumulating. The need for such a requirement was exposed by some of the early fatigue tests on the PABST program. Quite misleading conclusions, both positive and negative, could be drawn from durability tests on short-overlap coupons, as explained by Thrall Jr. and Shannon (1985).

The key to the success of these designs was the acknowledgment that the adhesives' shear stresses were, and should be, highly nonuniform. There are enormous differences between the way adhesives behave, under what appear to be the same external loads, in short-overlap test coupons and long-overlap structural joints, as explained in Fig. 16.

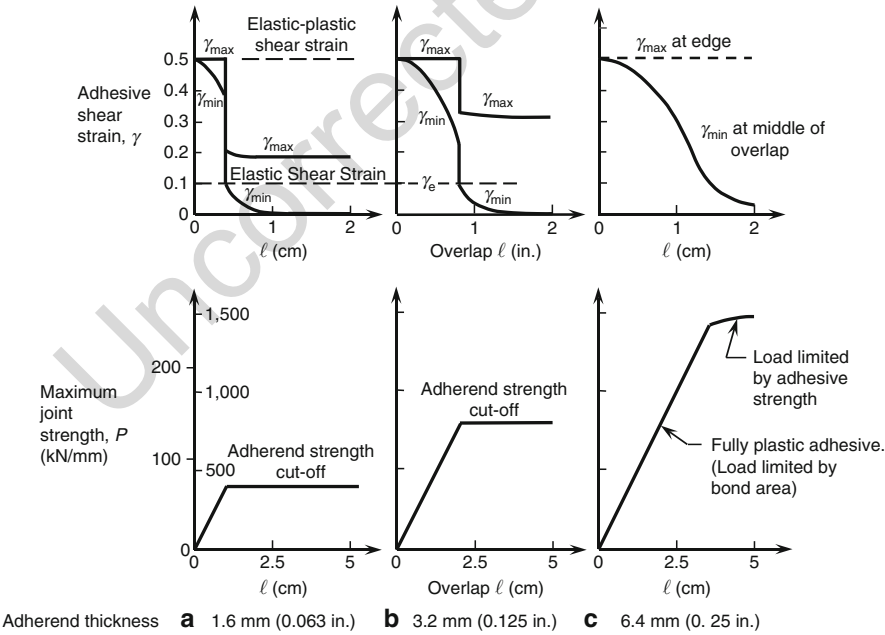

Tests on short-overlap coupons cannot be relied upon to differentiate between adhesives (and surface treatments) that will endure in service and those that will (or have) not. At best, they can make comparisons between slightly different adhesives in the same class. It is almost impossible to prove in the short term that a bonded joint will last 30 years or more in service. Any test under representative load conditions would have to last at least 30 years to indicate a satisfactory result. If the load intensities were increased or the test environment aggravated, to ensure a test result in a short time, there would be no way of knowing what the corresponding service life would be under realistic conditions. And the best adhesive systems would last for 30 years under realistic loads even when tested in artificially severe environments, unless the structural elements wore out first. The only saving grace is that the surface treatments associated with premature in-service interfacial failures could be accelerated and made to fail rapidly under adverse conditions. In other words, the inferior systems could be identified rapidly, but the best systems could be identified only by not appearing on the list of unacceptable systems.

**Fig. 16** Differences between short-overlap test coupons and long-overlap bonded joints. (a) Realistic overlap for structural joint. (b) Short-overlap test coupon

The reason why properly designed bonded joints do not suffer from mechanical fatigue failures is that the most critical conditions are not developed where the adhesive is protected by the adherends. This can be understood by characterizing the minimum and maximum adhesive shear strains firstly as a function of bonded overlap and secondly as a function of adherend thickness, accounting for the effect of the environment in each case. This is illustrated in Fig. 17, for room temperature.

The reason why short overlaps should not be used for structural joints is that even the smallest loads can result in the critical conditions being developed at the ends of the overlap, under sustained load, or by an accumulation of incremental loads, because there is no restraint on the minimum shear strain developed in the middle of the overlap. Once the overlap has exceeded a critical value, proportional to the thickness of the adherends, there is such a constraint on the minimum shear strain, at the middle of the overlap, that simultaneously imposes a limit on the peak shear strain at the ends of the overlap, through compatibility of deformations. No matter how long the loads are applied, the peak shear strain at the ends cannot grow indefinitely. Testing during the PABST program showed that creep did accumulate steadily at the ends of the overlap as long as the load remained. However, it recovered during periods of unloading, every time, with exactly the same shear strain at the end of 8 h into the 5th load cycle as the 14th, for example. There is no counterpart to this behavior possible for short-overlap test coupons, in which such creep occurs but accumulates cycle by cycle instead of recovering. For still longer

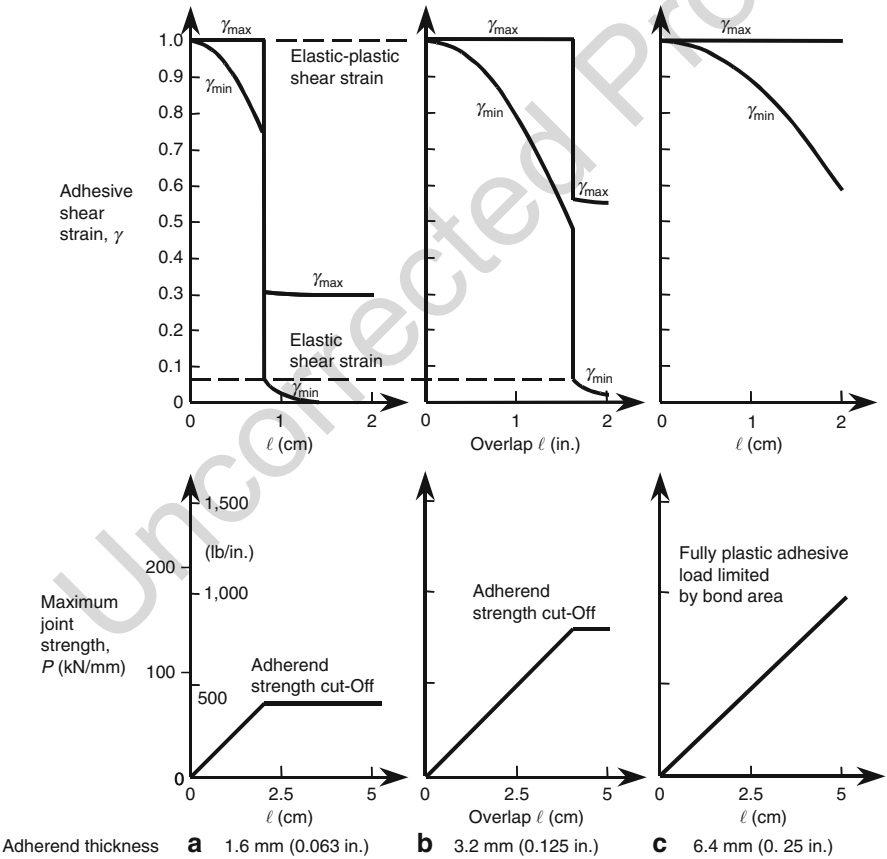

**Fig. 17** Effects of adherend overlap and thickness on maximum and minimum shear strains at room temperature

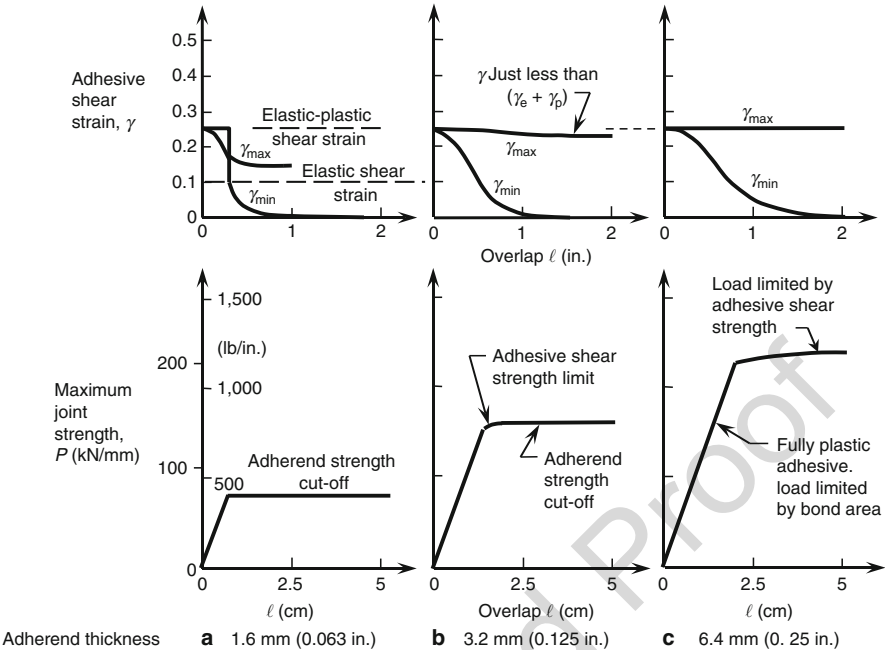

overlaps, the minimum adhesive shear strain decreases asymptotically toward zero, but the peak values remain constant, since the load that can be applied to the bond is limited by the strength of the adherends. So, provided that the design overlap is long enough to extend to the far side of the transition between short- and long-overlap behavior, for the most critical of the environments, any further increases are of no benefit (apart from the provision of a reasonable assembly tolerance).

The influence of the environments on the design overlaps is shown in Figs. 18 and 19 for the hot/wet and cold environments. It is usually found that the upper service temperature limit sets the design overlap because then the adhesive is at its softest and weakest, while the lowest temperature establishes the limiting joint strength because that is the condition of least strain energy, but not by much, as noted in Fig. 1.

Figures 17, 18, and 19 also show that, for the thinnest adherends, there is a deep precipice on the peak shear strain when crossing the critical overlap and that the

**Fig. 18** Effects of adherend overlap and thickness on maximum and minimum shear strains, at maximum service temperature

**Fig. 19** Effects of adherend overlap and thickness on maximum and minimum shear strains, at minimum service temperature

precipice decreases with increasing adherend thickness. There was absolutely no precipice left for 6.35 mm (0.25 in.) thick adherends, indicating that the whole concept of preventing bond failures by limiting the peak adhesive shear strain would no longer prevail, even though the minimum adhesive shear strain could be made low enough. The key to success is that both limits on adhesive strain have to be present. This is why stepped-lap joints are necessary for thicker adherends. But with that design feature to limit the strains in the adhesive, the joints have proved to be just as durable as for the simpler joints used for thinner adherends. The stepped-lap titanium-to-carbon/epoxy-bonded joints at the wing roots on the F/A-18 aircraft are a testament to this, at load intensities of almost 5.25 kN/mm (30,000 lb/in.).

## 44.7 Load Redistribution Around Flaws and Porosity

One of the most remarkable characteristics of well-designed bonded joints, as defined earlier, is their tremendous tolerance for quite large local defects. Provided that the surface treatment and processing were correct, the damage would not spread. (On the other hand, quite the opposite was true in the case of global processing errors, for which it was only a matter of time for absorbed moisture to attack the interfaces on poorly bonded metallic structures. The mechanism for spreading initial failures on

**Fig. 20** Adhesive shear stress distribution for bonded joint with no defects

improperly bonded composite structures is not clear, but the result was just as inevitable.) The same state of nonuniform stress and strain that ensures the durability of properly designed bonded joints is responsible for the ability to tolerate local flaws with no loss of overall strength. It is self-evident that, if the adhesive layer ever was uniformly critically strained, there could be no tolerance to even the slightest flaw.

Figure 20 shows the calculated adhesive shear stress distribution, at room temperature, for a bonded splice on the side of the pressurized PABST fuselage. What is remarkable is that, even at the 1.3-P proof pressure condition of 175.13 N/mm (1,000 lb/in.), the adhesive was not even strained beyond its elastic capability at the ends of the overlap. (The lightly loaded elastic trough appears to be unnecessarily long, but it is actually sized by the hot/wet environment, not by any room-temperature event.)

If it is now supposed that there is a half inch disbond one quarter of an inch from the edge of the 2 in. overlap per side, the adhesive stresses would be modified slightly, as shown in Fig. 21.

The increment of load that used to be transferred through the now defective area is now shared by extra loads in the immediate vicinity of each side of the defect – without affecting the peak stress at the ends of the overlap. This is indicative of a robust capacity of properly designed bonded joints to tolerate large local defects, provided that one can rely on the remainder of the bonded area remaining stuck. (This capacity is lost whenever the adjacent bonded areas are also on the point of failing.)

If it is further supposed that the same defect, or damage, had occurred right at the edge of the overlap, the redistributed adhesive stresses would be as shown in Fig. 22. Again, remarkably, the value of the peak adhesive stress would not be affected. It would simply be moved to the edge of the defect, where load transfer again becomes possible. This kind of defect would need to be sealed to prevent the intrusion of water, which would freeze and expand at high altitude, thereby spreading the initial damage or defect, under what is known as the freeze/thaw cycle. However, the same size defect in Fig. 21 would best be recorded but otherwise left alone. Any attempt to repair it

**Fig. 21** Load redistribution due to local bond flaw near the edge of the overlap

**Fig. 22** Load redistribution due to local bond flaw at the edge of the overlap

would break the environmental protection, by cutting through the primer and exposing bare untreated metal on the edge of any hole that might be drilled to enable resin to be injected to fill the gap and make the discrepancy undetectable in future. All that would be accomplished is to decrease the remaining life, without any increase in joint strength. If the surfaces have been prepared properly, most local damage will not spread. If they were not prepared properly, local repairs are pointless, since the adjacent bonded areas will soon need to be repaired themselves, as noted earlier.

**Fig. 23** Load redistribution due to local porosity in a bonded overlap

If the defect was created in the form of a trapped bubble in the middle of the overlap, as in Fig. 23, when the edges of the overlap were pinched off and there were too few small vent holes in the splice plates (this omission is really usually only a problem with large-area doublers), there would be a large area of porosity where the gap between the adherends was too great for the adhesive layer to fill. The natural occurrence of porosity is discussed by Hart-Smith (1982b). Obviously, since there was no load being transferred there anyway, the presence of such occasional areas of porosity may be considered unimportant, unless it were to cause a misfit with adjacent stiffeners (which is a problem with larger-area bonded doublers with no vent holes). It should also be noted that it is impractical to fill every little bubble in the area of porosity and that, even if this were possible, the gap between adherends could not be reduced and the locally thick bond layer could never pick up its designated increment of load anyway. The thicker bond layer necessarily associated with porosity, unless it occurred everywhere as the result of pre-bond moisture in the uncured adhesive film, ensures that the porous area will not fail, even if it occurred in an area of high nominal shear stress. What most porosity does is to transfer extra load to any adjacent thinner regions in the adhesive bond layer.

Figures 20, 21, 22, and 23 are typical of local flaws in and damage to thin bonded structures. They are usually innocuous and should not be repaired, except when it is necessary to seal exposed edges to prevent the ingress of moisture. This is because of the large excess of strength of the bond over the adherends. For thicker structures, this excess strength is diminished, and flaws and damages can become more significant, as explained by Hart-Smith (1982a).

The preceding examples refer to one-dimensional situations. When bond flaws are assessed in two dimensions, the need for the bond to always be stronger than the adherends becomes abundantly clear. If the adherends are stronger than a properly

**Fig. 24** Two-dimensional load redistribution around a large flaw in a bonded overlap: (a) adhesive stronger than the adherends; (b) adhesive weaker than the adherends

processed bonded joint with no defects, any large defect or damage acquires the characteristics of a through crack in metallic skins, as explained in Fig. 24.

Provided that the bond outside the defective or damaged area is stronger than the adherends, the initial damage cannot possibly spread. Instead, the diverted load will either initiate fatigue cracks in the skin, just outside the damage, or delaminations in composite laminates, at the same locations. In either event, there will be a long interval in which the damage can be detected before it becomes critical. Without such protection from what appears to be merely excess strength in a one-dimensional assessment, large bond flaws would behave like cracks in metallic structures, even if all of the surface treatment and processing had been the best in the world. This is why it is always necessary to design bonded joints so that they can never become the weak link in the load path.

#### 44.8 Effects of Thermal Mismatch Between Adherends on Strength of Bonded Joints

When thermally dissimilar materials are bonded together, residual thermal stresses are developed that usually detract the remaining strength available for transmitting mechanical loads. These phenomena occur whenever titanium edge members are bonded around the edges of composite panels to permit the use of mechanical fasteners during final assembly of the structure or to permit disassembly in service

**Fig. 25** Effects of adherend thermal mismatch on adhesively bonded joints

for inspections and repairs. These thermal stresses are roughly proportional to the difference in temperature between the curing and operational temperatures. Their analysis is explained by Hart-Smith (1978) and illustrated in Fig. 25.

The key issue is that, whereas the shear stresses and strains in the adhesive that are caused by mechanical loads have the same sign at each end of the overlap, the shear stresses and strains caused by adherend thermal mismatch have opposite signs from end to end. Consequently, the thermal effects weaken bonded structures below the strength that would be expected if such considerations had been omitted from analyses. Also, the critical end of the joint can change between tensile and compressive lap-shear loads. The issue is complicated by the fact that some of the thermal strains can creep out of short-overlap test coupons, but they cannot be ignored in long-overlap joints. These effects are more pronounced on thicker structure than on thinner adherends and, in extreme cases, can cause bonded joints between thermally dissimilar materials to actually self-destruct during cooldown after curing at elevated temperatures. The problems are significant for aircraft structures and can be the critical load cases for most space structures. For this reason, acrylic adhesives are used more on space structures than on aircraft structures, for which epoxy adhesives dominate.

## 44.9 Inspection, Testing, and Quality Control

Inspection of bonded and composite structures is one of the most contentious issues associated with these two technologies. A few years ago, the author was told by USAF colleagues of a PhD thesis at WPAFB in which it was estimated that

inspection accounted for over one third of the life-cycle cost of composite structures in their fleet, while the material cost was less than 2% of that total. In spite of the willingness to spend so much money on inspections, mostly in service, the inability to guarantee the quality of such structures after they have been built is a great impediment to their more widespread use. One is forced to conclude that the inspection programs in place have not provided good value for money, as is explained in the next section. In fact, the service record of these structures is far better than this image suggests. The only problems of any significance have been those associated with failure to detect the use of inappropriate processing at the time of initial manufacture. One post-manufacture inspection method can reliably assess whether or not the glue is still stuck at any time during the service life of the structure. This is the bonded pull tabs described by Hart-Smith (1995) and illustrated in Fig. 26. If the surface has deteriorated, the tab will easily be pulled off the surface if a drop of water is applied in conjunction with the peel load. This is known to work on metal-bond structures, per the tests run during the PABST program. It has yet to be applied widely on composite structures, possibly out of concern to damage the underlying structure if the bond were not defective. However, the one manufacturer who did so as part of the process of evaluating and solving a problem reported that it worked just fine.

The inherent inadequacies of some of the expensive standard inspections for bonded and composite structures are described later after describing the various kinds of defects. It is first necessary to differentiate between mechanically induced damage, which is relatively easy to detect, and weaknesses created by inappropriate processing, which can be found reliably at the time of manufacture only by a combination of shear and peel test coupons. This condition cannot be detected by standard ultrasonic inspections because, initially, there is no gap to be found. However, if the defects are not detected until much later, it is necessary to examine the fracture surface to confirm that the failure was interfacial (for a processing error) and, therefore, that it could potentially extend over the entire bonded area. Impact

**Fig. 26** Use of bonded tabs to assess bond strength at any stage in the life of bonded structures

damage tends to be far more localized, and it is unlikely to spread because it takes far more force to break bonds cohesively. Such failures are characterized by a rough fractured adhesive surface on both adherends. Discrepancies found by ultrasonic inspections at the time of initial manufacture fall into a different category. These are misfits that cause voids and porosity in bonded joints. That is the one valuable contribution that these expensive and time-consuming inspections can make. However, there is an even quicker and far more reliable technique for securing the same information. At SAAB, instead of discarding the bleeder pack after the parts are made, it is part of the inspection process for the fuselage panels of the SAAB 340 and SAAB 2000 aircrafts (Hart-Smith and Strindberg 1995, 1997). The local absence of any squeeze out, or any local excessive squeeze out, is an unambiguous indication of where the detail parts did not fit together properly, as explained in Fig. 27. (The need for such bleeder packs, which were not needed for the bonded wing panels, arose because of the use of standard rigid external bonding tools.)

Such local defects are usually structurally insignificant, as explained earlier, but, once detected, cause inordinate inspection costs during service to prove that they have not grown, even though extensive service history indicates that they will not if the processing had been reliable.

However, if such discrepancies are repetitive, considerable future costs can be eliminated by modifying the bonding tool or the individual parts so that such misfits are eliminated from future production, as explained by Hart-Smith and Strindberg (1997). While it may seem contrary to intuitive thinking, by anyone who has not read and understood Deming's books on Total Quality Management, defect-free bonded

**Fig. 27** Use of bleeder pack to indicate the location of any misfitting detail parts

and composite structures really are the least expensive to make. The absence of defects is the path to even more reductions in inspection costs since, after ten consecutive defect-free assemblies have been made, it is permitted to switch to a sampling inspection plan instead of having to inspect 100% of every assembly. In the same vein, there are two positions on whether or not it is necessary to attach traveler coupons to every single part being anodized or if it is sufficient to validate the temperatures, chemical concentrations, voltages, and the like, in the tank farm only at the beginning and end of each shift. The only additional information that traveler coupons on every detail part can provide is assurance that the electrical connections needed for anodizing have been attached correctly. But that detail can also be verified by visual inspection and is sometimes nullified by stringing all coupons in a single patch together to save time in testing them, instead of attaching them to parts one at a time in such a way that they could be anodized only by current that first flowed through the part it was validating. The issue is clouded by the need to measure both voltage and current flow to ensure complete anodizing and not merely the use of polarized light inspections to detect anodizing. This method has failed repeatedly to detect under-anodizing, as noted during the PABST program. This condition has been created by undetected corrosion in the electrical circuit that reduced current flow, even though the correct voltage was maintained, and by too low temperature in the tank farm. In other words, all that the use of 100% traveler coupons ensures, beyond what validating the tank farm twice a shift can do, could have been ensured by diligent visual inspections during the processing. It would seem that, if these 100% inspections were detecting discrepancies not found by the twice-a-shift inspections, the processing specifications were not being followed carefully enough. The author would suggest that the extra tests should be superfluous if there is a stable fully trained workforce in the bond shop but that they serve as a useful insurance policy if there is so much labor turnover that additional training ought to be occurring. These shear and peel coupon tests are neither expensive nor time-consuming. However, it should always be remembered that increments of the inspection budget once dissipated on unnecessary tests will not be available at some future date to resolve some unanticipated real problem. Inspection dollars are most valuable when they are solving problems or confirming their absence, rather than in buying off discrepant parts as is – without causing the discrepancies to be eliminated from subsequent parts.

Once reliable process specifications have been established, their application for metal bonding is customarily validated by two tests on coupons referred to as traveler coupons that are processed with the part. One of these tests is the lap-shear coupon (ASTM D-1002), tested at room temperature, and the other some form of peel test in a hot/wet (hostile) environment. Common peel tests are the wedge-crack test (ASTM D-3762 with a far more stringent requirement on the absence of interfacial failures than in this specification) and the climbing-drum peel test (ASTM D-1781). As noted earlier in this chapter, the first test ensures only that the resin in the adhesive has been exposed to the correct thermal profile, while the second ensures durability in service. Both tests are needed. The parts processed with the coupons are primed within the strict limits on exposure after the

915 etching, anodizing, and rinsing have been completed. (In the auto-industry, the  
916 priming is often an electro-dip process at the end of the other surface treatments,  
917 but the lower volume of production and greater size of the parts have not favored this  
918 approach for aerospace. It would help if it had, since the need for such critical control  
919 of the primer thickness being sprayed on might then be avoided. But that appears to  
920 be a development for the future.) The bare surfaces will deteriorate with time if not  
921 primed promptly but can safely be stored after priming. They are then left on hold  
922 until the traveler coupon tests have been completed, typically in an hour, and not  
923 released to the assembly area until the coupon tests have been satisfied. The surfaces  
924 of the actual parts have to be reprocessed if the coupons fail the test. This delay is  
925 avoided when the tank farm is validated only twice per shift, rather than for each tank  
926 load of parts. But the saving must be weighed against the risk of far greater recovery  
927 costs if parts have been bonded together before some discrepancy is discovered.

928 In the case of bonded composite parts, the standard process inspections are  
929 incomplete, in the sense that only lap-shear coupons are mandated. There is rarely  
930 any use of a peel test to ensure that the adhesive is stuck properly. In the author's  
931 opinion, based on years of observation of manufacturing and in-service experience,  
932 there ought to be because there is no other way of discontinuing the use of surface  
933 treatments that have been found to be inadequate. This issue is discussed by Hart-  
934 Smith (2003).

935 It is vital to understand that each kind of test evaluates only one factor. The  
936 shear test cannot assess durability, and the peel test cannot ensure complete cross-  
937 linking of the resin. Perhaps the worst violation of this principle is the use of  
938 ultrasonic inspections to overrule failure to pass the coupon tests for parts that are  
939 deemed too expensive to scrap. There are never any written specifications allowing  
940 this, but there are also no written instructions prohibiting material review boards  
941 from making such decisions. Fortunately, since the introduction of phosphoric acid  
942 bonding and phenolic-based adhesive primers, the processes have become more  
943 robust than the testing techniques, and such decisions have not created a safety  
944 problem.

945 There is a similar confusion with bonded composite structures, related to a  
946 widespread failure to understand that process-verification coupons cannot do so if  
947 the requirements are set so low that even badly processed parts can exceed the  
948 requirements. It is therefore often necessary that the coupons *not* have the same fiber  
949 pattern as any individual part. Only an all-0° lap-shear coupon can impart enough  
950 load to fail a properly processed adhesive layer. Failure outside the bonded overlap  
951 in a far weaker quasi-isotropic laminate tells nothing whatever about the strength of  
952 the adhesive layer or whether or not it had been fully cured. So the use of such fiber  
953 patterns as bonded-joint test coupons is always inappropriate, no matter what the  
954 design of the structure is. Similarly, all-0° peel test coupons are needed to evaluate  
955 durability because it is so easy to divert any interlaminar crack through any layer of  
956 90° fibers. Sadly, not only is there yet any agreement on the need for durability tests  
957 of bonded composite joints, there is not even a universal recognition of the need for  
958 the composite coupons that are used to be strong enough to pass only when a full-  
959 strength bond has been created.

Ultrasonic inspections can, at best, tell only that no impact damage has occurred that was of sufficient magnitude to create internal delaminations and that the parts did or did not fit together properly when they were first bonded together. However, there are some far more reliable and far less expensive visual inspections that can ensure proper fit – and reveal a lot about the processing too! This is explained in Fig. 28, taken from Hart-Smith (1995). The fillet cannot achieve the preferred shape if the adhesive was not heated up correctly to make it flow; it cannot wet a contaminated surface; and it cannot even form if the parts are too far apart. The shape of the fillet is an invaluable reliable indicator of a good bonded joint, and such an inspection is both rapid and inexpensive. The total absence of any fillet indicates a gap just as reliably as any ultrasonic inspection. Indeed, it is necessary to seal any edges where there is no fillet before attempting to use ultrasonic inspections because liquid that could ingress through an open edge could mask the extent of such gap from any ultrasonic inspection, which relies on gaps to create signals of discrepancies. A porous spew for an epoxy adhesive would indicate the presence of pre-bond moisture but would be expected for a phenolic adhesive. (Despite their excellent service record, phenolic adhesives tend not to be used much in aeronautical structures today because of the higher pressures needed than for curing epoxy adhesives.)

To summarize the salient points about inspections and quality control for bonded structures, it is vital that appropriate processes be specified – and followed. Verifying this requires both shear and peel tests in a hot/wet environment for metal bonding and bonded composite structures. Ultrasonic inspections can be relied upon to find only in-service impact damage, not progressive degradation. However, ultrasonic inspections at the time of manufacture can identify gaps and misfits and point the way to major cost savings by eliminating such discrepancies from future parts, even if they were structurally insignificant. Any defect, once detected, incurs enormous subsequent inspection costs to prove that it has not grown. It is far less expensive to make parts with no defects than to buy them off as is. Although it is usually not

**Fig. 28** Importance of visual inspections of bonded structures

mentioned in any specifications, visual inspections can be incredibly valuable, even if they do not eliminate the need for all other tests.

---

#### **44.10 Concerns About the Misplaced Emphasis of the Quality-Control Inspections for Bonded and Composite Structures**

Just as the primary purpose for the structural analysis of aeronautical structures should be to make the structures better than if the analyses had not been performed, the primary purpose of inspections should be to make the structures better than if the inspections had not been performed. Unfortunately, because analysis and inspection seem to be done too late in the construction process, both fail to achieve their best potential. Indeed, the primary emphasis seems to be to respond to regulations that the structures must merely be shown to be safe. In both cases, the products would be even safer if those tasks were performed much earlier.

The current illogical emphasis on after-the-fact ultrasonic inspections would appear to have its origin in practices developed for the assembly of rivetted metallic aircraft many decades ago. Instead of step-by-step inspections during manufacture, reliance was placed on thorough after-the-fact inspections. Most mistakes could be corrected by drilling out and replacing a few badly driven rivets. This would restore the structure to 100% of its design strength, with no loss of safety or reduction in fatigue life. It may or may not have been the least expensive approach to inspection, but at least, in that context, it was reliable. Fixing any problems as they were created would have been far less expensive (in the author's opinion, based on his experiences and observations), but if there were no defects to find, the intermediate inspections were perceived as a waste of money and repeated interruptions to the assembly schedule. The problem with adhesively bonded and fiber-polymer composite structures is that after-the-fact repairs are usually incapable of restoring 100% of the loss of strength caused by the defects, particularly in components with large loads in them. In short, it is not possible to inspect quality into such parts after they have been made and assembled. The only way to ensure high quality in bonded and composite structures is by appropriate process control, before and during the manufacture and assembly of the parts. Sadly, many of the approved process standards and inspections fail to do so reliably. Worse, many of the approved repairs merely conceal the existence of the damage from further inspections without any increase in strength. The author must conclude that many of the inspections that are performed are done merely because it is possible to do so, rather than as part of a rational quality assurance program. This problem is exacerbated by the absence of what are perceived as critical after-the-fact inspection capabilities. But that excuse misses the fundamental point – belated repairs to bonded structures are inherently incapable of restoring 100% of the design strength. And, with bonded metal structures, these same after-the-fact repairs break the environmental protection that was created during bonding and thereby decrease the service life of the structure.

The purpose of this section is to draw attention to some of these issues, in the hope that their exposure will encourage improvements. It should be noted at the

outset that this is not a matter of simply spending more money doing the same things more thoroughly. There is widespread irrefutable evidence that improved quality during manufacture greatly decreases the cost of making and inspecting the parts. If there are no defects to be found, there are no costs incurred by fixing them and no interruptions to the flow of manufacturing through Material Review Board (MRB) activities. The focus here will be on bonded structures, but many of the same considerations apply to composite structures, too.

It is first necessary to distinguish between the two possible mechanisms of failure of bonded joints. The first, which has proved to be by far the most troublesome, is adhesion failures in which the adhesive was never stuck to the adherends, even if there was no gap between the parts to be detected by ultrasonic inspection. This is an interfacial failure that has not degraded the adhesive itself but totally destroyed its capability to transmit load. The second is cohesive failure within the glue line, which results from impact damage. Such damage tends to spread extremely slowly, if at all, because in a properly designed bonded joint, the undamaged joint itself is never the weak link, as explained earlier. The adherends will fail before such damage can be spread. With interfacial failures, however, there is no need for a load to cause the nonbond to spread. There is a third kind of defect, porosity, that occurs during assembly when the parts do not fit together properly or when the bonding tool prevents them from fitting together. The importance of interface control is explained by Hart-Smith (1997). Whereas there is a standard tolerance on the parts on the order of  $\pm 0.75$  mm (0.03 in.), the tolerance on a glue line that is nominally  $\pm 0.125$  mm (0.005 in.) thick is only  $\pm 0.025$  mm (0.001 in.). This is impossible to satisfy unless the parts being bonded are able to drape to fit, as with skin/doubler combinations. If the gap between the parts is more than about 0.25–0.50 mm (0.010–0.020 in.), the adhesive will flow out of the gap if it is cured by high temperature. Only paste adhesives can be used to fill gaps between parts, and they tend to have lower environmental durability than high-temperature-cured film adhesives. More critically, they take far longer to cure, requiring that the parts be left in assembly jigs for far longer. Worse, since paste adhesives start to cure as soon as they are mixed, this imposes severe limitations on the permissible lay-up time. But the problem with misfitting parts does not end with the creation of porosity or voids. Gaps between parts to be bonded together are not uniform over the entire bond area. Consequently, there are adjacent areas of ultrathin bonds, which are very stiff and attract all the load transfer, and excessively thick bonds, which shed the load they should have been transferring to adjacent thinner bonds, as explained in Fig. 29.

This nonuniformity in load transfer is in addition to the nonuniformities discussed earlier whereby most of the load is transferred immediately adjacent to the ends of each bonded overlap. What the variable bond-line thickness causes that is totally overlooked when one thinks of a uniform adhesive shear stress throughout the entire bond area (which is still a popular model in spite of the evidence) is that, once the thicker bond areas have been established, whether by porosity or voids, even if it were possible to fill the cavity with adhesive, let alone ensure that it adhered, the thick bond regions would not transfer load anyway. This false perception has even worse consequences. The believers in the concept of a uniform adhesive shear stress

**Fig. 29** Load-transfer redistribution caused by variable bond-line thickness

1075 throughout the bonded area consequently believe that increasing the bond area  
 1076 increases the joint strength. The reality, as explained earlier, is that the strength  
 1077 increases with bond area only until a plateau in strength is attained. Further increases  
 1078 in bond area are futile; only the addition of more steps can increase the shear strength  
 1079 of the joint.

1080 The *only* way to deal with this potential problem of unanticipated variation in  
 1081 shear transfer is to ensure that it never occurs by properly coordinating the design of  
 1082 the structure and the bonding tool(s) before the parts are bonded together. When this  
 1083 has not been done, it is standard practice to identify and locate any thicker gaps and  
 1084 to insert additional adhesive, so that no voids or porosity are created. It is then quite  
 1085 wrongly believed that this must be a “good” bond because ultrasonic inspections  
 1086 cannot identify any defects.

1087 In a similar vein, it should be obvious that, if the adherend surfaces are not  
 1088 processed appropriately, there is no way to make the glue stick other than to  
 1089 disassemble the parts and start all over again. But, if there are no gaps between the  
 1090 parts, the inability of the standard ultrasonic inspections to detect any of the defects  
 1091 that they are assumed to be capable of detecting results in the bonds being accepted  
 1092 when they should not have been. There has, for decades, been a lot of effort devoted  
 1093 to detecting the so-called kissing bonds. But even if such a method were established,  
 1094 discovering the problem at the end of manufacturing leaves absolutely no possibility  
 1095 of restoring the strength of the bonds to anywhere near their design capacity or,  
 1096 sometimes, even to achieving any increase in strength. At most, such “repairs”  
 1097 would simply conceal the existence of the zero-strength bonds. Worse, such defects  
 1098 would be global, not local the way porosity tends to be.

1099 The only bonds that are capable of being restored are cohesive failures from  
1100 impact damage, which is usually found visually, provided that the repair is  
1101 performed before contaminants have entered the cavity.

1102 With very few exceptions, adhesively bonded structures have demonstrated  
1103 excellent durability in service. The problem is that processing errors, whether they  
1104 were caused by inappropriate approved processing specifications whereby the pro-  
1105 cess was being diligently but unknowingly done wrong or by undetected lapses in  
1106 process control with processes that would have worked if they had been done right,  
1107 have tended to involve hundreds or thousands of parts that needed to be fixed. Even  
1108 so, the author knows of only one fatality to which a poor bond contributed – and,  
1109 even then, that contribution was the result of an inappropriate choice of adhesive, not  
1110 to a lapse in quality control or inspections at the time of manufacture. (Even then,  
1111 there were many missed opportunities to prevent the final failure long before it  
1112 happened; the nonbonds were merely the trigger that started the process, not the  
1113 ultimate cause.) The problem with the interfacial failures has been one of cost to  
1114 rebuild those structures, not safety. Most bonded structures have been in secondary  
1115 structures. But, because of the few fleet-wide problems that have occurred, there has  
1116 been a reluctance by most aircraft manufacturers to apply adhesive bonding as  
1117 widely as it should have been, based on its technical merits. This reluctance has  
1118 been compounded by the erroneous belief that doing so required better inspection  
1119 techniques rather than better process control. It has been intensified by the observa-  
1120 tion that the most reliable manufacturers of bonded aircraft structures had a stable  
1121 workforce, so that the skills built up could be maintained. This is contrary to the hire-  
1122 and-fire mentality in other countries in which the existence of special skills is  
1123 denied to support the prevailing business plans.

1124 Much of the porosity generated in large-area bonds could have been prevented by  
1125 proper venting during cure. This can be achieved by a grid of small holes in doublers  
1126 to overcome the tendency to pinch off the edges and trap any air inside. This was  
1127 standard practice for the bonded fuselage panels on the SAAB 340 and SAAB 2000  
1128 commuter aircraft. The wings of the same aircraft were bonded in a special nonrigid  
1129 bonding tool that totally eliminated all bond defects, resulting in far better bonded  
1130 structures at a far lower price. This is described by Hart-Smith and Strindberg  
1131 (1997). In this case, the vents were achieved by having loose fasteners in the  
1132 determinate assembly holes used to keep the skin, doublers, and stiffeners located  
1133 properly. This technique permitted a complete visual inspection of the parts inside  
1134 the vacuum bag to ensure that they all fitted together properly before the parts were  
1135 bonded together because the creation of short escape paths for any trapped air or  
1136 volatiles eliminated the need for bulky bleeder packs which, in many other applica-  
1137 tions, did more harm than good because the associated bridging prevented the  
1138 application of pressure in some areas. Because pressures are uniform inside auto-  
1139 claves, there is no mechanism to displace the air in voids, only to compress it.

1140 This reluctance to apply bonded structures more widely has had one beneficial  
1141 result, in the author's opinion. Apart from the titanium-to-composite stepped-lap  
1142 bonded joints used on the wings of the F/A-18 aircraft and on the tails of many  
1143 military aircraft, there have been relatively few applications of bonded structures

where the local loads have been of high intensity. This is a good thing, in the sense that bonded joints should never be allowed to become the weak link in the structure. Unfortunately, this need usually is not even acknowledged, let alone understood. This is easy to achieve when only thin or laminated components are bonded together. Rivetted joints are more appropriate for higher load intensities since the multiplicity of discrete fasteners retards the spread of any damage. A bonded design in which the adhesive is the weak link, even if the processes are all performed correctly, is tantamount to a weak-link fuse over the whole area, with the potential for damage to spread rapidly once started, as was explained earlier. In addition, there is not yet enough acceptance of what is needed to manufacture thick bonded structures. (Fokker was smart enough to use bonded laminated wing skins on the F-28 aircraft so that no single bond line was heavily loaded, even though the total load intensity in the skin was substantial.) This is most evident in the widespread failure to understand how to deal with induced peel stresses when the ends of the bonded overlaps are too thick. This problem does not arise with stepped-lap joints or laminated structures with the ends of the overlaps staggered, because the outermost end steps where the peel stresses would develop are always thin, which is consistent with Fig. 12. But these high-load bonded joints achieved their reliability because of their complexity, which comes at a higher cost.

In the absence of a proper understanding of induced peel stresses, it has become fashionable to believe that a fracture mechanics analysis of the peel stresses is what is needed. The author believes that this approach has arisen because the standard shear-transfer analyses can be applied to adherends of any thickness and contains no interaction with peel stresses to cause a reduction in the predicted shear strength of the bonded joint. This, in turn, has arisen because, prior to the recent development of the SIFT model for predicting the strength of fiber-polymer composite laminates (Hart-Smith 2010), it had not been appreciated that there was no interaction. Also, the SIFT model does not require the assumed existence of a preexisting crack at the end of the bond line. The two cohesive failure mechanisms for the adhesive really are governed by independent criteria, both of which must be satisfied. The two mechanisms are governed by different power laws related to the adherend thickness, as noted earlier. It is not clear to the author how fracture mechanics methods developed for cracks in homogeneous materials can ever be related to the peel failure of adhesively bonded metallic structures or to delaminations in distinctly heterogeneous fiber-polymer composites; the calculations seem to him to have all the feel of fitting an analysis to test data by use of adjustable parameters that cannot be measured directly. Nevertheless, it is now common for such analyses to be carried out as part of the certification process. But, the author is unaware of any use of such output to improve the design of bonded structures. They seem to be accepted as an unavoidable burden. Indeed, in some cases, these analyses have caused the rejection of what experience has taught the author to bonded joints that were not critical in peel. Regardless of their technical merits, or otherwise, a valid peel-stress analysis which identifies that a bonded joint is critical under induced peel stresses is an unambiguous warning that the design is unsatisfactory because the peel-stress failures will undercut the potential shear strength of the joint. The most appropriate

response to the results of such an analysis is to reduce the thickness of the adherends where the peel-stress failures are predicted to occur, at the edges of the overlap, until further analysis shows that peel stresses are no longer critical. This can always be done in such a way as to maintain the joint shear strength. Indeed, it can actually enhance the shear strength by eliminating the pinch-off that can occur at the ends of uniformly thick adherends. At this stage, the peel stresses would no longer govern, so even a crude analysis would suffice. The problem with now being capable of performing an analysis for peel stresses has led to a failure to employ the good design practices that were developed during the time it was not possible to perform any such analysis. The author's concerns about the use of fracture mechanics as an analysis tool for bonded joints is exacerbated by its inherent incapability of establishing what the overlap should be because this is governed by the minimum shear stress in the middle of the overlap where there is absolutely no possibility of a preexisting crack that would allow fracture mechanics to be employed and where, even if there were, it would never show up as being critical in a fracture mechanics analysis because the bond stresses are almost zero there.

In the same vein, overly complicated co-cured composite parts with embedded wrinkles in the fibers are often "passed" by ultrasonic inspections that detect no voids in the structure. Wrinkles in the fibers, which cause a far greater loss of measured strength than typical levels of porosity in parts that are rejected, do not count as defects because of the widespread acceptance of the myth that fiber-polymer composites are homogeneous. Sometimes, the complexity of co-cured parts is so great that detectable voids are created. But, no matter what is done after that point, it is impossible to straighten out the fibers to restore the strength of the laminates. In other words, the inspection comes far too late to permit the structures to be restored to their design strength, and, in some cases, there is not even an acknowledgment that there is a problem with the parts.

The author would recommend that it is time to totally rethink the quality assurance programs for bonded and composite structures. It is known, from experience, which currently approved processes should be banned, and it is known what needs to be done to ensure low-cost defect-free parts by proper coordination of the parts and the bonding tools and by adherence to reliable processes. It is necessary to stop relying, instead, on the approach of pretending to inspect quality into the parts and assemblies after they have been bonded together because, by that stage, any defects that have occurred will ensure that the parts can never be restored to 100% of their design strength.

---

## 44.11 Bonded Repairs

Bonded repairs should be looked upon as joints that are made at some time after initial manufacture. They need to be made under the same rules and procedures, but it is obviously not possible to repeat the very same surface treatments for bonded metal structures or even for composite structures if a peel ply had been used. In both cases, low-pressure grit blasting has proved to be the most reliable surface treatment

for repairs. This is often followed by the application of a silane coupling agent when composite patches are bonded over cracks in metallic structures. Such patches have been found to be both very reliable and effective (Baker and Jones 1987); they have most often been used when there is no other alternative but to scrap the part because rivetted repairs are sometimes impossible or ineffective (not stiff enough to restrain a crack from any further growth).

As noted earlier, local bonded repairs to bonded metallic structures that were made according to inappropriate specifications are an exercise in futility since the remainder of the structure is also about to disbond. Such structures need to be totally remanufactured in accordance with better processes even when the specific repair manual states otherwise. The most critical issue about the repair of damaged or disbanded composite structures is the difficulty of thoroughly drying the laminates before the repair is executed. Absorbed water takes a very long time to remove from both face sheets and honeycomb cores. This causes such parts to be out of service for a long time.

---

## 44.12 Other Industry-Specific Factors

A little publicized fact about adhesive layers is that they act as electrical insulators. Today's jet transports made from aluminum protect the passengers and crew because they are contained in a complete Faraday cage. There are a number of adverse consequences if that cage is interrupted by insulators between the individual metallic skin panels. The most obvious is that lightning strikes will cause far more damage if there is no continuous conductive path between the strike zone and discharge point. Indeed, simulated lightning-strike tests during the PABST program showed extensive local burning of the adhesive layers at the bonded joint between adjacent skin panels. This is why composite aircraft need special conductive coatings to compensate for the poor conductivity of even carbon fibers and for the periodic total interruptions through bonded joints. A lesser-known issue is that the establishment of even small potential differences between the panels on aluminum aircraft caused by the overzealous application of sealant to prevent corrosion can interfere with some of the small voltages involved in transistorized communication systems. The possible interferences with these systems that are responsible for the powering off of electronic devices during takeoff and landing are of concern. It is therefore important that the individual panels that make up the exterior skin of aircraft, and presumably rockets and missiles also, are grounded together with sufficient connections. The notion of an all-bonded structure is really a myth. Some minimum number of tight-fitting dry rivets is needed to provide electrical connections. These are easily located in the many low-stress areas in bonded joints without causing any fatigue problems. A rivet hole in the middle of a bonded overlap, where the stress level is only half that of the surrounding skins, has a fatigue life some 20 times longer than in a rivetted joint between the skins. Once this need for some holes is acknowledged, it makes sense to use such holes for determinate assembly, to minimize the need for most of the traditional costly assembly tools, and to simplify bagging by eliminating the need

for holding fixtures. This concept was used on the bonding tools to both simplify and improve the manufacture of the bonded stiffened wing skins used on the SAAB 340, as discussed by Hart-Smith and Strindberg (1997). There needs to be a balance between coating every fastener and every faying surface with sealant to prevent corrosion and the need for electrical continuity. Perhaps the cost savings from determinate assembly may provide the encouragement to include the necessary connections to create a true Faraday cage on aerospace structures.

Another issue about bonded aircraft structures is that the surfaces created by anodizing and etching to enhance the adhesion of adhesive primers are more prone to corrosion than normal rolled or machined aluminum surfaces. It is therefore necessary to be very careful, particularly in bilge areas and around galleys, to create and maintain reliable corrosion protection. The polymers used in adhesives tend not to degrade with time and environmental exposure, but some do absorb water and other chemicals. Even so, the primary concern has been for the durability of the interfaces.

---

#### 44.13 Examples of Use of Adhesive Bonding in Aircraft Structures

---

Some aircraft manufacturers have made far more extensive use of adhesive bonding than others. De Havillands (now absorbed into BAe) and Fokker were the pioneers in using adhesive bonding in primary aircraft structures. The Fokker F-27 Friendship and F-28 Fellowship aircraft are renowned for their successful widespread use of adhesive bonding. SAAB and Cessna used primary structural bonding widely after the PABST program had validated the second successful generation of materials and processes. However, other major airframers have restricted the use of adhesive bonding to mainly secondary structures, primarily because of the failures created by the pre-PABST bonding processes and surface treatments developed in the USA. The most significant difference between the two levels of application would appear to be the stability in the labor force, for a variety of reasons. It is not the result of technical ignorance of what is needed to make bonding work, or of the benefits it can create.

Figure 30 shows the extensive application of adhesive bonding to the aluminum airframe of the SAAB 340 aircraft. This aircraft has an incredible structural efficiency and durability, which could not have been achieved with conventional rivetted structures.

Cessna made even more extensive application of bonding to the fuselage of the Citation III jet aircraft and used the same technology to make wings on other aircraft with far fewer fuel leaks than on conventional rivetted wing boxes. Figure 31 shows a typical frame/longeron intersection point on the Citation III fuselage skin, showing how not only the waffle doubler and longerons are bonded to the skin but the outer half of the frame is, too. What is significant about this design is that both stiffener flanges are continuous where they contact the skin; there is no weakness associated with the traditional mousehole in the frames to allow longerons to pass through.

**Fig. 30** Application of adhesive bonding to SAAB 340 fuselage, wings, and tail

**Fig. 31** Cessna Citation III bonded frame/longeron intersection

1314 The secondary structures, control surfaces, and fixed panels on the Boeing  
 1315 747 made extensive use of metal bonding, mainly with honeycomb. Many of these  
 1316 components have been replaced by composite structures on later models, but most of  
 1317 these components should still be classified as bonded structures. For example, the  
 1318 777 composite tails (see Fig. 32) are made by co-bonding pre-cured stiffeners to  
 1319 green skins. These are classified as primary structures, surpassing in both size and  
 1320 load intensities the earlier NASA-funded flight demonstration programs on the  
 1321 737 and DC-10. All current-production Airbus aircraft have primary composite  
 1322 structures in their horizontal and vertical tails. Today, virtually all modern transport  
 1323 aircraft have composite control surfaces, wing-root fillets, and various other second-  
 1324 ary structures.

**Fig. 32** Co-bonded composite primary structure on Boeing 777 tail

Military aircraft have made much more use of primary composite structures than on commercial transport aircraft, but most new general aviation aircraft since the resurgence of this industry a decade ago have made even more extensive use of composites, co-cured and bonded, in their primary structures. Their smaller size favors this method of manufacture.

Adhesive bonding has a tremendous advantage over co-curing of composites for high production rates. Co-cured structures require the use of the largest tools for a greater time than bonding together of simple details, many of which can be cured in a single autoclave cycle. This was recognized by the team that developed the Lear Fan all-composite executive transport aircraft over 20 years ago. It was planned for a production rate of one aircraft a day. The tooling costs would have been unaffordable if the design had been based on large integrally stiffened assemblies. This issue is still important today. The minimum-cost prototype development program is often a co-cured design because the effects of production rate are not considered. Once the structural tests have been completed, the option of less expensive more dispersed production is lost, and high production costs are often locked in place. It would make more sense not to minimize the cost of the prototypes in isolation but to build prototypes of the lowest-production-cost design instead.

---

#### 44.14 Conclusion

This chapter has focused on adhesively bonded joints in aircraft structures, emphasizing why and how they work, when they are superior to mechanically fastened joints, some examples of great successes, and an explanation (with cures) for less than successful applications. There is more coverage of experience with bonded joints than the science that enabled them to work. Those details are found in much greater depth in other chapters in this book. However, there is also some discussion of devoutly held beliefs about bonded joints that are so wrong that they have inhibited the more widespread use of bonding because of unwarranted concerns about durability and monitoring degradation. Despite having been able to characterize the nonuniform transfer of load through bonded joints for decades, the most widely taught method simply, and quite erroneously, assumes that the load distribution is uniform to “simplify” design and analysis. Inspections have not been used wisely since so many of them are applied at the wrong time in the life of the product. Sadly, the most valuable inspections, visual, are downgraded as being too primitive to use because they rely on skill, a variable human factor, ignoring the fact that most of the instruments used can never find some of the most critical information that is sought. There is a tendency to conduct an inspection for reasons more related to the existence of an instrument that is supposed to be able to detect some defect rather than that there is any real need, or likely benefit, from the inspection. Worse, the most critical source of bond failure – the failure to adhere in the first place – is often not acknowledged as the most critical (because any such error will have global impact). Instead, there is too much focus on inspections for local damage, which the adhesive

is often able to tolerate with no loss in strength by rearranging the load-transfer distribution. The reason for the misplaced emphasis is merely that it is possible to detect that kind of discrepancy. The hope is that, by exposing these issues, and how to address them, there will be a greater willingness in the future to use bonding where it really is the best approach – and to not knowingly take shortcuts (even if they are “approved”) that give it a bad name because the impact is so widespread. The confirmed success stories about adhesive bonding in aircraft structures are substantial and have been for decades; they just need better publicizing to neutralize the bad press from the failure cases, none of which can reasonably be blamed on ignorance. The author concludes with the following suggestion to encourage the more widespread use of bonded aeronautical structures. Waiting until someone devises a reliable after-the-fact inspection method for bonded structures before accepting the advantages of bonded structures, where they make sense, is going to take an extremely long time if it is ever accomplished. And, in any case, as explained earlier, such a technique could not enable the design joint strengths to ever be restored; it is too late to try to inspect quality into a part after it has been built. Some aircraft manufacturers have already demonstrated that carefully following appropriate processes is both feasible and reliable. The service record of properly bonded aircraft structures is exemplary. There is no need to wait for an additional safety net, for which no need has yet been found, to justify less diligence during the manufacturing processes before committing this proven technology to production.

**Abstract**

30 This chapter aims to introduce some of the specific bonding-related issues that

31 face those responsible for bonding operations in space applications. We have to

32 consider two cases: structures for launchers and structures for satellite where the

33 environment in terms of load is different. In the case of launchers, extremely high

34 mechanical loads over a short time occur, and for satellites, there is the gravity

35 magnified by about 20, followed by exposure to extremely high temperatures

36 over a very long period, with the observation and telecom satellites under zero

37 gravity.

38

39 To design for such broad specifications and to select materials, such as

40 adhesives, it is just the first in a series of challenges.

41 To perform tests on Earth reproducing space-like environments while subject

42 to terrestrial gravity is the second and not the least significant.

43 This chapter is intended to be an introduction to the issues which have to be

44 considered together in the case of spatial bonding from the bottom, on Earth,

45 upward, to space.

**45.1 Introduction**

46

47 At the beginning of the space conquest in the 1960s, the structural parts of launchers

48 and satellites were mainly made of metal. Here and there, lighter aluminum foil or

49 fiber glass-reinforced plastic composite parts replaced metal as the satellites grew in

50 mass and volume in parallel to the launchers. The word “composite” began to be

51 used to designate structures built up using several different types of materials from

52 various origins (metallic or organic). One found, on one hand, the monolithic

53 composite parts, which refers to the organic stacking of woven glass fabric at various

54 angles, pre-impregnated with resin and cured under pressure. On the other hand, one

55 found mainly 100% metallic, light plane structures made with aluminum foil skins

56 bonded with an organic film to honeycomb core material. At the very beginning,

57 based on conventional design reflexes, the metallic and organic parts were mechan-

58 ically fitted together, and those first composite parts were reserved for no structural

59 parts. This was also due to a lack of experimental feedback, i.e., of confidence, in the

60 behavior of such polymeric parts in a spatial environment.

61 For assembly, the mature aeronautical industry used nut/bolt and rivet systems

62 after drilling, which came from the general mechanical industry. If saving mass

63 was obviously an issue in aircraft, it was even more critical in spacecraft. Before

64 escaping the grips of gravity, the energy required for launching is directly dictated

65 by the weight, and the amount of energy is borne by the launcher. It was the space

industry that applied the aeronautical principles, as far as the arrival in the scene of composite materials was concerned. At the beginning of the 1970s, the epoxy resin associated with glass and boron fibers brought improved specific strength (strength divided by density), enabling the introduction of composite monolithic structural parts instead of metallic ones. Finally, carbon fibers arrived in the 1980s and with them, their assembly at the stage of primary structural parts, in monolithic truss structures or sandwich panels, as parts of the bodywork of satellites. At present, aircraft manufacturers are developing processes capable of one-shot 5-m-diameter-wide, 20-m-long main structural parts. They use several processes like automatic tow of carbon fiber placement, 3D mixed carbon/aramid woven fabric, out-of-autoclave curing, and unidirectional or fabric, pre-impregnated with resin. Dry fibers preformed and consolidated after resin injection or with infusion process are also in production line. In conclusion, priority is given to innovation to make as much headway as possible to reduce the weight of planes, to switch the more numerous parts in gray aluminum to black ones. An Airbus A300–600 was 5% composite material in 1970; this proportion is ten times higher in Airbus A350 XWB today.

The same trend can be seen in the launcher industry. The composite rate increased from 15% in Ariane 5 launcher to up to 63% in the new launcher Ariane 6 and even more in A6 with four booster versions where the level of composite reaches 63%.

Thanks to the adhesive bond technology, 40% cost savings in production were achieved in aeronautics in comparison with riveting where the weight has been divided by 2.5 for some parts.

Bonding in spacecraft dates back to the same era as composite materials, with composites including, on one hand, the previously mentioned fibers reinforced with plastic, like fiber glass, carbon, aramid reinforced with epoxy, phenolic, and thermoplastic resin and, on the other hand, lighter metal alloys, mainly such as aluminum and titanium. Even more so than aircrafts, spacecrafts were the ideal candidates for composite material application and especially carbon fiber-reinforced plastic (CFRP), characterized by high specific stiffness and specific strength, i.e., the ratio values of the Young's modulus and strength to failure divided by the density. These specific mechanical properties associated with a low coefficient of thermal expansion (CTE) result in a light, highly loaded, dimensionally stable structure. For a designer, composite design generates potentially sizeable weight savings, keeping in mind that for space injection by a launcher, "mass is money."

Since the nut/bolt and rivet systems after drilling are dedicated to joining metal, bonding is mandatory for assembling composite parts, and the rules of designing and justifying holes are well known with metal. Because of its anisotropic behavior, designing and justifying a hole in a composite part is much more complex. In principle, local reinforcement is generally performed. The lay-up sequence is also optimized. Drilling composites is not a safe operation as delamination can occur.

Since adhesives with thermo-structural resistance became available, bonding was implemented in aircrafts, more largely in helicopters than in airplanes, such as filling agents for rooms and load-wide spreading agents between the bolted or riveted metal parts.

Let us be reminded that in the 1960s, two phenomena appeared with metallic structures assembled with adhesive bonds:

- Adhesive bond corrosion. It was the degradation of the oxide layer on the metal junction due to hydrolysis of the polymer of the adhesive.
- Sandwich structure corrosion. This phenomenon was generated by the confined atmosphere in the cell with the presence of humidity and corrosive gas coming from the polymerization residues.

Solutions have been founded with:

- Hydrophobic adhesives
- Deposition of anticorrosion primer based on chromate and suppression of plating aluminum
- Improvement of the stability of the oxide layer with chromate or phosphorus anodic conversion (protection of honeycomb cells)

The protection against atmospheric corrosion was also one of the first applications of the bonding agents between metallic parts, as wet barriers. With the arrival of composites, the issue of assembling composite and metal parts together was brought sharply into focus. If the resin formulators went a significant way to meeting requirements (mechanical, thermal), dedicated metal surface preparation prior to bonding had to be developed, most of the metals being subjected to surface corrosion with the production of brittle oxides, especially aluminum alloy. Prior to functional application, to bond, particular attention is paid to the behavior of adhesives in a space environment, that is to say, the vacuum, the thermal cycling, and the radiations. Most of the time, adhesives exhibit very different behavior according to the materials with which they have been brought into contact in the space environment against temperature; here, one is referring to the possible damage under thermo-mechanical fatigue.

There is now a choice of composite material made from various compositions, fibers, resins, and adhesives, capable of dealing with the space environment provided that the preliminary selection fills such stringent specifications.

---

## 45.2 Specific Requirements

Adhesive bonds in the launcher and the spacecraft have an eminent place in the aerospace industry.

### 45.2.1 Launchers

Launchers are built in several stages and assembled together. Each stage is separated from the launcher at different altitudes in order to release weight when propellant is

fully used. Depending on the architecture, solid or liquid propulsion or a mixture of both systems, the launcher has to be protected against the high temperature met on the surface of the structures.

After 141 s of flight, the launcher Ariane 5 reaches an altitude of around 67 km at about 2,000 m/s!

Ariane 5 is considered as a “powered launcher” due to its two solid boosters. The initial thrust delivered by the two boosters and the cryogenic engine Vulcain 2 is around 13,000 kN (90% coming from the boosters).

The most demanding mechanical load occurs in the launch phase mainly during booster combustion with a very high acceleration (more than 20 g). Even if the propulsion phase with solid propulsion lasts around 2 min, a lot of vibration over a broad range of frequencies and heavy acoustic environment (150 db) are generated. Therefore, a damping solution is searched and adhesive bonds with damping materials are used.

When cryogenic propellants are used for liquid propulsion, cryogenic insulation is needed to limit propellant evaporation ( $-253^{\circ}\text{C}$  for LH2 and  $-183^{\circ}\text{C}$  for LOX) and ice formation.

## 45.2.2 Spacecrafts

To illustrate the challenge when using bonding in spacecraft, here are some figures that will need to be dealt with.

One must distinguish three phases which is the specificity of this task.

In the first phase, lasting several months, one needs to deal with the integration of the satellite at the launch pad. Care has to be taken to avoid any risk of contamination and damage. As soon as the satellites are covered and protected by fairing, the atmosphere inside the fairing (temperature and humidity) is permanently controlled until the launch.

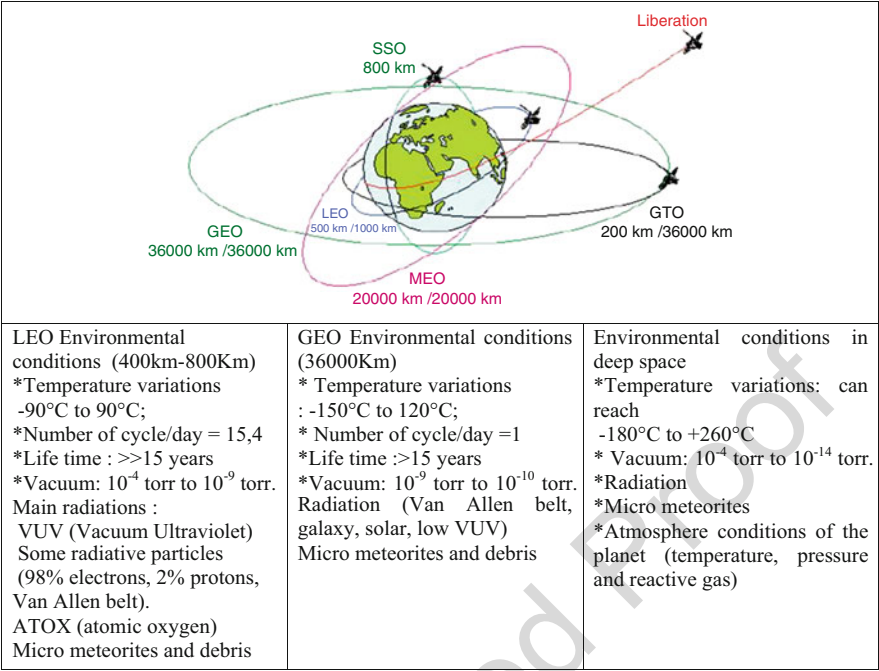

The second phase lasts few minutes, starting from the ignition of the launcher up to the orbital injection of the payload (telecom, Earth, and deep space observation satellites, transportation vehicle for International Space).

The most demanding mechanical load occurs in this phase during booster combustion with 20–30 g acceleration, 30 Hz/8,000 Hz vibration, and 150 dB, 5 Hz/120 Hz acoustical environment. The payload must be qualified to sustain these severe conditions. The separation of the stage from pyrotechnic system generates an energetic shock which could damage some sensitive equipment of the satellite (especially scientific satellites).

This is followed by the orbital phase, of a very long duration, 15 years or more of orbital life for telecom satellites.

The main environmental conditions with which compliance is required are temperature, thermal cycling, outgassing vacuum, radiation, and electrostatic drain (see Fig. 1).

Here, one has to distinguish the spacecrafts dedicated to work in low Earth orbit (LEO) from those in geosynchronous Earth orbit (GEO).

**Fig. 1** Overview of the environment conditions met by satellites in space

For the LEO applications, further issues regarding the external surface exposed to space are to be taken into consideration like atomic oxygen flux (ATOX) combined with solar ultraviolet radiation (UV), ions' radiation, and various high-energy photonic exposure like gamma rays and micrometeoroids and dust collisions.

The GEO satellites are mostly telecom orbits. In this case, the external equipment is subjected to a thermal environment depending on the Sun exposure, under a secondary vacuum for 15 years. The main source of radiation to consider is from the ultraviolet. Thermal cycling and radiation exposure met during long missions are the main mechanisms responsible of the aging of the structures.

The space telescopes, due to their high thermal stability requirements, are confined in chambers. The Herschel and Planck telescopes built under the responsibility of Thales Alenia Space operate between 1.2 and 1.8 billion kilometers (L2 Lagrange point). The Herschel SiC mirror, the highest ever placed into orbit, and the composite Planck mirror, designed and manufactured by Airbus Satellites, operate at -250 °C.

As one can see, there are two families of constraints with which the bonding will have to deal successively: the constraints due to the launch, mainly static and dynamic, over a short period of time, and the constraints due to the space environment over a long period of time, mainly thermomechanical. Aging due to the thermal-mechanical stresses, mismatches between adhesive and adherents, metallic or composite, especially in extreme temperature variations, is the prime concern compared to mechanical fatigue.

If the spacecraft is manned, flammability in microgravity conditions, offgassing, and toxicity are added requirements as for simple aircrafts.

45.2.3 Where Are the Adhesive Bonds?

Launchers

Structural adhesive bonds are defined as any rupture of the adhesive bond will cause significant damage of the mechanical part and hence the loss of the mission.

Thermal protections and thermal insulations are bonded to the structural parts which are made of metal or composite materials (see Fig. 2).

External thermal protections of the stages are used depending on the design of the launcher and the aerothermal conditions. Because of their low thermal conductivity, structures made of composite materials must be protected against high thermal flux met during the flight.

Thermal protection is required when the launcher is powered with solid boosters. Compared to liquid propulsion, solid propellant cannot be used to cool down the hottest part of the nozzle. The thermal protection is achieved with ablative materials

**Fig. 2** Ariane 5 launcher artist's view – main thermal protection and structural bonding locations (ASL)

which are bonded onto the structural parts. For all these cases, thermal protection systems do not sustain general mechanical loads but only thermal loads.

The design of adhesive bonds must take into account thermal gradients and thermal expansion mismatches with the structural part which is in general metallic.

A detailed description of the nozzle design allows to see the complexity of this part due to various material properties mixing composite (carbon/carbon, carbon/phenolic resin, glass/phenolic), elastomers, and metals (see Fig. 3).

**Fig. 3** Examples of adhesive joint solutions for solid rocket motor

Pushed by the constant need of reducing the upper stage weight in order to launch more payloads, engineers use composite materials and, as much they can, adhesive bonds.

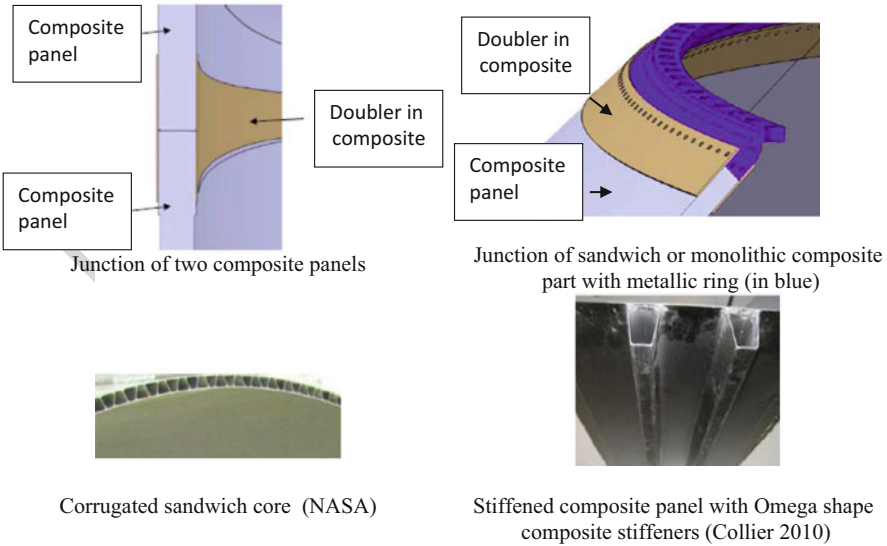

The first example is the sandwich structure used for the upper part of Ariane 5 launcher. The sandwich is made of two composite skins glued on an aluminum honeycomb core. This structure provides the best compromise lightweight/rigidity, and it is one of the best solutions to cope with buckling requirement which is very critical for slim structures.

Adhesive bond solutions can be chosen to assemble two composite panels and to make a junction between an aluminum ring and a composite structure. An alternative solution of designing composite structures to be buckling resistant is to reinforce the structural part with bonded stiffeners (Collier et al. 2010) as used in aircraft fuselage (see Fig. 4).

A good example of an optimized structure which uses adhesive bonds is the composite structure used in Ariane 5 to launch two heavy satellites (dual launch); named SYLDA (see Fig. 5). SYLDA is manufactured by Airbus Safran Launchers (ASL).

**Satellite**

Satellite design is mainly governed by minimization of the weight of its skeleton structure for the benefice of telecom equipment or scientific devices. Two other stringent requirements are taken into account by satellite designers, the management of thermal exchange and the electrical “exchange.” The satellite is built with a central tube from which platforms for equipment, antenna reflectors, and solar panels are attached. The propulsion requires a high pressure tank located inside the central tube.

**Fig. 4** Examples of adhesive bonds for structural parts of launcher

**Fig. 5** View of SYLDA structure (height, 4.6–6.4 m) made in sandwich with carbon fiber-reinforced plastic designed with adhesive bonds

All these structures are made of composite materials which provide lightness, stiffness, and thermal stability. Metal or ceramic parts are glued on composite materials (see Fig. 6). Junctions with bolts are used for assembling electronic equipment and mechanisms of jettisoning with constraints (dismounting requirements).

The central tube is actually the vertebral column made of sandwich using high performance carbon fiber.

The equipment platform made of a sandwich structure is linked to the tube via struts also made in composite. The parts are bonded with bolts via metallic interfaces. When the strut is designed with metallic straps, an adhesive bond with a composite part is used.

The design of reflectors is driven by high thermal stability requirements. These requirements can be fulfilled by using composite materials with specific carbon fiber and lay-up sequences. All the parts are stuck together (see Fig. 6).

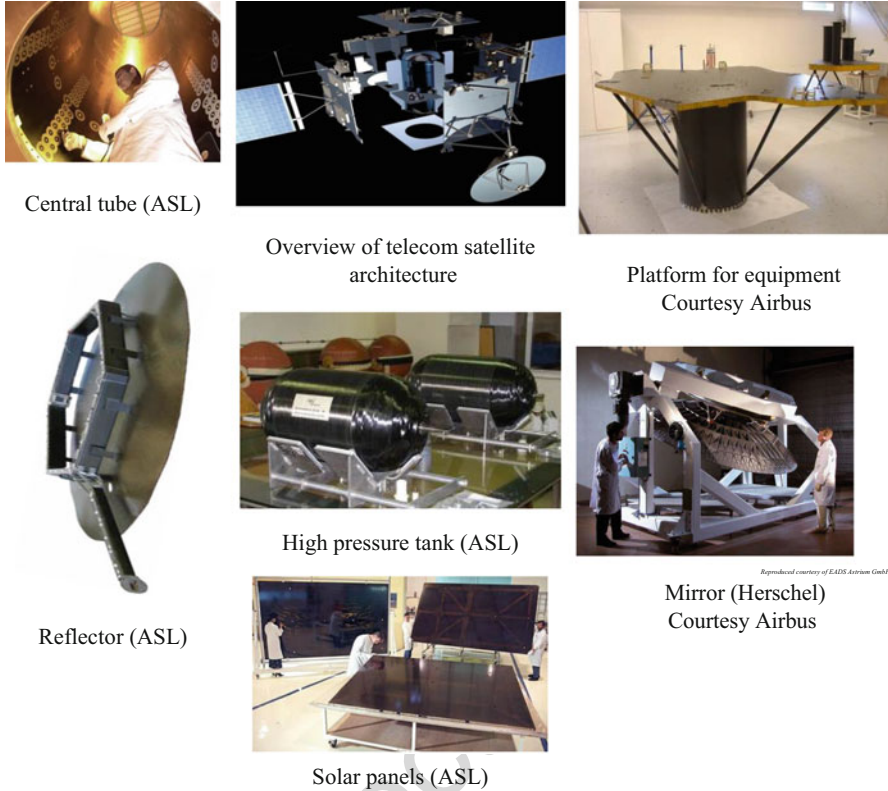

Solar panels are made of composite frames where all the solar cells are glued on it.

Mirrors or optical systems can be glued on their stands. Very large mirrors like Herschel's mirror (diameter of 3.5 m) made of silicon carbide cannot be manufactured in one piece. The retained solution was not to use glue to assemble the eight petals but brazing because of its better resistance to dynamic loads during the launch and radiation in its space life.

#### 45.2.4 Which Adhesives for What?

For the most part, adhesives are formulated in order to offer behavioral properties related to those of the composite and metal substrates, regarding the fluctuating and extreme stresses flowing between the adherend and the adhesive, both having to work together.

**Fig. 6** Satellite exploded view – various cases of structural bonding on all the parts displayed

## General Design for Launchers

The structures using composites such as interstage, intertank, equipment bay, and fairing are submitted to static, dynamic (vibration, acoustic, shock), and thermal loads. Pushed by the competition with metallic solutions, designers try to use as much as possible aeronautics composite materials. The aeronautical industry uses pre-impregnated epoxy resins. Because of their limited temperature resistance, composite parts submitted to thermal aerodynamic fluxes are protected. One of the solutions is to glue thermal protection panels with silicone or epoxy-based adhesives (see Fig. 7a). But this efficient method is expensive and a projection process is preferred (see Fig. 7b). However, all the thermal protection cannot be sprayed.

The spray process can be easily automatized with robot assistance and does not need adhesive since only a surface preparation or a primer is required.

The same approach is followed with the thermal insulation of the cryogenic tanks (see Fig. 7c). Cryogenic insulation could be done by gluing foam panels on the aluminum alloy tank or by spraying the foam.

Manufacturing of composite sandwich structures can be done with a two-step process. Preliminary cured skins are glued with a honeycomb core. In order to reduce

Spain

b) Example of sprayed thermal protection (ASL)

c) Ariane 5 cryogenic tank –thermal insulation bonding (CRYOSPACE image)

**Fig. 7** Example of thermal protection of the structural parts of the launcher

cost, the structure can be done in one step usually called co-curing process. In this case the skins are cured together with the core with or without an epoxy adhesive film in between.

Again when composite structures are made with a skin reinforced with stiffeners, both solutions are also used depending on the complexity of the part. In case of co-curing process, stiffeners made of resin pre-impregnated carbon fiber are pre-shaped, sometimes semi-cured and laid down on the mold. The second step consists in making the skin with same process of pre-impregnated deposition. At the end, both skins and stiffeners are cured together. In general an epoxy adhesive film is used.

The transmission of the loads between composite structures is generally done with an aluminum interface. The rationale comes from the separation requirements of the different structures of the launcher during its flight. The junction of the metallic interface with the composite could be done with two composite or aluminum splices bolted or glued together.

Because of the toroidal moments generated at the interface of each stage, designers are reluctant to use adhesive joint solutions to transmit the loads. The

performance of adhesion is driven by shear, and peeling effects due to bending must be avoided.

In some cases, adhesive solutions are selected as illustrated by SYLDA design (see Fig. 5). Drilling holes in composite structures leads systematically to local reinforcement of the structure, and when weight optimization is searched, adhesive bonding is one of the solutions especially for the structures located in the upper part of the launcher close to the satellites where the ratio weight/performance is 1/1.

Solid propulsion uses a lot of adhesive bonds:

- The first case is one of the most critical interfaces between propellant and internal thermal protection. Both are complex materials and the mechanisms of adhesion are not simple to solve. This interface called liner is generally formulated by the manufacturer of the propellant who has also a great knowledge of the composition of the thermal insulation, generally an elastomer (EPDM, NBR, etc.)-based material reinforced with fillers and sometimes with chopped fibers.
- The second one is the interface between the protection and the vessel which can be metallic (e.g., steel for Ariane 5) or composite (e.g., Vega). Specific adhesives are also required to be compatible with the elastomer and epoxy resin used in the composite. Adhesives formulated with phenolic resins are generally efficient.
- The third one concerns the composite motor case design. The composite vessel is bonded to the composite skirts via a compliant material, the role of which is to adapt the deformation mismatch of the two structures (mainly hoop strain of the vessel and the longitudinal strain of the skirt). The junction of the composite structures with the compliant material is done with an epoxy adhesive. The nozzle design requires proofed adhesive joints because of the harsh thermal environment. All the pieces such as the throat made on carbon-carbon composite and the divergent made of carbon and or glass fiber-reinforced phenolic resin are glued to metallic parts. Epoxy-based adhesives are generally used.

The last example can be illustrated by the flexible bearing. This a laminate made with elastomer reinforced with sheets of metal or composite. All the elements are glued together.

Flexible bearings are used for the steering nozzle. This concept can be also used for the load transmission from the booster to the cryogenic tank (A5 concept) with a specific function of filtering vibration and then participating in the payload comfort.

One can summarize that launchers which are designed with composite structures use adhesive solutions when no alternative solution is available as seen for the motor case with its nozzle for solid propulsion or when significant advantage in weight reduction is gained compared to bolted or riveted solutions.

Adhesives such as epoxy, phenolic, and silicone-based products are usually provided by different suppliers (3M, SOLVAY, STRUCTIL, HUNSTMAN, LORD, DOW, etc.). Some adhesives could need a specific formulation to meet the required thermomechanical performance or to be adapted to specific processes. This last point is crucial because adhesive suppliers are reluctant to develop specific adhesives for a narrow or niche market (complex formulation and low volume).

## General Design Purposes for Satellites

Satellite designers use a lot of solutions based on adhesive bonds. Adhesive bonds allow:

- To save weight
- To easily assemble tiny pieces
- To not degrade composite structures
- To improve vibration damping
- To cope with tightness requirement
- To avoid electrochemical coupling effect
- To link different types of materials which have significant different thermal expansion coefficients

Sandwich structures are manufactured with standard processes or with co-curing process in the same manner than sandwich structures for launchers. But we can highlight that high modulus (polyacrylonitrile based) or very high modulus (pitch based) carbon fibers are preferred to increase the rigidity and the thermal stability. For electrical constraints, aluminum skin is used to manufacture sandwich panels.

The central tube of more than 5 m height can have more than 100 interfaces. A lot of internal (propellant tanks junction) and external (communication modules webs, Earth panel) metallic inserts (aluminum, titanium, invar, etc.) are glued with epoxy-based adhesives (see Fig. 8a, b).

Aluminum inserts, frames, and titanium telecom reflector parts are bonded by bicomponent epoxy adhesives that cure at room temperature (see Fig. 8c, d).

Control of heat exchanges inside the satellite is crucial to provide thermal stability of the optical instruments and electronic devices. The internal temperature is around 25 °C, and the external temperature can vary from –100 to 100 °C depending on the mission, the orbit. The conditions of the environment with respect to the orbits are reported in Fig. 1.

Heat exchanges with the environment being only by solar radiation, the structure of the satellite is protected with solutions providing the appropriate thermo-optical properties (multilayer insulation system, paintings, etc.). Optical surface reflectors are small pieces glued on the surface exposed to solar radiation.

The list of adhesives which can sustain the harsh environment met in space is limited, and silicone-based adhesives are often selected because of their stability at high temperature (up to +250 °C) and are easy to handle. For instance, solar panels are glued on the substrate with a silicone-based adhesive.

But silicone is not selected to stick mirror because of contaminant risk.

Reentry vehicles are designed with a front shield able to sustain the high aerothermal fluxes met during the high speed flight in the atmosphere of the planet (Mars, Venus, Saturn's satellite Titan, etc.). Ablative thermal protection is usually used and the tiles are glued on the structural part. Epoxy adhesives and room temperature vulcanized adhesives are commonly used. For instance, a space-grade silicone-based adhesive has been used with success for various spacecrafts

a) Aluminum insert embedded in sandwich panel (ASL)

b) Wedges glued on sandwich panel (Courtesy Airbus Satellite)

c) Rear reflector face bonded to composite monolithic backing structure (ASL)

**Fig. 8** Example of assemblies with adhesive bonds

developed by Airbus Safran Launchers such as Beagle and ExoMars for Mars exploration and Huygens for Titan exploration (see Fig. 9). The same adhesive was used for bonding and also for sealing the junction lines between panels or tiles.

This adhesive choice is driven by a complex dynamic distribution of the thermal flux with regard to the time against the deviation of the thermal insulation properties.

The choice of room temperature vulcanized silicone has more to do with the thermal resistance of that particular adhesive family than shear strength. In such an application, a minimum of 0.5-MPa-out-of-plane resistance is currently specified. In applications at such high temperatures, the choice of a silicone adhesive combines the mechanical resistance with a thermal insulation. No toughening properties are required since there is no creeping against the mechanical load.

Engineers in charge of the selection of adhesives must be aware of the contaminant risk which is a major source of satellite failure:

- Weakening of the performance of the optical system
- Damage of the electronic equipment due to electrostatic discharges
- Weakening of the electrical production of the solar panels
- Modification of the thermo-optical properties (emissivity, absorption, etc.)

**Fig. 9** Examples of reentry vehicle design with ablative front shield

413 On can summarize that different types of adhesives are used depending on the  
414 following applications:

- 415 – Load transmission
- 416 – Thermal continuity
- 417 – Electrical continuity
- 418 – Optical compatibility

419 For long mission in space, organic materials must be protected against the  
420 radiation. This is the reason why an aluminized blanket covered the thermal shield  
421 of Huygens during the 7-year journey through the solar system via Venus, Earth, and  
422 Jupiter up to Saturn and during the 22 days of ballistic phase between the jettisoning  
423 of the Cassini orbiter. Cassini spacecraft was launched from Earth on October  
424 15, 1997; Huygens landed on Titan on January 14, 2005.

425 Keep in mind that while anything can be bonded with anything else, there is no  
426 universal adhesive despite the slogan for space applications: the main driver is the  
427 temperature of the joint. This means a selection of adhesive which is compatible of  
428 the thermal expansion mismatch between the adherends.

429 Films or pastes are selected according to the environmental specifications to  
430 which they are subjected, as already said (mechanical and thermal), with respect to  
431 the design of the parts and the implementation of the bonding assemblies. For  
432 instance, the dimension of the part, especially if the parts are at the scale of the

launcher, 5.4 m in diameter, can dictate the process, i.e., the choice of a room temperature adhesive, for economic reasons (there is always an economical aspect in bonding to be taken into account): this prevents investing in an autoclave which a hot temperature adhesive would require. But this investment can appear as mandatory for technical reasons; one can understand that for the most parts, the higher the curing temperature, the higher the thermal resistance.

### 45.2.5 What Are the Adhesive Selection Drivers?

As one has seen, adhesives for space applications are designed to withstand loads of mechanical origins during launch and from thermal origin in orbit, while the fitted parts have to deal with different thermomechanical loads.

Bonding is a dedicated process to assemble dissimilar components and requires a rigorous approach to selection according to its properties, not only chemical but also physical, such as viscosity, in order to deliver the controlled thickness of the joint during implementation and restrain the creeping during polymerization. Aside from that, the bonding line control means to point out, at least in practice for a two-component room temperature (RT) paste, (1) the ratio of the mixing, (2) its homogeneity, (3) the pot life of the mixing at RT, (4) the pressure for full intimacy during the hardening, and (5) the minimum waiting time for hardening before handling, all these precautions observed and carried out under regulated temperature and hygroscopic conditions. To give a preliminary example, it is not rare that one has to bond a low CTE titanium part to a high CTE two-part epoxy adhesive. The issue that the design office and the material and process experts have to deal with is to guarantee a cohesive failure at the predicted margin level.

### 45.2.6 And the Adhesive Tapes?

The space industry makes extensive use of adhesive tapes. The major formulator companies propose such space-grade tapes as Kapton, Tedlar, and Teflon, polyester or foam coated with various very high bonding capabilities, sensitive to pressure. Kapton tape is the most appreciated with respect to the high temperature resistance of Kapton, intensively used as dielectric insulator of solar cell panels. The Kapton tape is associated with acrylic or fully reticulated silicone adhesives: outgassing is the driving factor for the choice of the adhesive part of the tape, the unwanted event being the bubbling between the tape and the adherends under vacuum. Acrylic foam is also widely used in association with Velcro fastening. The Velcro fasteners, nylon based and easy to manage, were bonded 10 years ago with space-grade silicone (Dow Corning 93500). Its high release properties led to implement the silicone at the end of all epoxy bondings. Occasionally, with respect to the manufacturing flow chart, this was time consuming and required a mandatory dedicated location to insulate the silicone adhesive implementation from other adhesive families, in space and in time. Since Velcro coated with self-adhesive very high bonding acrylic

472 foam is available, it can be easily implemented at anytime and anywhere according  
473 to the breakdown of the integration process by simply pressing it on by hand.

---

## 474 **45.3 Material and Process Characterization**

### 475 **45.3.1 Structural Bonding or Not?**

476 Roughly, two kinds of bonding can be identified:

- 477 – Structural bonding where high mechanical and thermal loads are required,  
478 designed by the strength of cohesive failure of the adhesive or the adherends
- 479 – Bonding subjected to loads where the properties of the adhesive far exceed the  
480 requirements of the adherend assembly whatever the strength to failure, in the  
481 adherends and in the adhesive

482 Whatever the definition might be, for space applications, the loads taken into  
483 account for the design are those calculated, increased by the margin factor for the  
484 considered application, and the cohesive failure mode (in the adhesive or in the  
485 adherends) will be the mode expected.

486 As a result, one will admit that bonding shall be referred to as “structural”  
487 when the bonded joint is designed with respect to the safety policy margins,  
488 the higher the residual allowance, the better the design. In other words, it  
489 means that, most of the time, the adhesive joint should have high thermo-  
490 mechanical properties often approaching the ultimate ones in the interests of  
491 optimization, i.e., mass saving, the higher residual allowance being not far  
492 from the ultimate.

493 Considering metal to metal bonding (aluminum alloy, titanium alloy, stain-  
494 less steel, Invar), composite to metal (carbon, glass, aramid fiber-reinforced  
495 resin, epoxy or cyanate based), and composite to composite, the adhesion level  
496 will depend on the ability of the adhesive and the surface adherend preparation  
497 to sustain the combination of various mode stresses (3D static, dynamic) with  
498 loads displayed in peeling, cantilever, and pull-out configurations, rarely  
499 according to a pure shear strength to which the adhesives are dedicated: there  
500 lies the challenge.

### 501 **45.3.2 What Specific Properties Do Space Applications Call for?**

502 Before implementation in space equipment, adhesives are subjected to extensive  
503 characterization, from the elementary state according to standard tests and in context  
504 through representative working configurations, in terms of geometry and adherends,  
505 for validation and finally tested at the real scale for qualification, all properties  
506 having to comply with the specifications according to the predicted space environ-  
507 ment enhanced by security margin company policy.

Selection and validation of adhesives are based on their intrinsic properties which must be compatible with engineering and manufacturing process requirements (ECSS-Q-70-71A rev 1). Therefore, the following parameters are generally determined:

- Pot life ASTM D-2471
- Viscosity (key parameter for processing which is sensitive to environmental conditions: temperature, humidity); ASTM D 1824
- Thixotropy (property required when adhesive deposition is handmade)
- Gel time (determination of time of adhesive processing before it reaches solid state, interaction with tooling and pressure application)
- Degree of curing (compatibility with the manufacturing process of the hardware, sensitivity to stoichiometric deviation in case of combining multiparts)

The key properties of adhesives for space environment are:

- Glass transition temperature (T<sub>g</sub>): ASTM D-3418
- Outgassing

This test expresses collected volatile condensed matter (% CVCM), total mass loss (% TML), and recovered mass loss (% RML) according to ECSS Q-70-02A. This test is performed in vacuum with or without thermal cycling. ECSS-Q-70-20A specifies 100 cycles. The temperature range covers the application conditions. It could be more than  $-150$  to  $+150$  °C. The adhesive for space qualification does have an amount of RML and TML less than 1% and a CVCM less than 0.1%. These acceptance limits are submitted for derogation depending on the absolute quantity of adhesive implemented:

- Thermal coefficient of expansion (CTE): ASTM D-696
- Moisture ingress: ASTM D-1151 and D-570

It is well known that a plasticization phenomenon occurs in epoxy polymers which affects the overall characteristics such as T<sub>g</sub>.

General mechanical properties of the adhesive (Young's modulus, shear modulus, elongation at break) are obtained by performing:

- Tensile tests (dog bone sample ASTM D-628, EN ISO 527-2 -butt joint; ASTM D2095)
- Shear test (thick adherent shear test ISO 11003-2; double lap joint ASTM D-3528)

Single-lap shear tests (ASTM D-1002, ASTM D-3165, ISO 4557) are very often used because test samples are easy to manufacture and to test.

However, it is well known that stress field in a lap joint is rather complicated and that relationship between failure and true bond strength between adhesive and substrate cannot be determined with confidence. This test is generally used for quality control acceptance of adhesives:

– Shore D Hardness (ASTM D-2240)

In general, the validation of the adhesive is based on several test samples with a minimum of five tests for each type of test, and some of the tests are done for three batches of adhesive to cover the variability of the product.

The validation phase of the adhesive is also linked to the final application. Shear tests are, for instance, tested at different temperatures and for different conditions of curing.

Moreover two additional tests are sometimes performed.

The Arcan test allows combining tension/shear and compression/shear modes. This test is well appropriated to validate failure criteria of the adhesive and to identify plasticity. Due to the complex behavior of the adhesive, this test must be accompanied with simulation being able to take into account plasticity phenomena. Plastic yield behavior depends on both the deviatoric (von Mises) and the hydrostatic pressure. This model allows describing the difference observed when the adhesive is in tension or in compression. Such criterion proposed by Raghava et al. (1973) is rather effective to predict quite well biaxial test results.

More sophisticated models such as those proposed by Drucker and Prager (1952) and Prager (1995) are not yet fully used by design offices. They prefer to deal with conservatism approaches based on experimental test campaigns.

To justify damage tolerance initiated by a lack of adhesive or the presence of porosity, the energy of crack propagation in mode I ( $G_{IC}$ ) is also characterized. Double cantilever beam test (ASTM D-3433, ISO 2009) is the most common test to measure  $G_{IC}$ . This test is not easy to master due to the strong influence of the boundary conditions. Such test can be performed with composite adherends. Best results are obtained with unidirectional composite adherends; otherwise, damage generally occurs between the first and the second ply inside the laminate. In space applications, high modulus carbon fibers are often used to improve the ratio stiffness/density enabling a better performance in buckling. However, due to the lower adhesion properties with epoxy resin compared to composite made with high resistance carbon fiber, the performance in adhesion with very high modulus carbon fiber is often less.

Fracture test on bulk adhesive coupons is not a common test because it is not always possible to manufacture such coupons without microporosity and introducing machining defects.

Other characteristics are determined depending on the application. It could be:

– Electrical resistance:

Composite materials and adhesive joints are not good thermal and electrical conductive materials compared to aluminum alloys. This is one of the drawbacks of composite materials.

Thermal conductivity	Aluminum alloy 150 W/m.°C
	Epoxy resin (0.18–0.20 W/m.°C)
	CFRP 54 W/m.°C in the fiber direction, 1 W/m.°C in the transverse direction
Electrical resistivity	Aluminum alloy: 4.6–4.8 μohm.cm
	Epoxy resin: 1E21–6E21 μohm.cm
	CFRP: 97,100–287,000 μohm.cm in the fiber direction and 210,000–1.58E6 μohm.cm in the transverse direction

Research programs have been launched to improve these properties by adding carbon nanotube fillers. If increasing electrical conductivity has been obtained at laboratory scale, no industrial application has come out.

The solution used by designers to guarantee the continuity of the electric conductivity is to fix metal braids with conductive glue enriched with silver fillers:

- Thermal cycling ECSS-Q70-04
- Offgassing of toxic materials: ECSS-Q70-29
- Flammability: ECSS-Q70-21
- Particle and UV radiation: ECSS-Q70-06

The verification of the adhesive bond is based on several tests performed on samples which have to be representative of conditions applied on the real part. This is the key issue because the statistical analysis of the main nonconformances of adhesive bonds is generated by wrong cleaning or bad surface preparation (particulate and molecular contaminations) and poor adhesive processing (insufficient training of the operator, bad monitoring of the curing process, etc.).

**Tests for Adherence Verification**

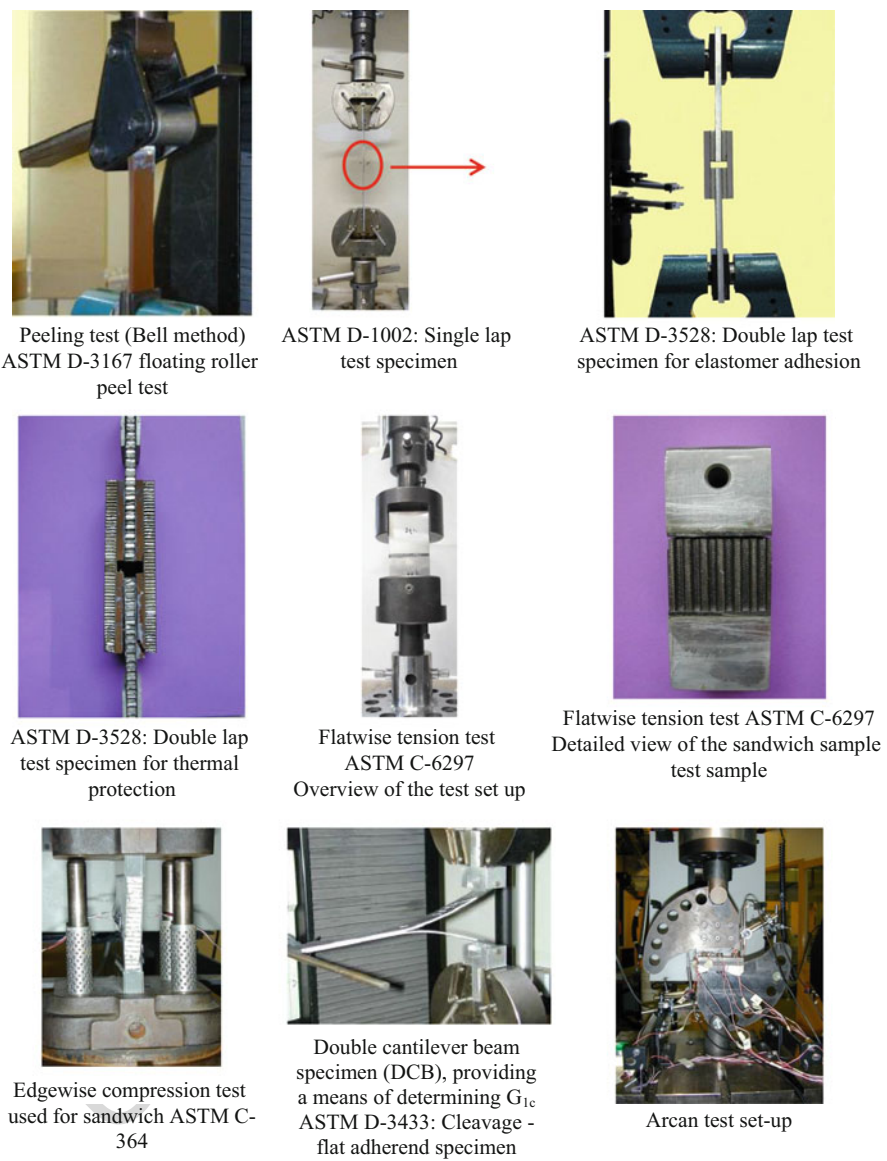

The objective of these tests is to verify the adherence level (load or energy to separate the bodies linked together) in different environments met during the whole life of the parts. Several tests generally recommended by space agencies are used by the space industry. ESA publishes numerous ECSS documents elaborated with the industry and laboratories in Europe.

Peel and shear tests are commonly performed and cleavage as well. For sandwich structures, flatwise tensile tests (ASTM C-6297) and edgewise compression tests (ASTM C 364) are usually performed.

For thermal protection glued on the surface (metal or composite), flatwise tensile tests or peeling tests are performed (see Fig. 10).

The adherence verification is based on a test matrix which must be compliant to the justification requirements.

Peeling tests (ASTM D-1781, D-1876, D-3167, D-3933, ISO4578) are very often used at the beginning of the development giving a first qualitative estimation of the adherence. Illustration of a good or a bad adhesion based on the load curve and failure mode is given in Fig. 11. But care must be taken with peeling test definition

**Fig. 10** Examples of main tests used for adherence measurement

especially when it concerns adherence with elastomers. The peeling test is a geometry-dependent test.

This is the reason why the verification of the adherence is much more reliable when determined with double shear tests and flatwise tensile tests for which cohesive failure is required for both.

Example of good adhesion (rupture of the elastomer without peeling)

Example of good adhesion (rupture inside the adhesive)

Example of bad adhesion (rupture in between the adhesive and the elastomer)

**Fig. 11** Illustration of different peeling behaviors of adherence between metal and elastomer

The environmental effects are taken into account, and the main difficulty is to find out the right method to accelerate aging when performed on ground which is representative of the real life in space environment.

### On Ground

Moisture ingress combined with temperature and mechanical loads is the main contributor of adhesive performance reduction. It is important to highlight that water is not an active factor of aging but rather than a powerful actor to reveal and to enhance defects at the interface or the interphase of adhesive joints.

If accelerated aging is generally performed, natural aging is sometimes considered for specific cases. Aging cycles combining temperature and moisture are determined via Arrhenius's law. Care must be taken to choose adhesives from which moisture ingress is reversible (Fickian diffusion) in order to avoid any damage of the molecular chains, especially at the interface with the adherends.

The effects of moisture ingress are threefold:

- Plasticization of the adhesive and adherends in some cases. This affects the mechanical properties ( $T_g$ , for instance) and modifies internal stress distributions in the joint.
- Hygroscopic expansion which could affect the stress field in the adhesive.
- Weakening the interface/interphase.

The wedge test (ASTM D-3762, ISO 15107) is an effective test to determine the bondline durability as a function of the adherend surface preparation whether it is metal or composite. This test allows discriminating tough adhesives with the environment effect from brittle ones. Though adhesives enable the crack generated by the wedge to grow slowly and stop, for brittle adhesives the crack grows faster running out of the specimen length. The stability of the crack is time dependent with respect to the environment, usually the combination of temperature and humidity (see Fig. 12).

Durability tests performed by Popineau (2015) on composite/aluminum adhesive joint have revealed the mode of failure changed during aging. Cohesive rupture observed in the adhesive in the initial state became adhesive with a rupture at the interface adhesive/aluminum. This test shows that care has to be taken with hybrid joints where the mechanism of osmotic pressure can be responsible for the performance reduction of the adhesive joint.

### In Space

For satellite design, the following environmental factors are systematically taken into account:

- Vacuum (outgassing)
- Thermal cycling
- Electromagnetic radiation (UV, X, g)
- Particles (electron, proton)

**Fig. 12** Effect of moisture with time (a) Tg evolution with EC2216 adhesive when immersed in water at 35 °C, (b) evolution of energy release rate  $G_{IC}$  of composite/aluminum joints immersed in water at 19 °C and 35 °C (Popineau 2015)

- 672 – Atomic oxygen
- 673 – Micrometeorites

674 For manned spacecraft, two additional tests are required:  
675 Offgassing represents the substances liberated by materials in microgravity that  
676 are harmful to the crew. Offgassing has to be avoided (ECSS-Q-70-29).  
677 The flammability test measures the capability with which a material is set on fire  
678 (ECSS-Q-70-21, ISO 22538 1-4 dealing with oxygen safety).  
679 For satellites, the main problems to overcome are linked to:

680 (a) Thermal cycling in vacuum

681 The most critical properties (mainly shear properties) are evaluated before and  
682 after thermal cycling according to the aging test agreed upon in the space industry.  
683 ESA specifies standard aging of 100 cycles under  $10^{-5}$  torr vacuum, between  $-100$   
684 and  $+100$  °C with a heating and cooling rate of  $10$  °C/min with a 5 min dwell (ECSS  
685 Q 70 04 A). It is not rare that 2,000 cycles are implemented. The thermal cycling is  
686 subjected to deviations with respect to the particular operational needs. For infor-  
687 mation, this thermal cycling is to bring closer the LEO external equipment typically  
688 subjected to a  $[-90$  °C,  $+90$  °C] temperature range, under  $[10^{-4}$  torr,  $10^{-9}$  torr]  
689 vacuum range, with 16 cycles/day and that of the GEO is exposed to a  $[-150$  °C,  
690  $+120$  °C] temperature range, under  $[10^{-9}$  torr,  $10^{-10}$  torr] vacuum range, with  
691 1 cycle/day. These figures depend on the spacecraft mission, the location of the  
692 equipment on the spacecraft regarding its exposure to the Earth and the Sun, and the  
693 properties of the materials in relation to their thermal balance. So, if the properties of  
694 the materials, i.e., the adhesives, are assessed after thermal cycling, the equipment at  
695 its final stage of manufacturing is also thermally cycled under vacuum. For instance,  
696 the telecom antenna reflectors in GEO are qualified in the  $[-180$  °C,  $+180$  °C]  
697 thermal domain, requirements due to a stabilization of the composite on Earth at the

end of manufacturing (monolithic composite stress relieving, completion of the chemical conversion of the resins and adhesives, complete degassing of all the materials and assemblies).

For the cases of telecom reflectors, the final thermal cycling aims to guarantee a misshaping variation under operational temperatures compliant with the focus control of the radio-frequency signal against the temperature directly exposed to the Sun or completely shadowed by the Earth, ranging with the seasons. In this respect, the thermal load cases for distortion analysis are assessed in order to highlight the most severe cases with respect to the maximum and minimum temperatures on the different parts of the reflector shell. With respect to this, the various cases below are distinguished:

- EQBOL, equinox period at the beginning of reflector's life
- SSEOL, summer solstice at the end of reflector's life
- EQEOL, equinox period at the end of reflector's life
- WSEOL, winter solstice at the end of reflector's life
- OSRBOL, optical surface reflector reflection at the beginning of reflector's life

Depending upon the telecom mission, an EQBOL may correspond to the shell cold case and the maximum gradient, and the OSRBOL may correspond to the shell hot case.

It is impossible to reproduce the space environment for ground testing of space system elements because of the variety and complexity of the environments which can generate more or less degradation of the material.

The reliability of the test results depends on simulating the critical effects of the space environments for a particular mission (ISO 15856 Simulation guidelines for radiation exposure of nonmetallic materials).

Since the International Space Station is available for such experiments, a lot are mounted on board. Among other programs from the USA and Japan, the European Technology Exposure Facility (EuTEF) was mounted outside the station for carrying out experiments that required exposure to space environment for monitoring degradation dynamics in low Earth orbit and acquiring information in terms of contamination, atomic oxygen, ultraviolet and X-ray radiation, micrometeoroids, and debris (see Fig. 13). These international experiments, where the results are shared by the scientific community, increase knowledge and guide the development of new materials (like nanomaterial-based materials). If new materials are to be qualified in real conditions right from the outset, the qualification of large functional parts is not for the near future, and space equipment is still really only declared good for qualification when they start to work well.

(a) The generation of contaminants has a strong effect on:

- Modification of heat exchange by modifying thermal optical (emissivity)
- Thermal and physical properties (influence on thermal coefficient of expansion which could affect thermal stability of the structure)

**Fig. 13** European Technology Exposure Facility (EuTEF) mounted on the International Space Station (NASA images)

- Electrical perturbation of the electronic devices (dielectric discharge, perturbation of the measures, etc.)

It is well known that polymers are sensitive to radiation, particles, and atomic oxygen generating micro-cracks, surface modification, and production of contaminants. The effects are limited to the surface with varying penetration depth (few microns for protons, several millimeters for electrons). Ceramic fibers are less sensitive, and composites made with carbon fiber are not much sensitive to ultraviolet radiation. For long-term exposure, composite structures are overwrapped with a protective film. Concerning outgassing which generates contaminants, resins less sensitive to moisture are selected such as the new generation of epoxy resins displaying moisture uptake less than 1% or even less, but for specific missions, cyanate resins with moisture uptake less than 0.2% are selected.

The atomic oxygen test is only performed for materials which operate at low Earth orbits.

For structural applications, the adhesive is usually protected by the adherends. The evolution of the adhesive properties with UV and particle radiations concerns those used for the optical devices or system glued on the surface for thermal control, for instance.

### Tests on Technology Coupons

The process validation of adhesive joints is carried out through demonstrators where the different bonded parts are manufactured to scale 1 and the bonding

implementation defined: surface preparation, adhesive conditioning, film implementation or multipart mixing, tooling assembly under pressure, curing parameters, temperature- and moisture-regulated conditions for room temperature adhesive (typically  $22 \pm 3$  °C,  $50 \pm 10\%$  moisture content), autoclave curing cycle (120 °C or 180 °C in the case of co-bonding process), and inspections before and after bonding. All these methodological steps are to ensure an effective and homogeneous adhesion.

The adherence verification of the adhesive joint is not limited to simple shear or peel tests, but to more complex tests which are representative of the real design, the real manufacturing processes and of course the real surface preparation are needed to reproduce load configurations.

These tests are generally well instrumented in order to validate numerical simulations (see Fig. 14).

Tensile and shear are generally performed for the inserts. Web, wedge, or cleat junctions are tested in tensile, shear, and bending.

Then, comes the qualification of the equipment for delivery to the customer, bonding included, according to the dynamic, acoustic, thermal loads, under nitrogen and vacuum atmosphere, with safety margins.

Reduced scale structure loaded in tension to validate the performance of adhesive skirt / vessel junction (ASL)

Out-of-plane strength to failure test on elementary bonded cleats (ASL)

Bending test on elementary adhesive bond (ASL)

**Fig. 14** Examples of technology test sample able to load adhesive joints in representative conditions

Damage tolerance justification is generally done at subscale level or even with coupons. For adhesive bonds, this consists in including the bondline, defects which are mainly representative of lack of adhesive and of process variation.

**Part Qualification**

The qualification of structures is carried out via scale-one tests generally in static conditions at ambient temperature (in some cases with temperature) with a numerical justification for margin of safety (see Fig. 15). The qualification model is loaded up to rupture.

In the framework of qualification with proto-flight model (approach quite often used for satellites and rather seldom for launchers), the limit load is applied, and the structure must be healthy without any damage at the end of the test campaign. One hundred percent of the structure is then controlled with nondestructive inspection.

**In Production Phase**

Structural adhesive joints are 100% controlled. This could be via nondestructive inspections or via proof tests. In some cases, such as adhesive bonds of thermal

Static test on scale-one motor case to test the adhesive vessel/skirt joint (ASL)

Thermal cycling with or without vacuum of the reflector (ASL)

Dynamic tests of an antenna reflector (ASL)

Acoustic test of an antenna reflector (ASL)

**Fig. 15** Illustration of some tests performed on scale-one structures for qualification

protection, the health of the bond is determined by the control of the parameters which monitor the manufacturing process.

For satellites the acceptance of adhesive bonds is in fact done via series of tests performed on the scale-one part.

The health of adhesive bonds is controlled after thermal cycling tests and dynamic or static tests. For some brittle parts like antenna reflectors, acoustic tests are also performed.

---

## **45.4 Surface Preparation**

### **45.4.1 The Case of Composites**

When faced with a bonding case, there is a motto which should not be forgotten: “The Devil is in the details.” Among all the details, surface preparation is the decisive one. The aim of such a preparation is to remove anti-adhesive contaminants like grease or release agent residues which are in the air of the workshop (aliphatic hydrocarbon) and to promote a chemical–physical roughness deemed favorable to adhesion. Composite preparation is realized by sanding (silicon carbide paper, alumina oxide fabric, grade 240 up to 1,000) and wiping with solvents (acetone, ethanol, isopropanol), now often substituted by wiping with alternative liquids without volatile organic components according to the new REACH (Registration, Evaluation, Authorization and restriction of CHemicals, the new health and safety and environmental regulations enacted by the European Union) regulations. All these operations are performed with disposable talc-free gloves if carried out by hand or via an automated process in the case of extensive surface preparation. It should be stressed that surface preparation by hand depends on the skill of the operator. This is a major issue concerning bonding in the workshop. An alternative solution is to cure composites with a peel ply covering the surface to be glued. Peel ply is removed (tear-off) from the surface before gluing. This solution is very cost-effective and efficient. The main drawback is the risk of leaving on the surface undesirable products (small pieces not detectable and pollution), since the operation is done manually.

Among the reliable surface preparations which can be automated and which are taken into consideration to contribute to the improvement of quality assurance, without material drawbacks, are the low pressure plasma to break organic molecular bonds, laser, and blasting methods. All these automated processes are from now progressively introduced in spacecraft equipment manufacture since they are growing in size.

The automated inspection of the surface preparation also remains an issue.

Several research initiatives have been done investigating several techniques. Among them, a recent program has been carried in the framework of European project called ENCOMB (extended NDT for composite bonding – FP7 – third call). The most representative contaminants met in the workshop have been studied, among them hydraulic fluid, release agent (pollution generated by release film),

834 and moisture (see Table 1). The most pertinent techniques proposed by the labora-  
835 tories involved in the consortium were tested.

836 Automated infrared spectroscopy probe surface analyses are a promising  
837 approach, but aerosol wetting technique (AWT) is more mature and applicable in  
838 the workshop.

839 Up to now, the surface inspection (the adhesiveness through the surface energy  
840 displayed by the chemical–mechanical activation) is checked by the classic and  
841 simple so-called water break test or water drop test: after wetting with an aerosol on  
842 the surface of the composite which has just been prepared for adhesive application,  
843 low surface energy deemed unfavorable for bonding shall translate as separate  
844 droplets of water, whereas high surface energy meaning good surface preparation  
845 shall translate as a continuous film (the reader shall note that the words employed are  
846 qualitative and not quantitative, and verbs are to be understood in the conditional:  
847 because bonding is an art before being a science). This test is not so simple, as it  
848 requires more visual analysis performed by an inspector who can only rely on his  
849 memory (see Fig. 16). Currently, within the framework of a European research  
850 program, Airbus Company is conducting extensive industrial bonding studies.  
851 Among those, a robust and reliable surface monitoring method based on the manned  
852 model has been developed: after spraying water droplets at the range of about  
853 0.1–0.3 mm, the wetting is characterized by the mean droplet size and their distri-  
854 bution. The image is recorded by a camera and analyzed by software. A hot air gun  
855 then dries the surface of the composite, if needed.

856 THz/GHz reflectometry is very sensitive to moisture but this emergent technique  
857 is not yet used in space industry.

858
45.4.2 The Two-Part Epoxy Adhesive

859 It is not necessary to put the importance of the surface preparation and its sensitivity  
860 under the spotlight, especially for composite surfaces. For economic reasons, manual  
861 sanding is still often the way for (1) removing dust and surface decontamination  
862 (aliphatic hydrocarbon, release agent residue contaminants) and (2) chemical

activation (electron peeling, micro roughness generation), and everybody knows how sensitive epoxy adhesives are to deviations in the surface composition. These operations will be entrusted to skilled workers.

In the case of two-part room temperature adhesives, the adhesive is applied on the facing sides of the adherends after manual or automated mixing during the open time period of the mixture (45–90 min), and afterward, pressure tools are placed on the assembly for delivering the pressure required for bonding (between 200 and 1,000 hPa).

An illustration is given of a bonding process after such a preparation in the case of the Ariane 5 satellite adaptor (see Fig. 17).

### 45.4.3 The Metallic Parts

The metallic parts on spacecraft are mainly made of aluminum and titanium alloys because they are lightweight. Prior to structural bonding, they are subjected to proven surface standard treatments from the aeronautical sector. Due to the short open time period for bonding after the surface treatment (8–24 h), the metallic parts are often coated with organic primers to postpone their ability to bond and to procure or increase their resistance against corrosion if at risk (atmospheric, galvanic).

The application of a primer raises the same issues as the adhesive, a primer being an adhesive coating, but in this case, two interfaces are to be held in place, the first one between the metal and the primer and the second one between the primer and the adhesive.

In all the cases, because of the great variety of compositions of metal parts, combined with the extensive number of hardening and annealing treatments, there is

**Fig. 17** Room temperature bonding sequence for composite assembly (from *top* to *bottom*, from *left* to *right*: two-part adhesive tube, mixing device, bond deposit on monolithic composite part, on sandwich part, docking of the two part, pressurization, assembly achieved ready for inspection (ASL))

not “a” standard treatment by alloy family but various possibilities, even if aluminum alloys have historical feedback from experience. However, preliminary tests should be conducted to determine the performance of the bonding in the case in hand.

#### 45.4.4 Aluminum Alloys

The surface preparation of aluminum before fitting, such as painting and bonding, is mandatory because aluminum alloys offer high sensitivity to superficial oxidation with the natural and instantaneous appearance of a brittle aluminum hydroxide coating.

This phenomenon which can be compared to what happened with a highly sensitive photographic film upon exposure to the light is more or less pronounced, depending on the ambient atmospheric conditions, i.e., the temperature and the moisture level. With respect to bonding, the challenge was in producing a compatible and suitable surface for the application of the adhesive prior to bonding operations. The idea was to chemically favor the growth of a stable and hard thin coating of aluminum hydroxide. As a result, two main different pretreatments are used, the first one in the USA based on phosphoric acid anodizing and the second one in Europe, consisting in a sulfochromic acid etching by a chromic acid anodizing (ASTM D-2651-01). For structural bonding, it has been demonstrated that the optimum values are achieved when the anodizing is partially sealed, despite a loss of corrosion protection. See also Part B – Surface treatments for more details on this subject.

Alternate surface preparations are now introduced due to the new REACH regulations prohibiting implementation of listed chemical elements without enhanced health and safety protection and the release into the environment without significant recycling, in particular for the cancer-inducing hexavalent chromium. The chromium substitution was deployed a few years ago in the automotive industry, and the aeronautical industry can benefit from the studies performed following such substitution. Some alternate formulation packs are proposed mainly based on  $\text{Cr}^{3+}$  solutions, and they have been compared via extensive tests with regard to all the requirements for aluminum applications on aircraft. The space industry in turn benefits from these advances, where it appears that there is not only one alternate chemical solution but several, depending on the specific application. For structural bonding cases, the complicated ones are not necessarily the best. Green surface pretreatment qualifications are still in progress.

These alternative Cr6 free solutions are in their final step of qualification and are progressively introduced in surface treatment supply chain. There are new axes of research in order to evaluate new treatment generation totally exempt of heavy metals.

#### 45.4.5 Titanium Alloys

The surface pretreatment for titanium is the well-known nitric hydrofluoric acid etching by a sodium bifluoric solution (ASTM D-2651-01). Some proprietary deviations from this basic treatment are taken by manufacturers. For example, hold release mechanism brackets in titanium alloy (Ti6Al4V) are used for mounting on antenna reflectors as parts of pyrotechnic mechanisms in order to deploy the reflectors in orbit before entering in operation.

---

### 45.5 Nondestructive Inspection

In space industry, high quality of the structures is required because no failure is allowed. The demonstration of the high level of reliability of the structures must be proved either by demonstrating that the process is well mastered (well-known

operation done by certified operators) or by the demonstration of the health of the structure. The second issue can be assessed by performing proof tests or by performing nondestructive controls. In fact, a combination of these three methods is carried out.

If a large panel of techniques is now available based on standard physical principles (perturbation of electromagnetic wave motion, mechanical wave motion, heat wave motion) to control the health of metallic and composite structures, the determination of the health of adhesive bonds is still a challenge. The main sources of difficulties come from:

- No direct access to the joint and the recorded signal can be disturbed by the heterogeneity and anisotropy of the adherends which are also different in nature (composite/metal).
- Complexity of the shape of the piece.
- Contactless method is sometimes needed to avoid any contamination.

If a design to cost approach is followed by designers, design to control is also to be considered to avoid further trouble in nondestructive investigation. This could be illustrated with a simple example showing the detection of local debonding in titanium/CFRP composite joints with pulse-echo ultrasonic mode (see Fig. 18). Control via the titanium adherend is the worse method which could be imposed by the design (no access to the composite part).

In some cases, when overlap of the reflected signals occurs, the diagnosis can be improved, thanks to the numerical simulation of the wave propagation. Simulation can improve the reliability of the diagnosis but also to replace the numerous and costly test samples being manufactured with defects. One can refer to CIVA software able to simulate control with X-ray technique, eddy current, and ultrasounds. Such tool is able to establish the probability of detection curves by simulation.

The main nondestructive methods used in the aerospace industry are:

- Ultrasounds
- Infrared thermography

**Fig. 18** Illustration of potential difficulty in defects detection in a hybrid adhesive joint

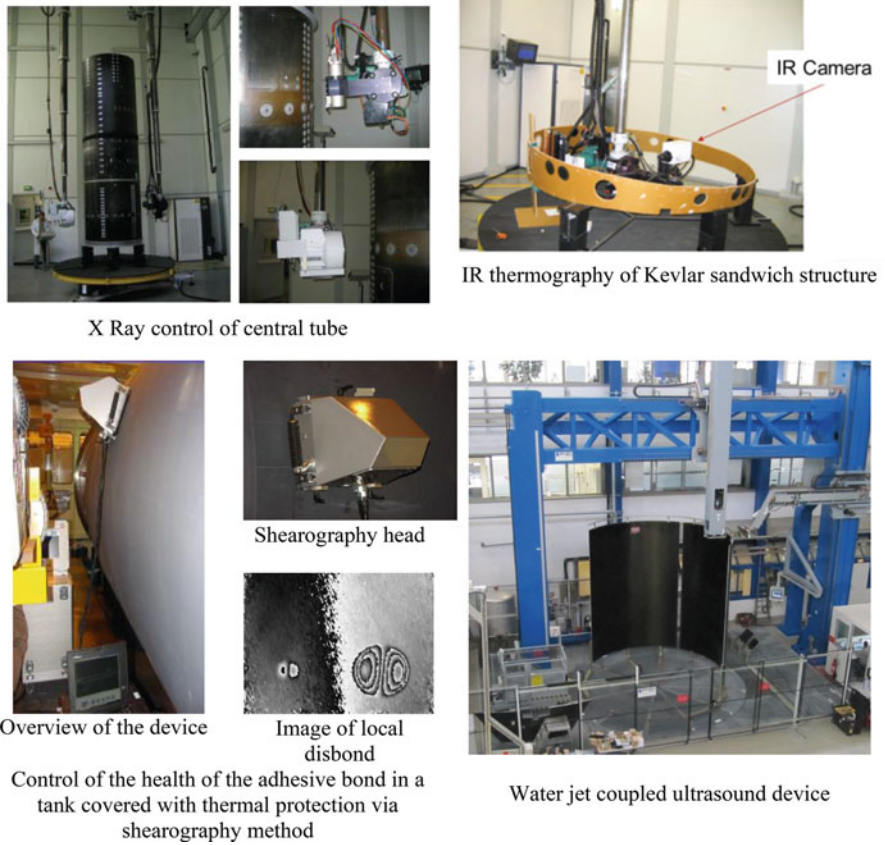

- 959 – Shearography (interference of coherent electromagnetic waves)
- 960 – X-ray

961 All these methods are able to detect debonding between the adhesive and the  
962 adherends or a lack of adhesive (see Fig. 19). Ultrasound techniques are able to do  
963 more with the detection of porosity and cracks or even a lack of curing of the  
964 adhesive.

965 The defects that can be detected with the infrared response (IR) of the bonded  
966 equipment subjected to heating are lack of adhesive, bubbles, and discontinuities  
967 between the adhesive and the adherends (meaning, for instance, discontinuous  
968 adhesive distribution at the interfaces), air blade between skins to honeycomb  
969 core, or composite to composite or composite to metal bubbles in the joint.

970 The numerous literature sources reviewed recently by Ehrhart et al. (2010) clearly  
971 show no nondestructive industrial methods are available to discriminate a “structural  
972 bond” from a “kissing bond,” even if efforts are continuously done at research level.

**Fig. 19** Illustration of the principal nondestructive techniques used at ASL

This is the reason why adhesive bond technology is not used so much for high-loaded structures in aeronautic because of the cost to demonstrate robustness and reliability of the adhesive joints. See also ► [Chap. 42, “Nondestructive Testing”](#) for more details on nondestructive testing.

Two principal definitions of kissing bond are met in literature:

- (a) Two surfaces in contact but not bonded
- (b) Smooth bond consisting of two surfaces separated by a thin layer of liquid such as contamination

Finally, kissing bond reflects the cases where the two parts are in intimate contact but with a weak adhesion force.

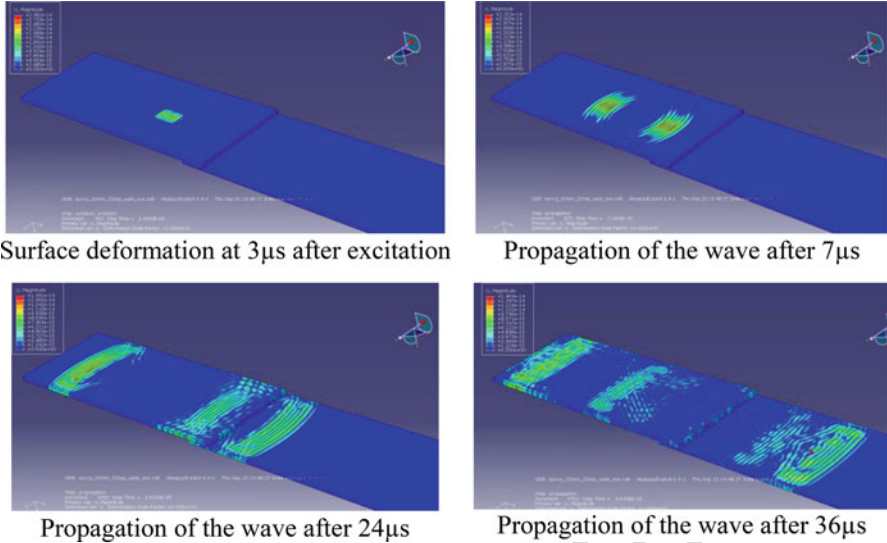

According to the Ehrhart et al. (2010), ultrasonic alternative methods (US spectroscopy, nonlinear US, guided waves, oblique incidence, shear wave resonance, etc.) as well as laser proof tests (LASAT, LBI, laser ultrasonic) and other methods like shearography and active thermography have high potential for the measurements of adhesive bond strength, thanks to the new generation of sensors which are more sensitive (mK for IR thermography and few nanometer for shearography).

The shearography technique consists of generating a small deformation on the surface of the structure and measuring the out-of-plane deformation (mechanical loading with low depression). This technique is similar to a proof test but performed at low stresses. This fulfilled technique is very relevant to control the health of the adhesion of the thermal protection. This solution is cost-effective, thanks to an automation control with robot.

Recent researches in the detection kissing bonds have been initiated with ultrasound-guided wave pushed by aerospace industry needs. One of the potential solutions is to generate specific guided waves able to capture information provided by the interface/interphase which has in principle a different rigidity than the bulk adhesive. Castaings (2014) and his coworkers have deeply investigated this route, and significant improvements have been achieved, thanks to advanced computation tools which enable better understanding of wave propagation (see Fig. 20). Validation of the models has also been improved with experimental measures based on 3D laser velocimetry. The expected results are not possible without the development of appropriated sensors providing the generation of the desired guided wave at the right range of frequencies and the right level of power.

The research has started with the detection of defects in single-lap shear test samples with no dispersive materials (aluminum plates).

SH0 guided wave mode was generated and detected via Electro Magnetic Acoustic Transducers (EMAT) in 3-mm-thick aluminum plates with a 50 mm overlap in single-lap shear tests (see Fig. 21). Three samples were investigated, each with the aluminum/adhesive interfaces prepared differently (with or without sanded aluminum surfaces) applied, the third was polluted using an oily agent, and the last one the adhesive was a thin glass-epoxy self-supported film. Signals transmitted past the various lap joints revealed good signal-to-noise ratios, good uniformity in the

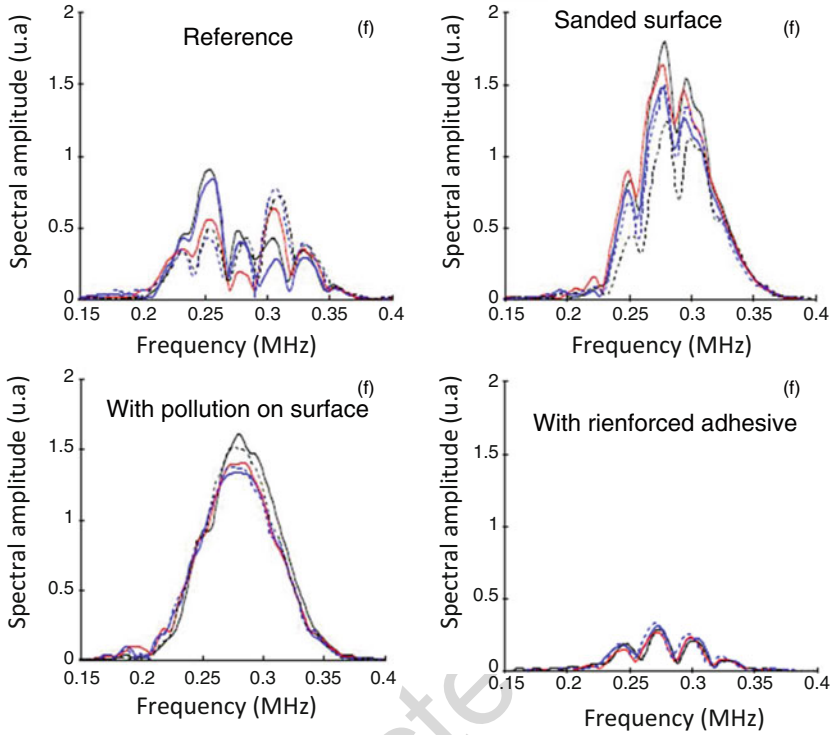

**Fig. 20** Simulation of SH0 wave propagation in single-lap shear test samples: ABAQUS computation

**Fig. 21** EMAT sensors in pulse and catch configuration over the bondline in single-lap shear samples (*dot red line*, different positions of EMAT sensors)

1016 adhesive bonds, and high sensitivity of the investigated transmitted SH0 mode to the  
1017 adhesion quality.

1018 This academic study has shown a good reproducibility of the signals measured for  
1019 five positions of the sensors in the width. Thanks to EMAT sensors development, the  
1020 signals are different with respect to the type of defects. But the shape and the  
1021 amplitudes of the signals are not easy to analyze without the help of simulation  
1022 where the main blocking point is still the quantification of the ultrasound properties  
1023 of the interfaces (see Fig. 22).

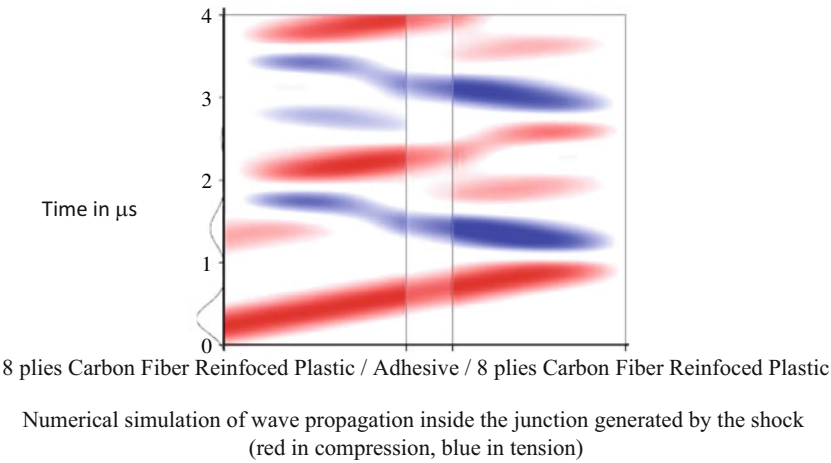

**Fig. 22** Evolution of SH0 guided wave signals generated with EMAT 250 KHz sensors; reproducibility of five measures (Castaings 2014)

The same study has been done with quasi-isotropic composite materials as adherends. Even if the signals are repeatable, they cannot discriminate the defects with the same accuracy. Therefore, new development of sensors and more sophisticated data processing tool in relation with simulation are needed for composite materials.

Other authors investigated nonlinear ultrasounds (Yan et al. 2009). It is assumed that when a large amplitude ultrasonic wave propagates through the kissing bond region, the system will behave nonlinearly, and so detection and quantification may be possible. They showed that an imperfectly bonded specimen exhibited much higher nonlinearity than that of a perfectly bonded specimen. These experiments are still performed with academic samples made with metallic adherends.

Laser shock adhesion test (LASAT) is a new promising technique. Considered as proof test, the thermoelastic excitation produced by the multiple pulse laser induces an ultrasonic surface and bulk wave propagation in the material. The combination of the incident and reflected wave can create tension stresses inside the material enough to test interface/interphase adhesion and to detect weak bond (see Fig. 23).

The main target is to find out the appropriated laser shock parameters which strongly depend on the adhesive bond definition to position the maximum traction stresses at the interface (Pertion et al. 2010; Gay 2011).

Shock generating 0.46 GPa pressure  
No decohesion

Shock generating 0.62 GPa pressure  
Decohesion of the two interfaces

**Fig. 23** Micrographic observations of adhesive joints of two eight plies laminate adherends after laser shock (Gay 2011)

All the difficulties hinge on mastering the stress field in terms of intensity and location. Too much energy provided by the laser can damage the surface of the material especially for composite materials. Therefore, the determination of the conditions which guarantees the relevance of the proof test of adhesive bonds must be done with a good understanding of the phenomena, the development of accurate numerical simulation validated by accurate measures, thanks to real-time diagnostics with laser Doppler velocimetry of the free surface and transverse shadowgraphy. Even if some devices are now commercialized (mobile laser bond inspection (LBI) system), LASAT it not yet used in production line.

The diagram of wave propagation shows in this case the maximal tensile stress is located nearby the opposite site of the laser impact and the adhesive joint is less loaded in tension (see Fig. 23). In this case, the resistance of the interphase between adhesive and composite is lower than the interlayers and intra layers of the composite.

---

## 45.6 Strength, Failure, and Durability

Due to the fact that it is impossible to reproduce representative tests on Earth and that all is based on the reliability of the prediction, it is agreed in the space industry that the durability of the equipment shall be guaranteed by a policy of high safety margins: the margin given by the chemical behavior at high temperature (at the molecular scale) up to the mechanical properties at room temperature (at the macroscopic scale). It is also agreed that the equipment is qualified in simulation facilities according to conventional aging.

This attitude is essentially due to the specificity of composite materials, where the stresses are endured first by the interfaces, at the resin-to-matrix/fiber interface, at the resin pre-impregnated inter-ply, and finally at the bonding interfaces.

Companies are increasingly investing in automatic lay-up, heating-up, and line manufacturing devices to render the implementation of composites more reliable and robust despite the fact that the production rate of space industry does not justify by itself.

To illustrate a commercial bonding case, two generic bonding cases are presented below: a sandwich construction with an adhesive film cured at high temperature and then the room temperature bonding of two composite parts.

### 45.6.1 Sandwich Structure Bonding Construction

As a result, the compression resistance along the plane and the pull out-of-plane resistance, always as a function of temperature, are the drivers for sandwich structures. The selection of the adhesive film need to comply with all the thermo-mechanical needs at the elementary level, the outgassing space requirements, and

last but not least, the adhesive needs to satisfy the manufacturing process chart from the industrial point of view, technically (120 °C class for typical sandwich curing assembly, 180 °C class co-curing of the skins to honeycomb core, light areal weight supported or unsupported) and economically. A good film adhesive choice shall be a choice, where the compression load withstanding shall depend only on the composition of the skin (aluminum alloy, aramid, glass, or carbon high resistance or high modulus fibers), the thickness of the skin (in terms of space equipment, the count unit is 0.1 mm), and the honeycomb core definition (cell diameter often from 2 to 6 mm and density from 16 to 50 kg/m<sup>3</sup> varying with the foil thickness of the honeycomb core). From a technological point of view, the compression resistance need shall be guaranteed by a minimum pull-out resistance, bearing in mind that there is no pure compression load but a combination of various angular loads supposed to contribute to the failure strength.

To predict the behavior and prevent durability issues, as mentioned here above, the sandwich structure is fully characterized after numerous thermal cycles under inert gassing (to prevent nonrepresentative oxidation effects on Earth) such as nitrogen or helium (depending on the range of temperature (see Fig. 1).

The expansion characteristics (coefficient of thermal expansion, coefficient of moisture expansion) and the thermal properties (through-the-thickness conductivity and the calorific capacity) are checked in addition to the mechanical properties. In most cases, a 1 MPa pull-out strength associated with a cohesive failure in the honeycomb or in the composite skins is often considered as acceptable for satellite sandwich parts.

With such a result, a value of 300 MPa compressive strength associated with a Young's modulus of 150 GPa delivered by the implementation of ultra-high modulus carbon fiber is displayed by satellite composite sandwich structural parts designed and experimented.

Regarding the sandwich failure mode when subjected to a compressive load, the various failure modes have been set out in the ESA Handbook (ESA PSS 03 203). The failure modes generally observed are (1) facing failure which is the adequate mode rendering correct equilibrium of the spreading of the stress flux provided that the failure load complies with the predicted value, (2) intracellular buckling when the flexural behavior of the skins regarding the cell size induces such behavior according to a certain critical level of loading, and (3) outward face wrinkling when the secondary out-of-plane vector component of the main compressive strength is higher than the flat tensile resistance of the skins to honeycomb.

## 45.6.2 Monolithic Room Temperature Bonding

In most cases, a two-part room temperature adhesive with a tensile lap shear of 20 MPa at room temperature and 10 MPa at 120 °C shall be appropriate for bonding composite to composite and composite to metal on spacecraft. The choice of the adhesive shall be considered as appropriate when the failure is cohesive instead of adhesive, either in the bonded line, when the shear strength of the adhesive is lower than the shear strength of the adherends (metal or composite), or within the

1121 composite thickness, when the inter laminar cohesion (the ability of the resin-to-fiber  
1122 interfaces to withstand the loads) is lower than the adhesive cohesion. One specific  
1123 attention is required when characterizing this type of adhesive. Due to the cold  
1124 curing mechanism, the kinematic is slow, and time/temperature equivalence should  
1125 be used with a lot of precautions in order to determine the appropriate mechanical  
1126 performance of the assembly in real conditions.

1127 **45.6.3 A Commercial Bonding Case**

1128 The case of applying bonding in real life is illustrated by the case of a radio-frequency  
1129 antenna reflector. This reflector is dedicated to telecom satellite broadband service such  
1130 as television, Internet, and wireless access networking services in the Ku band  
1131 (12–18 GHz). This reflector belongs to the category of the high-throughput satellite  
1132 (HTS), meaning, in order to designate any satellite (Ku band or Ka band, 20–40 GHz), it  
1133 uses very small spot beams in order to obtain multiple orders of additional throughput  
1134 compared to classic fixed satellite service. This can be achieved according to a multi-  
1135 source antenna principle or shaped antenna principle according to the multi-beam signal  
1136 monitoring. Airbus Safran Launchers designs and manufactures both (see Fig. 24).

**Fig. 24** Multisource antenna reflector  $2.8 \times 3.5$  m (a, b) and multi-spot 1.6-m-diameter antenna reflector (c, d) – ASL

The backing structure is structurally bonded to the reflector shell of the Airbus Safran Launchers Ku-band reflector named ULR (for ultralight reflector): 2.2 m diameter CFRP sandwich shell and monolithic backing structure and titanium and Invar fittings for a total mass of  $10 \text{ kg} \pm 1 \text{ kg/m}^2$ . This reflector concept has been mounted on telecom satellites since the beginning of the third millennium.

The working environment is the following: (1) to withstand the dynamic and acoustic launching loads with a sine vibration environment of 10 g/out-of-plane axis and 15 g/in-plane axis, 7.90 g is reached on a shell equivalent to 1,000 N pulling out, a dynamic stress time of 1/2 h, and a few minutes acoustic stress time up to 150 dB, (2) to withstand the geostationary orbital thermal loads  $[-50^\circ\text{C}, +50^\circ\text{C}]$  up to jettisoning of the launcher fairing, and (3) to withstand a thermal stress time of 15 years.

First, the joints are tested at the elementary level and the loading cases predicted and margined according to out-of-plane, peeling, and cantilever directions after space-like aging thermal cycling. These tests will validate the design of the adherends and the industrial manufacturing process for the implementation of adhesives. Therefore, the mechanical tests demonstrate the ability of the bonded fitting to withstand the margined predicted loads. Then, it is necessary to validate the design at the margin loads. This is done through mechanical tests operated on representative artificially aged samples (preliminarily space aged by thermal cycling): static pull-out-of-plane test and cantilever for peeling tests.

The industrial step consists in using optimized tools to reproduce the elementary bonding conditions which have been established to provide the required properties. The more optimized (reliable and faster) it is, the cheaper it will be – the ever-present obsession at all stages of industrial productions, space industry included.

The cleats are bonded with an array of tools for ensuring a stress-free assembly after the surface preparation (sanding/ethanol wiping), the adhesive being applied in situ with a tube mixing device, with the dedicated static pressure application during hardening.

With the cure time over, an ultrasonic inspection is carried out for bubble detection in the joint. Repair is required if the defect exceeds the specification (filling of the bubble or debonding and replacement of the cleat).

Once the backing structure is bonded to the shell, the qualification tests are carried out to check that the equipment can withstand the launching loads and the thermo-mechanical behavior as predicted.

First, the reflector undergoes thermal cycles within the extreme temperatures under vacuum to reveal possible weakness at the bonding interfaces, before shaking through the acoustic test performed in a chamber reproducing the launcher conditions. Finally, the reflector is shaken according to the dynamic spectrum of the launcher.

At the qualification stage, the reflector being designed to work in all the launching cases, the dynamical and acoustical vibration spectra are maximized in order to cover the spectra of all the launchers existing (Ariane, Proton, Delta, Longue Marche).

A final ultrasonic check performed after thermal cycling will sign off the qualification for delivery to the customer.

There is no room for error in space, no return ticket, and the possibility of repair is unusual; the Hubble telescope in low Earth orbit still remains an exception.

In summary, the qualification tests performed on each flight model include thermal cycling and thermal stress distortion measurement, dynamic and acoustic tests representative of the launch margin load, and ultrasonic inspection after tests on each cleat junction for the structural bonding parts. Each reflector antenna, i.e., equipment, is considered as a prototype model where all the qualification tests are performed before launching.

---

## 45.7 Conclusions

### 45.7.1 By Way of Summary

The assemblies are key issues for mastering the cost of space structures as well as performance. A non-careful mastering of the quality of the process and non-appropriate design can lead to a dramatic impact in late assembly phase or during the in-life service of the product. The challenge is to design and manufacture, while ensuring optimal thermomechanical returns over mass investment keeping in mind the minimization of the production cost.

As surface bonding has been preferred to local fastening for spreading the loads with the result of optimizing the design to mass, the challenge then consists in the selection, for a joint where the resistance is governed like the cogs in a clock by the specific behavior of two adherends, the glue on one hand and the working environment on the other.

The design office associated with the material and processes experts deals everyday with these inputs for succeeding the correlation between the predicted margined level and the real level withstood, sign of an optimal combination and trust in structural bonding.

### Launchers

Upper-stage structures are made in composite materials and the load transfer between stages is still done via bolted solutions. Few parts are designed with adhesive bonds. The adhesive bond solution is only proposed when mass optimization is the main driver. Apart from sandwich manufacturing which is now obtained via co-curing process, the main drawbacks of the adhesive bond solution are linked to the low confidence of the designer regarding kissing bond detection not yet solved and the qualification cost. The main applications of adhesive bonds are met in thermal protection of structural parts, thermal protection for cryogenic vessel, thermal protection of the stages, and thermal protection of the solid rocket motor. The success of the adhesive solution is based on stringent manufacturing process requests to perform a lot of controls of raw materials and process parameters and last but not least to have skill and qualified operators. Rigorous procedures established in close collaboration between designers, material and process specialists, and manufacturing specialists are the key to successfully mastering adhesive bonds.

1222 The major difficulty encountered by material specialist concerns adhesion with  
1223 elastomers where the mechanisms of adhesion with metals and composites are  
1224 complex to master.

## 1225 **Satellites**

1226 Adhesive bonds in satellite design are the mandatory technology for fastening parts  
1227 enabling the optimization of the structures. Each gram of structural material saved is  
1228 a gram of propellant added and, consequently, satellite lifetime extended (remember  
1229 that for satellites “the lighter it is, the more profitable it is”).

1230 The selection of adhesives is based on the mission of the satellite governed by the  
1231 constraints of space environment (orbit around planet and deep space trip). If  
1232 moisture ingress (outgassing constraints) and thermal cycling are the key parameters,  
1233 radiation resistance is required for limited applications. In principle, adhesive joints  
1234 are not directly exposed to the aggressive space environment.

## 1235 **45.7.2 And Finally**

1236 “It is not the glue which makes the gluing” (Max Ernst) but preparation, inspection,  
1237 and deep control of the process. The adhesive shall determine the maximum loading  
1238 allowable for the bonding assembly, but structural bonding shall occur when the  
1239 adherend surfaces have been suitably adapted after the dedicated preparations to  
1240 provide conditions of interphase formations (this slight mixed layer on an atomistic  
1241 scale between the adherends and the adhesive). The cohesive failure mode is the only  
1242 mode which provides reliable prediction since one knows the separate properties of  
1243 the adherends and the adhesive on the whole. If somebody had to summarize the  
1244 particularities of bonding for space applications, he would formulate the following  
1245 equation: space bonding = high mechanical loads (launcher and satellite) over a  
1246 short time + high thermal loads (satellite only) over a long time, and it is the  
1247 challenge with which one is faced.

1248 The feedback from experiments in bonding is crucial because, apart from every-  
1249 thing one does know, there is everything one never knows, which is huge. Some-  
1250 times, it hinders technological breakthroughs having to balance the cost with risk  
1251 reduction up to almost zero, with the financial issues, the reduction of manufacturing  
1252 costs, and added payload mass.

## Abstract

Modern cars contain about 15 kg of adhesive (IVK 2017). Adhesives are used to avoid corrosion, to stiffen the car body, to obtain a better crash performance, to join different materials that are not weldable, and for sealing purposes. Adhesives are used in powertrain and car body applications. In the car body, up to 200 m of structural adhesives are applied. The trend toward a new lightweight design leads to the necessity to join different materials in a material mix. Here, the use of high strength steels, light metals, and fiber-reinforced plastics has expanded extremely in the last years. In terms of adhesive bond, one has to deal with different surfaces and thermal expansion. Additionally, the adhesive has to act as an electrical insulation to prevent the joint from forming contact corrosion. In this chapter, typical applications for automobiles are shown. Additionally, suitable adhesive properties and surface treatments are discussed.

## 46.1 Introduction

Adhesive bonding of automobiles started with sealing applications like the substitution of the windscreen gasket by a bonding seam of a rubber elastic adhesive or gap filling with an adhesive to prevent corrosion. The sealing adhesives led to a stiffening of the car body because the bonded windows could act as a shear field and the adhesively bonded joints were stiffer than spot welded flanges due to the complete connection. To further improve the stiffness, an increasing number of adhesives with a high modulus was used. Since these adhesives were not suitable to improve the behavior of the joint in a crash situation, they could not be used as a real structural element, which would enable to reduce the number of spot welds. The third generation of adhesives with enhanced crash properties finally offers the opportunity to use adhesive bonding as a real structural joining alternative in an automobile construction. We can generally distinguish between applications in the automobile body and the power train. Regarding bonding in the car body, you have to take into account that the body has to be painted, meaning that the adhesives have to be applied before or after certain painting processes. This is of high importance in terms of the selection of the suitable adhesive. In Fig. 1a, typical bondings on raw metal in the car body are shown. Fig. 1b gives examples of bondings on painted panels.

Regarding the strength of the adhesive bonds, one can distinguish between high strength and high stiff bonds and bonds with lower strength and a higher flexibility. To produce high strength joints, often epoxy adhesives are used with a low bondline thickness of about 0.2 mm. Windows are bonded with a highly elastic polyurethane adhesive with a bondline thickness of more than 2 mm (Fig. 2).

## 46.2 General

The process chain in an automobile production can be separated in the production of the **car body** and the components, respectively **the powertrain**. The stages of the body production are the **press shop**, the **body shop**, and the **paint shop**. The final

**Fig. 1** (a,b) Typical bondings in a modern automobile

**Fig. 2** Typical semistructural and structural bondlines

production step to finish the automobile is the **trim assembly**. While in the press shop besides of a possible use of bonded blanks no adhesives are used, adhesives are applied in the three other areas mentioned and have to undergo the following process steps.

#### **46.2.1 Press Shop**

Classically, sheets made of steel – uncoated or zinc coated – and aluminum alloys are cut and cold formed in a deep drawing process. To prevent the metals from corrosion and to facilitate the pressing process, the blanks have an oily surface. A modern approach is the use of a warm forming process where the deformation and the hardening of the steel (e.g., 22MnB5) is performed at the same time. Therefore, the sheets have to be heated to a temperature of about 850 °C, which could cause the formation of a thick oxide layer. To prevent the parts from this oxidation, a special coating is used, which has to be taken into account for the subsequent joining procedure.

#### **46.2.2 Body Shop**

The formed parts are brought together to assemblies in the body shop. Here, almost every joining technique is used. The standard method used for joining of steel is spot welding, whereas for light metals mechanical joining like clinching and riveting is commonly used. Independent of the material used and of the joining technique, the application of adhesives is necessary or beneficial to prevent the parts from corrosion. Adhesive bonding is used in steel and aluminum bodies to stiffen the parts and to improve the crash behavior. In a mix material design, the use of adhesives is essential to avoid the contact corrosion that could result from the contact of materials that have a different electrochemical potential. The adhesives applied in the body shop will be cured in the oven, which is needed to cure the electro-coated paint. Therefore, during all of the processes performed in the body shop, the adhesive is liquid and the handling strength has to be obtained by an additional joining technology.

#### **46.2.3 Paint Shop**

Before the paint is applied, different pretreatments like cleaning and phosphating are executed. The paint is applied in different layers. It starts with the application of the electrolytic cathaphoretic paint and the curing of that layer during about 30 min at a temperature of 180 °C. Afterward, more paint layers are applied and cured at temperatures from 110 °C to 150 °C. The resulting layer structure is shown in Fig. 3.

#### **46.2.4 Trim Assembly**

In the trim assembly, the windows and different panels and other optical elements are bonded to the painted body. Thus, the paint layer becomes part of the structure, which

**Fig. 3** Different layers of paint due to the current painting process of a car body

has to be taken into account if there is a demand for a higher strength. Additionally, the chemical base of the paint, the color, and the painting process are of a high importance in terms of the resulting properties. Because of the heat sensibility of the applied materials and the assembly process, only cold curing adhesives can be applied.

## 46.2.5 Power Train

In the power train, adhesives are used for shaft-to-hub connections, for sealing purposes and as a thread lock. Special demands for the adhesives used result from the high temperatures and the contact with fuels and lubricants.

## 46.3 Specific Requirements

### 46.3.1 Adhesively Bonded Sheets in the Press Shop

To reduce weight, metal sheets with a varying thickness are used for forming parts. In this case, the wrought products are made of sheets with different thicknesses by welding or differential rolling. Hence, to produce the so-called tailored blanks, different sheets are welded together in general by laser beam welding before they are formed in the pressing process. This is very common for linear and nonlinear joints. A new possibility to improve stiffness and corrosion resistance is the use of so-called bonded blanks where two sheets are bonded together prior to the pressing process. In this context, it is important that the adhesive has a sufficient green strength to ensure the right position of the blanks during the pressing process, but nevertheless there is enough plasticity to avoid the formation of cracks in the adhesive layer during the deformation process. One possibility to achieve this behavior is the use of an adhesive with two hardening procedures. The green strength results from a viscosity increase due to the cooling of the hot applied adhesive, and the final strength is formed by crosslinking due to the chemical reaction after the

pressing process that takes place in a furnace at 180 °C (Wisner et al. 2014). An example of a part made from bonded blanks is shown in Fig. 4.

**46.3.2 Adhesives in the Body Shop**

Adhesives are typically used in the body shop for structural flange bonding spot weld bonding, clinch bonding, etc. in a so-called hybrid process. Here, the adhesive is applied on one sheet and after joining of the parts the additional joining technique takes place. Further applications are hem flange bonding and antifleutter bonding.

Adhesives used in the car body structure have very specific and demanding requirements:

1. They need adhesion on oiled bare, electrogalvanized, or hot-dip galvanized steel and on aluminum metal sheets.
2. They undergo the complete pretreatment process for the electro coat including the heat curing in the EC oven. The adhesives are designed to cure under these conditions.
3. A temperature resistance of 200 °C over half an hour is needed, but due to the variety of production processes between the different manufacturers and even between different plants up to 220 °C is specified, or at the lower end under low bake conditions 160 °C for 15 min. Therefore, the curing properties of adhesives have to be adapted to the specific process conditions of the individual production line.
4. In certain cases, parts with uncured adhesive are stored or shipped. Under these conditions adhesives may absorb moisture from the atmosphere and when curing at 180 °C the absorbed moisture will cause bubbles, thus reducing the strength of the adhesive.

**Fig. 4** Bonded blank technology (Wisner et al. 2015)

5. Adhesives must be applied in a liquid stage to achieve a proper wetting, and thus they usually do not withstand the conditions of the pretreatment baths. Therefore, a precuring or pregelation is often required. Due to separate handling, this is easier for the bolt-on parts like doors and hoods since adhesives used for them are often cured in a separate prebaking oven or by induction curing. The newest generation of structural adhesives does not need such a precuring any more.
6. Since all body shop adhesives are applied directly on the metal surface, corrosion resistance is crucial. And it is even more demanding than the corrosion resistance of coatings, since there is no specific pretreatment, and the structural adhesives replacing welding operations must withstand much higher loads than a coating. Regarding the corrosion tests, every car company has its own test requirements, because they have individual longtime records with their specific test conditions. But in general, they have the following requirements in common: the combination of salt spray, high humidity, and temperature change. These conditions give usually similar results depending upon the time and the number of cycles.

### Structural Flange Bonding (Hybrid joining)

Typical configurations of the use of different joining technologies at one flange in a hybrid joining process are shown in Fig. 5.

To build up the structure of the car body, welding is the standard technology to join metals and especially spot welding is used for all steel cars. In the last 30 years, the requirements for car design have changed due to the pressure of lower fuel consumption and higher safety for the occupants, which revealed the limits of the spot welding technology in terms of durability, crash resistance, and production speed in connection with thinner high strength metal sheets or in a more obvious case, with aluminum substrates.

To overcome the drawbacks of spot welding, other joining technologies have been evaluated including riveting, self-piercing riveting, clinching, and bonding.

The structural adhesives marketed for the automotive industry at the beginning of 1990 were rather brittle and not really resistant under high-impact conditions. Consequently, the adhesives industry developed the new generation of high-performance structural adhesives in this decade.

These combine the strength of standard epoxy adhesives with higher deformability before break. These are often formulated as warm-melt adhesives

**Fig. 5** Hybrid joining of a flange in a car body

and applied at temperatures up to 60–80 °C, and after cooling, they get highly viscous enough to withstand the pretreatment operations. But these warm-melt properties have to be well balanced, because if the viscosity of the adhesive is too high after cooling, spot welding will lead to pocket formation as demonstrated in Fig. 6.

The welding will need more electrical and pressure power since a thicker layer of adhesive acts as an insulator. Usually, this is addressed as squeezability, which means the property of the adhesive to flow under a small pressure when the metal sheets are put together. The challenge for the adhesive formulator is to balance a low viscosity at the application temperature of 80 °C with a rather high viscosity at room temperature to achieve a good washout resistance and at the same time a good squeezability (Stepanski 2010).

Another critical point is linked with the reactivity of the adhesive. It needs heated pumps and tubes for the application at temperatures between 50 °C and 80 °C. But due to the inherent reactivity of such one-component adhesives, there will be a slow increase of its viscosity over time. The flow in the tubes will then be reduced and when increasing the temperature to keep the constant flow, the viscosity increase continues and the tubes will be blocked. This is important in cases where the consumption of the adhesive is rather low or the tubes are long. Therefore, not only the design of the adhesive is important, but also when planning the application equipment, it should be clear that the adhesive in the tubes should regularly not stay for a longer period at elevated temperature. Since this is specific to the adhesive and the equipment of the production line, it has to be evaluated in detail by the responsible engineers for every single application. For all adhesives application, it is recommended to use heated pipes since this guarantees a rather constant application viscosity.

The need to reduce the weight of a car leads to the use of alternative materials that have to be joined with a similar material or a different material in a so-called hybrid construction. Here, traditional joining and welding processes are often not suitable due to different reasons. One is the difference in between the thermal expansion coefficients of the materials, another is the electric potential of the material. Adhesives are suitable for bonding of almost any material and reduce the mentioned problems, thus increasing the use of adhesives in automobiles significantly in the last 10 years. In Fig. 7, the material mix in a modern car structure is shown.

**Fig. 6** Pocket formation when welding through a highly viscous adhesive

**Fig. 7** Material distribution in the Audi Q7 (Audi)

Here it is necessary to compensate the different elongations of the parts due to the different thermal expansion (CTE-Mismatch) by a thick and elastic adhesive layer. However, such an adhesive layer can reduce the stiffness of the part significantly so that adhesives with a middle modulus of 10–100 MPa are developed.

**Hem Flange Bonding**

Bonding of hem flanges has now been practiced for more than 30 years. At the beginning, the reason was more corrosion protection than the increase in stiffness. Meanwhile, the hem flange bonding contributes to the structural stiffness of hoods. And it is an important element for the resistance of the doors against side impact. The adhesive prevents the inner door panel with the reinforcement bar to slip out of the hem flange upon impact.

Regarding application, the hem flange bonding needs very specific processes. To fulfill the strength and corrosion requirements, the flange should preferably be filled completely. But in this case, the hemming tools and also the parts will soon become soiled, which would then require an additional manual cleaning step. Therefore, the application is carried out on the inner side of the outer panel to avoid the adhesive to be squeezed out. There is another difficulty. The high pressure of the hemming tools press the gap to almost zero, but the metal bounces back due to its elastic properties thus creating voids. Some adhesives use small glass bubbles as a filler in order to keep a gap of 0.3 mm, which reduces the number of voids.

In addition, the doors are seam sealed to achieve a proper corrosion protection. But when the air is entrapped in the hemming area, bubbles will be formed in the hem flange sealant on curing, while reducing the visual quality of the sealing bead. And if not sealed, the hem flange has a high risk for corrosion because of these voids. This problem has not been solved yet to the satisfaction of the engineers. A possible solution is the application of the seam sealer onto the hot hem flange when using induction heating, but then the cycle time will get too long, which means additional expensive tools. The different steps of hem flange bonding are shown in Fig. 8.

**Antiflutter Bonding**

A third important application is antiflutter bonding. To avoid rattling noises, the gap between the outer panel and the inside structural metal sheet of a hood must be filled

**Fig. 8** Main process steps of hem flange bonding

with a suitable material. This often is soft rubber foam to avoid any surface marking, but in this case no increase in stiffness is possible. With the push toward lightweight design, the gauge of the outer metal panels has become thinner and thinner. And when using a “semi-structural” adhesive, the stability of such a hood can be increased. This is also a structural adhesive because it contributes to the stiffness of the hood, but due to the requirements regarding surface quality with no marking on the outside panel, a balance between strength, modulus, and elongation must be found. If the adhesive becomes too strong, there will be an unacceptable surface marking (read-through) on top of the bonded area, and if the E-modulus of the adhesive is too low, there is no stiffening effect. The best solution would be a high modulus adhesive with no read-through. Unfortunately this “read-through” is caused only to 10% by the shrinkage due to the chemical reaction of the adhesive itself, the other 90% is due to the physical shrinking from 180 °C to room temperature.

The surface marking (Fig. 9) can go in both directions, but due to the thermal shrinkage of the adhesive, in most cases it is indentation.

In the phase of the heating-up in the oven, there are differences of up to 60 °C between the inner and outer metal sheet and when the adhesive cures at this stage, surface marking after cooling can be observed. Tests with a two-component adhesive curing at room temperature showed that with cold curing the marking was significantly reduced. Unfortunately, it is very difficult to get adhesion on oily metal sheets using two-component adhesives.

Figure 10 shows typical applications at a front hood. There is a hem flange area either around the whole perimeter or only in the front and the back, and on the side of a spot-welded area but with the same structural hem flange adhesive. The reinforcement bars of the inner panel are bonded with thick adhesive layers (usually around 3–5 mm thickness). In areas where higher pressure onto the outside panel is expected when closing the front hood by hand, a larger area is supported. To apply the adhesive on such a larger area, the multidot application is preferred. This has the

**Fig. 9** Surface marking by antifiutter bonding

**Fig. 10** Antifiutter bonding applications

advantage that there are gaps between the dots, and the electrocoat can flow into these gaps and provide the necessary corrosion protection.

Adhesives used in a car have to work at temperatures between  $-40\text{ }^{\circ}\text{C}$  and  $105\text{ }^{\circ}\text{C}$ . More demanding than the temperature is the resistance toward humidity because hot and humid conditions can reduce the strength of adhesives significantly depending on formulation and chemistry.

There is also a differentiation between inside and outside parts. Outside parts have not only to pass high temperature and high humidity tests but also the corrosion test cycles like the VDA 621-415. Inside parts are exposed to higher temperatures (in some areas up to  $120\text{ }^{\circ}\text{C}$ ) than outside parts but are not exposed to a corrosive environment (Table 1).

**46.3.3 Adhesives in the Paint Shop**

In the paint shop, there are only some minor applications of antiflutter bonding and seam sealing with materials which need similar properties like adhesives in terms of good weathering resistance and good adhesion. These sealants are polyvinylchloride plastisols in most of the cases, as they are used for underbody coating and do not provide high strength. In this case, the adhesion occurs on a coated surface, which offers more opportunities in the formulation and no issues regarding corrosion. Since the paints are cured in the paint ovens, their heat can also be used to cure the sealants. Temperatures are typically between  $140\text{ }^{\circ}\text{C}$  and  $160\text{ }^{\circ}\text{C}$  with the tendency to baking at lower temperatures. Since the paint process follows the body shop operations, all body shop adhesives have to withstand the baking conditions of the paint. There are efforts to move all non-paint operations out of the paint shop, thus bonding in the paint shop will be the exception.

**46.3.4 Adhesives in the Assembly Line/Trim Shop**

The largest variety of adhesives is used for all the parts assembled in the trim shop. Since many parts are produced at suppliers or subsuppliers and are installed in the car either by screws, bolts, or clips, there are only a few applications performed directly at the assembly line. This is also due to the fact that adhesives need a specific process for curing or hardening, which in most cases do not fit into the required short

**Table 1** Test conditions of VDA 621-415 corrosion test cycle (Available from VDA website [www.VDA.de/en/publikationen](http://www.VDA.de/en/publikationen))

One cycle		
Day	Duration	Condition
1	24 h	Salt spray DIN 50021 SS
2–5	4 × 24 h	DIN 50017 KFW
6–7	2 × 24 h	23 °C, 50% relative humidity

This cycle of 7 days is run ten times. The overall duration is 10 weeks

cycle time of often less than 1 min. Most bonded parts are preassembled and built into the car as finished parts. Adhesive bonding of these separately built-on parts is not within the scope of this chapter.

The most important structural bonding in the final assembly is the installation of the windows. Even if the adhesive for this purpose must be flexible enough to prevent a breakage of the glasses due to high stresses through deformation, the resulting increase in torsion stiffness (a high quality property of a car) depends on the car design in the range of 50–80% with almost no additional cost and no increase in weight. Therefore, direct glazing has replaced the rubber gaskets in almost all car production lines and has become an important element for the torsion stiffness of the car. This installation principle of direct glazing can also be transferred to the installation of other panels like a separate lightweight roof made of aluminum or carbon fiber composite.

The most important application at the assembly line is the bonding of the glasses. Figure 11 shows a typical cross section of a frame with the adhesive bead. Usually, a triangular bead with a height of 8–10 mm and a width at the base of 10 mm is applied onto the glass which is then installed into the car. This is necessary to cope with the tolerances of the frame and the glass.

The use of 1-C polyurethane adhesives is state of the art. Standard grades are applied at room temperature and need fixation for at least 1 h to get sufficient strength to hold the window in place. Warm-melt windshield adhesives are applied at temperatures between 60 °C and 80 °C and on cooling they build up sufficient initial strength to hold the windows in place during curing with no additional fixations. The adhesives are fully cured after 3–7 days depending on the climate conditions.

The warm-melt properties must be balanced very thoroughly. If the adhesive is setting too fast, it does not wet the surface enough and there will be disbonding under torsion stress. To increase the slow curing speed in cold and dry atmospheres, two component systems are available, which are either real 2C systems or 1C adhesives accelerated with water paste. These are used when the bonded structure has to bear load at a very early stage.

An important detail is the conductivity of the windshield adhesives. If such adhesives were formulated with higher amounts of carbon black as filler, the direct contact of such an adhesive with aluminum would lead to severe and fast contact corrosion and would destroy the aluminum in the case that the isolation through the paint is damaged. Also, if a radio antenna is integrated into the glass (e.g., a rear window), the impedance of the adhesive will play an important role for the quality of radio reception.

**Fig. 11** Cross-section of windshield bonding

When windshield adhesives are directly exposed to sunlight, the thin adhesion layer directly on the glass will be destroyed by UV-radiation. Therefore, a UV protection is a must. In the beginning of windshield bonding, this was achieved by a black primer, but under severe UV-radiation, even this rather stable UV-blocking primer was destroyed over time. With the application of a screen-printed ceramic frit (see Fig. 11) to the bonding area of the glass, the necessary high-quality UV protection could be achieved. More than 30 years of success in windshield bonding has proven the reliability and durability of this technology.

The replacement of windshields must be possible, too. At the beginning, this was an important criterion against the introduction of direct glazing. But with specifically designed cutting knives or with high strength steel wires, the removal for repair purposes was possible in a short time. To facilitate the repair, a minimum thickness of the adhesive layer must be guaranteed, preferably more than 3 mm.

The success of windshield bonding encouraged the designers to bond other panels onto the frame. In particular, the roof is in study, because saving weight on top with an aluminum or carbon fiber composite roof, will lower the point of gravity and improve the road handling. An overview on elastic bonding can be found in the booklet of Burchardt et al. (1998) and Cognard (2006).

For the fixation of model names and door trims as well as rubber gaskets, pressure sensitive adhesive tapes are commonly used. Such pressure sensitive adhesives (PSA) are highly sensitive to stress. The parts should be attached in a completely stress-free state and with a defined pressure. After the application, the adhesive continues to wet the surface and to build up the final adhesion. Brockmann (Brockmann and Grüner 2003) investigated the creep behavior of such tapes and he found out that under load the tape may creep over its whole overlap length and is still bonding with the same shear and peel strength as in the unloaded stage.

**Besides the areas described above, adhesives are used for different purposes in the engine and the gearbox. These applications are described below.**

### **46.3.5 Adhesives in the Power Train**

In the power train, adhesives are used for shaft-to-hub connections, for sealing purposes, and as a thread lock.

For shaft-to-hub connections mainly anaerobic acrylates are used. In most cases, the adhesive bond is supported by a shrinking of the hub to the shaft. By this hybrid joining process, both a high axial strength and a high torque can be achieved. A secondary effect of the shrinking is residual stresses in the parts, which can lead to a reduction of the fatigue strength. Especially for rigid materials like sinter metal this can cause problems; therefore that the shrinkage should be reduced and the adhesive part of the strength should be increased [17, 18] Lit.-Stellen ergänzen.

To produce these bonded shrink fits, the hub should not be heated up to more than 200 °C to avoid damage of the adhesive and the shaft should not be cooled to avoid condensed water.

Figure 12 gives an overview about the shrink fit process to produce a gear-shaft connection.

Thread locks are made by either anaerobic or microencapsulated adhesives. These adhesives have a defined initial breakaway torque.

Silicones are often used for As gaskets formed at a place in the power train. To enhance the curing time, there are UV-curing products on the market. It is important that – because of the bad paint adhesion on silicone-contaminated surfaces – silicones are only used for power train applications and it has to be ensured that no contamination of body parts is possible.

## 46.4 Other Specific Requirements

Adhesives used in a car body need a temperature resistance of at least 105 °C and must resist high humidity conditions as well as temperature change between –40 °C and +80 °C. Such adhesives are often tested under the so-called cataplasma condition, that is, 70 °C in a water saturated atmosphere. Each car manufacturer has its own test regime but they rely on the combination of high humidity and temperature. In addition, the UV resistance of the system must be checked either with exposure to sunlight in areas like Florida or in test chambers with UV-lamps in combination with heat and/or moisture. The interpretation of such artificial weathering needs experience, since the extrapolation for the real-life weathering cannot be done automatically.

On top of technical requirements additional properties are requested. One is low fogging of small ingredients or plasticizers in the adhesive and another is low odor, since customers became more sensitive toward the smell of adhesives.

For outside application, fuel resistance, resistance to cleaning agents, and washing fluid for the windshield and headlights are required in addition to water and corrosion resistance.

**Fig. 12** Bonded shrink fit

## 46.5 Surface Preparation

The right surface preparation is the key to successful adhesive bonding. Therefore, it is at first sight surprising that bonding in the body shop with the highest strength requirements occurs on oily surfaces. But to be sure, these systems have been tested extremely thoroughly and only those combinations of adhesives, oils, and metal surfaces are allowed to use which have passed all test. And then, it is up to the quality control system over the whole value chain from the suppliers of adhesives, oils, and metals to the stamping plant to make sure that all process steps are well under control. And all changes have to be communicated before implementation.

The fact that body shop adhesives are cured at temperatures about 180 °C helps the adhesive to absorb the oil and get in direct contact to the surface with good wetting. The weakest area of the surface is the thin oxide layer which is on all metal surfaces.

The phosphatation process which creates a good adhesion layer for the paint cannot be used since the adhesives are applied at an earlier stage during the assembly of the metal parts.

In the future, precoated metal sheets could probably be used, but then the spot weld bonding would be no more possible. In addition, one has to keep in mind that the adhesive strength on such coatings is lower than that of high strength structural adhesives. Even the adhesion quality of a hot dip galvanized steel coating has to be tested since with some structural adhesive the zinc layer debonds from the metal surface.

In case of aluminum, a pretreatment is necessary to achieve a long-term-corrosion-resistant adhesion. Whereas in the aerospace industry, anodizing processes are state of the art, automotive industry has been looking for more cost-effective solutions. A Cr (VI) passivation provided the best results and is now used as benchmark for new chrome-free pretreatments necessary due to the environmental impact of chrome. The best and most cost-efficient results are reached with a passivation of the aluminum in a coil coating process. But this implies that the lubricants needed for the drawing of the aluminum sheets is compatible with the adhesive. Otherwise a separate washing process of the stamped parts would be necessary which is not really economic. A new article from Rechner et al. (2010) discusses different surface pretreatments.

In addition to solvent cleaning, new methods with laser, CO<sub>2</sub>, and plasma treatment are available. A short overview has been written by Schulz (2010) (See also Part B).

As the oven for the EC coat can be used for curing, almost all body shop adhesives are one component systems. The heat curing helps to absorb the oil thus providing the necessary adhesion.

In contrast to such one component systems, it is very difficult to get adhesion on oily surfaces with 2-C adhesives. Due to the immediate start of the curing after mixing of the two components, the time to replace the oil on the surface is too short in comparison with the curing speed, because the monomer or prepolymer components of the adhesive resin and hardener react faster with each other than they are able to wet the surface. Only with very long open time adhesives there is some chance to get adhesion. Significant efforts are made to use 2-C adhesives for

bonding of hoods to reduce the thickness of the outer sheet without surface marking.

Also a challenge is the adhesion on painted surfaces. This has been intensively tested with the introduction of direct glazing. Since there are so many different paint surfaces due to the chemistry, process conditions, and requirements for the paints, there are three different approaches to achieve good adhesion for the windshield adhesive:

1. Bond on the surface of the filler or directly on the EC coat. This requires a cover tape applied before the coating of the paint. The masking tape must be then removable without any residues on the surface even after several bake cycles. And in addition, the paint must stick on the tape and should not chip when removed. The masking is an additional process with additional costs. The EC coat provides the highest adhesion strength with values in the range of 15 MPa.
2. The use of a primer to prepare the paint surface for the windshield bonding. This is a commonly used process. It is mostly a manual operation with the risk of contamination of other areas with the primer. But with specific formulated primers it is possible to achieve adhesion on all paint surfaces.
3. Bond directly on the top coat. This requires a thorough testing of all paint surfaces and a specific formulated adhesive adapted to that paint type. It means more quality control tests during production. But also in this case it is necessary to mask those car bodies which undergo a repainting process, because additional paint layers usually have less adhesion than the first one, which would create a weak interphase for the bonding system.
4. In general, the adhesion within the paint layers determines the strength of bonding on paint. High modulus windshield adhesive can build up stronger bonds than the paint which leads then to adhesive failure within the paint layer instead of failure within the adhesive itself. This applies also for other parts like, for example, a roof made of aluminum or carbon fiber composite installed at the assembly line.

---

## 46.6 Strength and Durability

Strength and durability is not inherent to an adhesive but it must always be seen in the context of the whole design of the bonded joint, the substrates, the expected permanent maximum and cyclic loads in combination with environmental influences like climate, radiation, and oxidation.

Figure 13 shows a relation between strength and deformation for the world of adhesives. It visualizes in which strength range different adhesive types usually work, even if there may be exceptions. And it helps to think about the balance between strength and deformation.

The range of strength of structural adhesives used in automotive production is marked at one end by windshield adhesives with rather low modulus and high elongation and at the other end by very high strength epoxy adhesives. The top end of adhesives for automotive bodies are crash-supportive epoxy-hybrid adhesives

**Fig. 13** Landscape of adhesives for structural automotive applications (PUR polyurethane)

which have a somewhat lower G-modulus than very high strength epoxies, but significantly higher elongation. In between, there is a large area where the mechanical properties of the adhesives can be varied. In automotive applications, this broad range can be covered with 1- and 2-C polyurethanes, rubber- or acrylic-based adhesives, and epoxies or modified epoxies. There are also PVC- or acrylic-plastisol type products, but these provide due to their thermoplastic properties no real structural strength. The right approach for engineers is to define first the required mechanical properties of the adhesive for given substrate combinations with respect to the expected mechanical loads and then select the adhesive with the corresponding profile. This differs from the standard approach where the adhesive with the highest strength is selected for structural applications without really taking into account other important adhesive properties and the mechanical behavior of the substrates themselves.

When designing bonded joints, the right bonding area and overlap length is the key element for a successful bonding to guarantee the required load transfer with respect to the given mechanical properties of the substrates.

For example, when bonding metal to glass, a too strong adhesive in combination with a large bonding area or length will lead to glass breakage when exposed to very low temperatures. Or a too strong adhesive for the bonding of glass fiber or carbon fiber composites will lead to the delamination of the matrix resin from the fiber thus not providing the desired bond strength. By reducing the modulus of the adhesive and increasing the bonded area, the required load can be transferred without such delamination.

It is important to know that adhesives need a certain area to be able to transfer the desired load. Adhesives with very high modulus and low elongation at break are limited when enlarging the bonding area since they have no uniform stress distribution within the bond line. By increasing the bonding area, adhesives with lower modulus and higher elongation at break can transfer even higher loads than hard and brittle high strength adhesives and are in addition more tolerant toward impact stress.

What is the real strength required for structural bonding? This central question cannot be answered in a simple way. The most important property is not the lap shear strength but the G-modulus or E-modulus, which can be used in calculations for the stiffness of a bonded structure. The bonding of a sun roof lid gives an idea about this effect. In this example, the lid is bent as shown in Fig. 14 with a force of up to 500 N, and depending on the modulus of the antifleutter and hem flange adhesive, the deformation is measured and calculated.

The calculation made by Deimel (1993) of the deformation depends on the modulus shows that the bending could be reduced from 7.8 to 4.8 mm at the given bending force of 500 N (Fig. 15). The maximum allowed bending was 5.8 mm. This is of real importance since at a car speed of more than 200 km/h the air would deform the lid too much and blow it away. The real bending measured with adhesives with 0 MPa (a deformable rubber), 5 MPa (a windshield adhesive), 20 MPa (a modified polyurethane (PUR) adhesive), and 100 MPa (a flexibilized 2C epoxy adhesive) showed a rather good correlation with the calculation. The stiffness increase was slightly higher than calculated which can be explained by the fact that the modulus was measured as secant modulus at one-third of the maximum shear strength. And in reality, at very low deformation, the modulus is higher. This example shows that for structural antifleutter bonding, a modulus of 50 to maximum 100 MPa will be enough to get the necessary stiffening effect. With a modulus of 1,000 MPa or more, the risk of surface marking will be much higher especially when using thinner metal sheets. And be aware that high strength steel sheets will not have less surface marking because it is the E-modulus of the steel which determines this property and not the yield strength.

In this real case, the requirement from the design was the necessity of a very thin lid to save space overhead. Plastisol-based antifleutter material did not provide the required stiffness, and when using a very strong epoxy adhesive to get the maximum increase in stiffness, surface marking occurred. The solution was a modified PUR-adhesive with a G-modulus of 50 MPa limiting the bending to 5.2 mm but with no surface marking.

The key to design bonded joints is the knowledge of E-modulus or G-modulus. These values can be used to calculate and predict the strength of a bonded joint. In

**Fig. 14** Bending of sun roof lid

**Fig. 15** Stiffness of sun roof lid depending on shear modulus

contrast, the value of the lap shear strength of a joint is of no use since this depends on the specific properties of the substrate and the geometry of the samples and thus not inherent to the adhesive properties. A good overview of the design and calculation principles of bonded structural joints can be found in a series of articles by Schlimmer (Bornemann and Schlimmer 2004a, b; Bieker and Schlimmer 2004). Design of joints with structural adhesives and sealants is also treated in ► Chaps. 27, “Design Rules and Methods to Improve Joint Strength,” and ► 28, “Design with Sealants,” respectively.

A short example of a calculation is used to demonstrate this effect. When bonding a lap shear sample made from mild steel with yield strength of 280 MPa, a metal gauge of 1 mm, and a bonded area of 300 mm<sup>2</sup> (12 × 25 mm<sup>2</sup>), the force to reach the yield strength is 1 mm × 25 mm × 280 MPa or 7,000 N. The lap shear strength of the adhesive will be calculated with 23.3 MPa. Due to the small increase of the strength of the steel on yield, in practice not more than 25 MPa can be expected. And there will be no adhesive providing more than 25 MPa, even if the inherent strength of an adhesive may be much higher.

The other example will be a lap shear joint sample with 1 mm steel and an adhesive with 5 MPa lap shear strength (e.g., a windshield adhesive). In this case, when the bonding area is 1,800 mm<sup>2</sup>, which corresponds with an overlap length of 72 mm, there is also a failure in the steel.

The lap shear strength is a measure which depends on the sample design whereas the G-modulus is an inherent adhesive property. The benefit of a lap shear test is a simple specimen for quality control of the combination of adhesive, adhesion, and surface quality.

**Fig. 16** Stress–strain diagram of a crash-suitable adhesive

**Fig. 17** Failure of a lap shear sample with a crash-suitable adhesive

The diagram in Fig. 16 shows three sections. Section 1 is the area where the adhesive shows almost linear behavior and the strength and the deformation of the bond can be predicted and calculated for the lifetime.

Section 2 is an area where the adhesive shows resistance against short time high load without damage. And it can be seen that the maximum load in this section is almost in the range of 40 MPa, which is far above the strength level of the steel in the calculated example above. Sections 1 and 2 are typical for high strength structural adhesive, also for the brittle types. Section 3 shows the additional benefit of a crash-suitable adhesive because such adhesives start to deform significantly without break absorbing enough energy to keep the parts together. Figure 17 shows that these adhesives really work with a broken lap shear sample which proves the calculation above. Two areas are remarkable in Fig. 17. In area 1, the metal broke after it exceeded its tensile strength, and in area 2, very high stress concentration occurred due to the metal deformation. At failure, it was observed that at the edge in area 2 the adhesive started to crack but due to the built-in nanoscale crack stoppers it did not break. Such adhesives are designed that during curing phase separation occurs and phase of elastomeric nanoparticles is built, which act as crack stopper published by Burchardt et al. (2009).

Such a property is crucial in case of a sudden overload through an impact. In particular, hard and brittle adhesives with very high strength (higher than 1,000 MPa

**Fig. 18** Impact peel test (crash) – ISO 11 343

**Fig. 19** Impact peel test specimen

G-modulus) fail under such loads very fast and these are not recommended for automotive applications where impact resistance is needed. The impact performance is tested with an impact peel tester shown in Fig. 18, where a weight on a pendulum drives a wedge through the specimen and the forces are recorded.

The test specimen is a wedge sample as illustrated in Fig. 19.

The diagram of an impact peel test in Fig. 20 shows the difference of a crash-suitable adhesive in contrast with a very good structural automotive adhesive.

The first peak of the curves is the initial peel resistance and the jagged curve gives the average value of the impact peel strength. Whereas the standard structural adhesive ends after 15 ms with an average peel force of 400 N, the crash-suitable one withstands for almost 20 ms providing a peel force of 900 N. The area under the curve is a measure of the energy absorption of the adhesives itself. Of course, the small amount of adhesive in a bonded structure is not absorbing the crash energy. It is the structure which is held together by such a high-performance adhesive thus providing better results than a spot welded part.

More information on impact is given in ► Chaps. 21, “Impact Tests,” and ► 29, “Design for Impact Loads.”

## 46.7 Durability

A key question of bonded joints is the durability since adhesives are not metals and their performance is more dependent on temperature and environmental influences. And an engineer has the responsibility for the function of the structure over the

**Fig. 20** Diagram of an impact peel test

designed lifetime even under harsh environmental conditions. How can the durability of an adhesive be evaluated?

The durability of adhesive bonding is determined by four elements:

1. Durability of the substrates
2. Durability of the adhesive itself
3. Durability of the boundary layer
4. Durability of the bonded system

The durability of the substrates and the bulk adhesives can be tested separately with shouldered test samples. These tests give an indication if the bulk material can provide the required performance.

Testing of the adhesion within the boundary layer needs more effort. Metal adhesion in automotive industry always means adhesion on the oxide layer. This layer is attacked by moisture in combination with oxygen which leads to disbonding over a certain period of time. All surface preparations and specific ingredients of the adhesives have the goal to slow down this deterioration of the oxide interphase as well as possible. This is usually tested by cycles like the VDA test. And it can be seen that under these conditions, the oxide layer will be destroyed over time. In order to have a correlation of this effect in comparison with real-life corrosion results, every car manufacturer has its own cycles.

An important contribution for a durable adhesive is the exclusion of moisture. This does not mean that the adhesive layer cannot get wet, but it must be able to dry up again and in cases where moisture may remain longer, it is recommended to protect the adhesive with a sealant, especially in the lower areas of the car. This is

**Fig. 21** Decrease in shear modulus of an epoxy adhesive after humidity storage

anyway a good solution, since the corrosion starts from the cut edges of the metal sheets which are not really protected by the adhesive squeezed out in an uncontrolled way. To simulate the effect of humidity on the adhesive, the samples should be conditioned in a humidity chamber (for example, according to DIN 50017) before testing, because the saturation of the adhesive with moisture will lead to a plasticizing effect and reduce the strength and modulus of the adhesive but reflect better the reality (see Fig. 21).

Figure 21 shows the decrease of the modulus of a standard epoxy adhesive after storage at high humidity. Of course, this effect is dependent on the formulation of the adhesive, but all adhesives are affected by humidity to a certain degree. This effect cannot be detected with simple lap shear samples because the lap shear strength is almost unchanged (see calculation above). There is sometimes even a slightly higher lap shear strength observed since the plasticizing effect of the humidity reduces the brittleness of the adhesive and the failure occurs at slightly higher forces.

The durability for a bonded system can be tested by applying cyclic loads on either simple lap shear specimens, more sophisticated H-specimens or on the whole bonded structure (e.g., the whole car body). It is recommended to run a corrosion test or at least a high humidity test upfront ( Fig. 22).

Since adhesives are plastic materials, they may creep under high loads and therefore the expected static load is a determining factor for the durability. Compared to lap shear strength or tensile strength measured with shouldered test bars, the resistance toward static load is significantly lower. It is recommended to use only in the range of 3% to a maximum 10% of the maximum lap shear strength for the calculation of the sustainable permanent static loads for the use phase.

**Fig. 22** Test specimen for durability

Under dynamic stress, adhesives can withstand much higher loads (up to 30% of the maximum load).

When measuring fatigue, the strength level of a windshield adhesive after more than 20 million cycles is in the range of 0.2–0.3 MPa, which is in the range of 3–5% of its initial lap shear strength (Fig. 23). When tested under the corresponding static load, nearly the same result occurs, but it is not clear if this correlation is valid for all adhesives.

For windshield bonding, an additional durability issue is the resistance to UV radiation. The directly exposed bonding zone of the adhesive is destroyed by UV radiation if not protected by a screen print on the glass with sufficient UV absorption or with other methods of masking. Using only a black primer is not sufficient to guarantee a durable adhesion for the predicted lifetime. The UV transmission must stay below a value of less than 0.2%. Inspection at cars after 8–10 years lifetime in various environments built in 1987 and 1988 have shown that there was reduced adhesion in areas where the UV transmission was higher, because at that time the quality of the screen print on the glass was not on the level of today. Nevertheless, the windshields were still bonded to the frame without leakage which shows the robustness of this technology. Even after more than 30 years of use, polyurethane windshield adhesives show no relevant decrease in strength and do not lose their mechanical properties significantly. A precondition for a durable adhesion is, as with the body shop adhesives, the exclusion of permanent moisture.

The combination of bonding with other joining methods like spot welding, riveting, or clinching called hybrid bonding or hybrid joining gives additional benefits. The punctual joining methods provide immediate fixation and they also take away the static load from the adhesive which gives superior dynamic fatigue strength due to an even stress distribution, especially in combination with very thin metal sheets. Hybrid bonding

**Fig. 23** Fatigue curve of a windshield adhesive

will allow lightweight design by using thinner metal sheet made from very high strength steel without reducing strength and durability. Due to the material savings, the additional process cost will not be higher since the number of welded spots or rivets can be significantly reduced and the application speed of an adhesive is higher than that of spot welding. Therefore, the overall number of robots in a real production would be the same. The weight increase by the additional adhesive is in the range of a maximum of 2 kg for a whole car body, but the weight savings can be in the range of 20%. Thus, the savings in material for steel compensates the cost for the adhesive.

The Wöhler-diagram in Fig. 24 demonstrates the difference in durability of different adhesive types. The 1C epoxy starts with the highest strength level but after ten million cycles, the remaining strength is lower than that of a polyurethane toughened epoxy which has a lower initial strength but due to its reduced crack sensitivity, a higher durability. The rubber-based adhesive and the 2C epoxy adhesive have a similar behavior. These tests were run with aluminum AlMg5Mn single lap shear samples and a surface treatment with Ti/Zr. The overlap length was 12.5 mm and the size of the metal plates 110 × 48 × 1.5 mm. The adhesives were conditioned with a 480 h salt spray test according to DIN 50021 before testing. Spot-welded samples would have already failed at the initial load level of all these adhesives.

Real-life experience from cars shows that spot weld bonded areas provide a much better corrosion resistance than spot welded areas alone because the adhesive fills the joint preventing the intrusion of moisture.

When bonding metal sheets with the typical thickness for automotive use in the range between 0.6 and 1.5 mm, bonded samples can typically bear higher loads during more cycles.

The diagram in Fig. 25 illustrates this case. Spot weld bonded H-samples (see Fig. 22) start the fatigue test at a stress level of around 60 kN and end after six million cycles at around 30 kN, which is the starting level of the Metal Active Gas (MAG)-welded sample.

**Fig. 24** Fatigue strength after 480 h salt spray test (EP epoxy)

**Fig. 25** Fatigue strength with different joining methods

Spot-welded single lap shear samples under the same conditions show a much lower force level at the end of the test. Since the performance of punctual fixations like rivets or spot welds is more sensitive to the thickness of the metal sheets, adhesive bonding exhibits even more advantage with thinner metals. Since this is a double

logarithmic diagram, the difference in the load level of spot welding and bonding is 6–32. Therefore, with such hybrid bonding, the bond strength under fatigue is determined by the adhesive bonding alone. Premium car producers like AUDI, BMW, Mercedes, and even VW use bonding in combination with high strength steel. For example, the newest AUDI A 1 reports a bond length of 60 m (ATZ extra 2010).

Whereas Fig. 17 shows the influence of adhesive properties on the durability, the diagram in Fig. 26 gives a comparison between the effect of adhesive bonding on steel and aluminum.

In this case, the samples are hat profiles preconditioned at 70 °C and 92% RH for 240 h and the distance of the spot welds is 50 mm.

The load is expressed in the torsion moment, and it can be seen that a spot-welded aluminum profile with 2 mm thickness gives the worst results, even if it ends up at nearly the same level as the spot welded steel with 1 mm thickness. Comparing the result of 1 mm spot-weld bonded steel with 1.2 mm spot-weld bonded aluminum, the aluminum shows already a better durability.

What is also obvious is how much improvement can be seen between the spot-welded 2.0 mm aluminum and the 2.0 mm spot-weld bonded aluminum. The distance between the spot welds is 50 mm which is longer than the usual 30 mm. With shorter distances between the spot welds, the results for the spot-welded samples would be better but will not reach the level of bonded samples.

This is not only observed with these test specimens, but it was also proven in the comparison of real spot weld bonded cars, as shown in Fig. 27.

Depending on the design of the car, the increase in static torsion stiffness is for steel cars between 15% and 25%. The 38% are a case where due to the longer spot-weld distance and the weaker structure the improvement was significantly higher. Car 3 was a convertible with additional stiffening bars at the bottom; therefore, the improvement was lower. But what was rather unexpected were the results obtained for cars 5 and 6. Car 5 was a conventional steel car with a high structural stiffness,

**Fig. 26** Fatigue strength: comparison of spot welded and bonded aluminum and steel

**Fig. 27** Stiffness increase of spot weld bonded cars measured before and after curing of the adhesive

and the improvement through bonding was with 20% in the expected range. The car 6 was the same design but made from aluminum. And since it was an experimental car, the aluminum sheets were stamped in the same tools like the steel sheets, which means the increase of the metal thickness for aluminum versus steel was in the range between 0.1 mm and 0.2 mm. But the increase in stiffness was 65%, which is much higher than with steel car and confirms the results of the hat profiles. And the weight for the car body in aluminum was 55% lower than for the same steel car. This concept is realized in the current Jaguar XJ.

As already mentioned, the lap shear strength of an adhesive is not very relevant to the strength of a bonded joint because when enlarging the bonded area, the force can also be transferred with adhesives of lower strength, but remember the G-modulus, which is important for the stiffness of the structure.

In the diagram in Fig. 28, the strength of spot welded and spot-weld bonded lap shear samples with 45 mm width and 16 mm overlap plus one spot weld is shown. It shows that strength level is only determined by adhesive bonding. After the failure of the bond, the spot weld can still bear the additional load as was shown in the research report from Hahn and his group (Hahn and Wißling 2007).

The calculated lap shear strength of the bond based on this diagram is about 11.1 MPa. One spot weld accounts for 3,500 N, and with a spot weld distance of 30 mm such a welded flange with a length of 1,000 mm, for example, would provide failure load of 116.6 kN. Assuming a lap shear strength for the adhesive of 11 MPa and an overlap of 12 mm for the bonded area, the corresponding failure load of the bonded flange with a length of 1,000 mm will be 132 kN. According to this calculation, a lap shear strength of 10 MPa is sufficient for bonding thin steel sheets in comparison with spot welding. The crack resistance of an adhesive is more important than its maximum strength.

**Fig. 28** Failure diagram of bonded and spot weld bonded lap shear sample

And for the stiffness, only the G-modulus is important and with the rather thin adhesive layers of 0.3–0.5 mm in a spot-weld bonded flange, there will be no significant difference between an adhesive with 100 and 1,000 MPa G-modulus in the overall torsion stiffness of the car body.

The diagram also shows the benefit of the hybrid joining since the failure of the spot weld occurs at higher elongation.

Another important property for durability is the glass transition temperature, abbreviated as  $T_g$ . Since adhesives are organic polymers, their properties are much more temperature dependent than metals. And a measure for the temperature stability is the  $T_g$ . In Fig. 29, the dynamic mechanical analysis (DMA) of a crash-suitable epoxy adhesive is shown with a  $T_g$  of about 90–100 °C depending on how the  $T_g$  is determined. Usually for body shop adhesives, the  $T_g$  should be above 80 °C to avoid a strong change in the modulus of the adhesive because the modulus changes about a factor of 100 between 60 °C and 120 °C (see diagram in Fig. 22). There are two different ways to determine the  $T_g$ . One is the intersection point of the two tangents at 85 °C and the other is the point of inflection of the storage modulus curve at 100 °C. Since the  $T_g$  is not an exact temperature, it is better to look at the storage modulus curve to see the real difference in modulus below and above  $T_g$ .

On the other hand, a low  $T_g$  (below –50 °C) does not mean that the adhesive does not fulfill the requirements. Typical windshield adhesives always work at temperatures above their  $T_g$ , as it is shown in Fig. 30. But the decrease in the modulus for this type of adhesive in the working range of –40 °C to +100 °C is from 20 to 2, which is only about the factor of 10 lower.

**Fig. 29** Determination of the  $T_g$  with DMA analysis of a structural adhesive

**Fig. 30** Torsion modulus over temperature of a 1C PUR adhesive

More information on the durability of adhesive joints is given in Part F.

### 46.8 Type of Failure

The same failures as in other bonding applications apply to adhesive bonding in automotive. They are:

796 Failure of one of the substrates  
797 Failure of the adhesive  
798 Adhesion failure

799 When designing a bonded joint, the goal is to achieve at least a break within the  
800 adhesive. This guarantees that the adhesion is higher than the cohesion and the  
801 adhesive is fully utilized. If failure in one of the substrate occurs, the bonding fulfills  
802 the requirements. Such failures can be much better predicted due to the inherent  
803 material properties of the substrates or the adhesive.

804 But in reality, failure occurs in most cases within the adhesion zone. This is the  
805 main reason that engineers have some doubts to use adhesives in structural  
806 applications.

807 When bonding metal substrates, it is the deterioration or corrosion of the oxide  
808 layer which destroys the adhesion zone. With plastic substrates, effects like plasti-  
809 cizer migration or residues of release agents are often reasons for failure, whereas  
810 moisture plays a less important role.

811 In real cars, bonded structures show overall an even better durability than spot  
812 welds since the overlap of the metal sheets is much better protected against  
813 corrosion.

814 When bonding plastic parts like Sheet Moulding Compound (SMC) or even  
815 carbon fiber composites, moisture will have the same plasticizing effect on the  
816 matrix resin as on the adhesive.

---

## 817 46.9 Quality Control

818 As mentioned in the introduction, adhesives are process materials. This is similar to a  
819 welding process. For these processes, it is very difficult to control the quality of a  
820 bonded joint in a nondestructive way. Therefore, it is crucial to control the process  
821 parameters of each production step, to check the properties of the adhesive with the  
822 real substrates and it is necessary to control the surface conditions of the substrates  
823 itself. And even with nondestructive testing methods, it is not possible to check the  
824 quality and durability of the adhesion itself. This can only be done with thorough  
825 adhesion tests upfront with original substrates and original process conditions.

826 Therefore, the way to a durable bond goes along with a survey of all relevant  
827 process parameters. If this is guaranteed, bonded joints have the same life expect-  
828 tancy as other parts of the car body structure.

829 It is recommended to run separate lap shear samples along the whole process  
830 which can then be tested separately to have a continuous process survey. But this  
831 does not differ from the quality control system of the paint process.

832 The quality of a bonding process depends to a high degree on the quality of the  
833 personnel. Therefore, a similar level of education is needed as for the welding  
834 specialists. The Institut für Angewandte Materialforschung (IFAM) in Bremen offers  
835 education courses for three different levels of expertise and everyone who wants to  
836 use structural adhesive bonding. See Part H for more information on Quality control.

---

## 46.10 Repair and Recycling

It is true the repair of bonded joints is different from that of bolt-on parts. But in comparison with riveted, spot welded, or welded structures, the removal of bonded parts may be even easier. When repairing bonded metal structures, the removal of a damaged part is done by mechanical abrasion or with hammer and chisel. The adhesive is then removed by abrasion like it is done with painted surfaces. More challenging in the repair case is to bond a new part on the old structure. It is not possible to use the same adhesive as in the production line since the process conditions are different. In this case, 2-C high strength adhesives with improved impact resistance can be used as published by Lutz (2009). And to process these adhesives correctly, well-educated personnel is required.

Windshield adhesive can be removed either with a steel wire or with specific cutting tools. This is nowadays a standard procedure in repair shop and it can even be done within 1 h on the road.

In this context, it is important that the bonding area is designed in a way that enough space for the cutting tools ore wire is available. There is no need to remove the old adhesive layer completely. It is recommended to bond on a maximum 1 mm thick layer of the old windshield adhesive after the proper surface preparation with a primer which gives additional corrosion protection when the paint layer suffered damage when removing the windshield.

With the idea of recycling, adhesively bonded parts are under pressure since the common perception is that such parts cannot be separated again. And it is true if dissimilar materials are bonded together the separation of the different substrates needs more effort. There are activities to develop adhesive which disbond on command, but it is almost impossible to have durable adhesion under all relevant conditions and in addition an easy disbonding, for example, under high temperatures or by chemical reaction. See Chap. 58.

For bonded metal parts, this is in the recycling case not a real issue since the amount of adhesive in a car body structure is with about 2 kg lower than the weight of the paint. When shredding the metal parts, adhesives as plastic materials can be separated in the same way as the paint and other plastic residues.

---

## 46.11 Conclusions

Adhesive bonding for structural applications has become an important joining technology in the production of cars. It is for decades a well-established method to join doors and hoods and install glasses. And with a new generation of impact-suitable structural adhesives, premium cars have introduced hybrid joining to build lighter cars with increased impact performance. This chapter may help to exploit the full potential and the benefit of adhesive bonding in combination with other joining methods for cars. In particular, the engineers of premium cars in Germany have already started to trust such a technology and use it to a larger extent. It takes time for

the implementation because the full benefit can only be achieved when the car body is designed for this technology.

The main obstacles are the lack of education and experience of the design engineers who have to implement adhesive bonding.

**Abstract**

Adhesion is an indispensable joining technology for railway industries. Adhesives are used for the fabrication of almost all rolling stocks. In the steel main structure of conventional rolling stocks, adhesives are applied for bonding decorated aluminum sheets of wall and ceiling to frames, bonding of floor covering to floor plate, and fixing heat insulating material to the inside of carbody. Large amount of sealants is also used even in the conventional rolling stocks. Recent high-speed trains have modern light-weight structures consisting of aluminum hollow extrusions, sandwich panels, or carbon fiber reinforced plastics. For the structures, adhesion plays an important role as a structural joining method. Even for conventional rolling

e-mail: [yasuzuki-1@nifty.com](mailto:yasuzuki-1@nifty.com)

stocks, the use of adhesives is increasing. For instance, weldbonding is nowadays experimentally applied to the aluminum body structures. Moreover, adhesive is used to smooth the outsides of each carbody and between the outersurfaces of carbody and window. As a result, aerodynamic noises inside and outside the train and energy consumption are considerably reduced.

Maglev trains will be increasingly use in the future, and the use of adhesives will expand due to the demand of reducing weight and energy consumption. In this chapter, the cases in Japan are mainly explained. World-wide cases are shown in Sect. 4.

---

## 47.1 Introduction

Railways have progressed with three important missions such as high speed, safety, and mass transportation. In particular, a high speed rail system called “Shinkansen,” which means new railway trunk line, has been developed in Japan over the last four decades and has significantly contributed to the development of Japan. Nowadays, the network is prolonged to many subsidiary regions including Hokkaido island through an undersea tunnel even though it is far from the main island of Japan.

In addition, Chuo Shinkansen as a detour of Tokaido Shinkansen that utilizes the Superconducting Maglev will be constructed (Central Japan Railway 2009a).

Rolling stock, which means railcars of broad sense, consumes the smallest energy per person-distance among all the transportation systems. It is about half that of buses and one-sixth of that of cars (Kamiura et al. 2000). In addition, since the power source is mainly electric, the consumption of fossil fuel by rail systems is relatively small. Therefore, we might say that trains are the most environmentally friendly transportation system.

Recently, high speed, passenger comfort, safety, and being environmentally friendly are indispensable for railway systems, and they lead to the importance of weight saving, high strength, high rigidity, noise insulation, vibration damping, thermal insulation, incombustibility, and recyclability. In addition, as the service life and model-change intervals of railcars are shortened, the cost reduction has also become an important factor (Miyamoto 1998). To meet such vast demands, introducing multimaterial structures, in which different materials are joined together and used respecting their own characteristics, is a good solution. The most promising method to join the multimaterial structures of trains is adhesion.

---

## 47.2 Adhesive Bonding Application for Current Rolling Stock

### 47.2.1 Railcar Structures and Their Fabrication

The main structure of railcars is called the “body structure.” It consists of six panels: side constructions, roof construction, end constructions, and an underframe. Stainless steel and aluminum alloy are increasingly used instead of carbon steel for weight

reduction and easy maintenance as the main structure. They are mainly fabricated by welding. By eliminating the thickness increment for corrosion, stainless steel body structure can be lighter than carbon steel body.

For stainless steel body structures, panels are joined using spot welding on a frame joined by welding. Figure 1 shows an example of the body structure of 205 series electric railcar for commuting made of stainless steel (Matsuzawa 1986). As shown in this figure, corrugated stainless steel plate are spot welded on an underframe.

Aluminum alloy cars are fabricated with another method. Large-scale extrusions are used in order to reduce the total length of welding and they are joined by metal inert gas (MIG) or laser welding technique. For instance, E2 series and 700 series Shinkansen cars have a double-skin structure consisting of large-scale aluminum hollow extrusions welded continuously along the longitudinal direction, as shown in Fig. 2 (Abiko and Kobayashi 1998). This method can use automatic processes because there are very few columns or beams and that contributes greatly for cost reduction. Recently, another novel method called Friction Stir Welding, whose thermal input to joints is smaller than the conventional welding methods, has been gradually adopted for new types of aluminum cars instead of MIG welding in order to reduce the thermal deformation and enhance the fabrication accuracy.

In the body structures, modules such as heat insulating materials, floor deck, floor covering (made of non-rigid polyvinyl chloride (PVC), polyolefin, or rubber), inside panels (made of decorated aluminum sheet with melamine resin, aluminum panels pasted non-rigid PVC film, or fiber reinforced plastics (FRP)), windows (made of glass or polycarbonate), interior parts such as seats, lighting equipments, air conditioning equipments, and wiring and piping are equipped. In addition, hard wiring

**Fig. 1** Body structure of 205 series electric railcar for commuting made of stainless steel (Matsuzawa 1986)

**Fig. 2** Body structure of 700 series Shinkansen made of large-scale aluminum hollow extrusions (Abiko and Kobayashi 1998)

and heavy equipments such as transformers or compressors are placed under the floor, that is, the complete sequence of rolling stock fabrication.

### 47.2.2 Application of Adhesives in Rolling Stock

In current rolling stock, adhesives are mainly utilized to join interior equipments. Table 1 summarizes typical adhesive applications for rolling stock use (Suzuki 2006, 2009). Figure 3 shows the share ratio of adhesive types and purposes in the cases of suburban electric cars and Shinkansen cars (Suzuki 2006, 2009).

The main applications of adhesives are:

#### 1. Ceiling board and air ducts

The ceiling board of cars has a sandwich structure consisting of decorated aluminum surface plates with melamine and incombustible lightweight board cores bonded with two part epoxy adhesives, as shown in Fig. 4 (Suzuki 2007). The space between the ceiling board and the roof sheet is used as air conditioner ducts in the case of electric railcar for commuting, as shown in Fig. 5 (Suzuki 2007).

#### 2. Partition panel

The partition of Shinkansen cars has a sandwich structure made of similar materials as the ceiling mentioned above. The bonding of the sandwich panels is performed with two part epoxy adhesives too.

**Fig. 3** Share ratio of adhesive types and purposes for suburban electric car and Shinkansen car (Suzuki 2006, 2009)

- 109 3. Ceiling of decks and inspection lid
- 110 The ceiling of decks and inspection lid for Shinkansen and limited express cars
- 111 are made of aluminum corrugated panels (Fig. 6) bonded with an epoxy adhesive
- 112 (Sugano 1992). Limited express is a special train faster than ordinary expresses in
- 113 Japan.
- 114 4. Heat insulating material
- 115 Heat insulating material (thickness:30–50 mm) is usually installed between
- 116 painted side plates and roof sheets because the temperature of the outside plates
- 117 can rise up to 80 °C and drop below –30 °C. Typical materials for heat insulating
- 118 are oxidized acrylic fibers or carbon fibers. They are bonded on the back of
- 119 outside plates with heat resistant nitrile rubber adhesives. In some cases, 20-mm-
- 120 thick heat insulating material is bonded on the back of decorated inside walls.

**Fig. 4** Sandwich structure for ceiling and duct board (Suzuki 2007)

**Fig. 5** Air duct between the ceiling board and the roof board (commuting electric car) (Suzuki 2007)

**Fig. 6** Sandwich panel for door deck ceiling and inspection lid (Sugano 1992)

5. Inside wall decorating sheets

Inside walls, which are made of aluminum sheets decorated with melamine resin or non-rigid PVC sheets, are joined to the frame using adhesives or screws. In almost all cases, a spacing plate made of flame retardant hardboard or rigid PVC is inserted between the inside walls and the frames to adjust their flatness and to prevent generation of creaky noise. The spacing plate is bonded on frames and the back of walls with nitrile rubber adhesives.

Decorated aluminum sheets with PVC are used for Shinkansen and limited express cars. Aluminum sheets are joined to the frame using adhesives or screws, and a primer is applied on the surface. Nonrigid PVC sheets having a pressure-sensitive adhesive layer are bonded on the surface.

6. Floor plate and floor covering

Typical floor structures of cars are shown in Fig. 7 (Suzuki 2007). The case of 700 series Shinkansen car is shown in Fig. 7a. A heat insulating material made of oxidized acrylic fibers is installed on the aluminum extrusions. Floor plates of aluminum-aluminum honeycomb sandwich structure bonded with a film type epoxy adhesive are screwed on it. Floor covering made of nonrigid PVC is bonded with a nitrile rubber adhesive.

Floor structures of limited express type, suburban, for commuting, non-governmental railroad, and subway electric railcars are shown in Fig. 7b. In them, floor compound material made of epoxy resin and light weight aggregate

Fig. 7 Typical floor structures of railcars (Suzuki 2007)

is plastered and cured on steel deck, and PVC floor coverings are bonded on the surface of it with nitrile adhesives.

Floor structures of subway electric cars made of aluminum are shown in Fig. 7c. PVC floor coverings are bonded with a two-component polyurethane adhesive on polyurethane-coated floor plate of aluminum hollow extrusions.

#### 7. Cover-all hood

As shown in Fig. 8, N700 series Shinkansen cars adopt cover-all hoods between cars to reduce external noise and running resistance (Central Japan Railway 2009b). They consist of soft elastic materials bonded adhesively and have led to energy savings as well as reduction of noise outside and inside the car.

#### 8. Other items

Door panels have a sandwich structure consisting of aluminum or stainless steel surface plates and aluminum or paper honeycomb core bonded with two part epoxy adhesives. On inspection lids, switchboard covers, and seat side panels, decorated aluminum sheets with melamine resin are bonded with second-generation acrylic adhesives (SGAs) to aluminum frames or stiffeners. Figure 9 shows the cross section of a railcar with adhesively bonded parts (Suzuki 2007).

#### 9. Carbon fiber reinforced plastic (CFRP) bogie (Nishimura 2014)

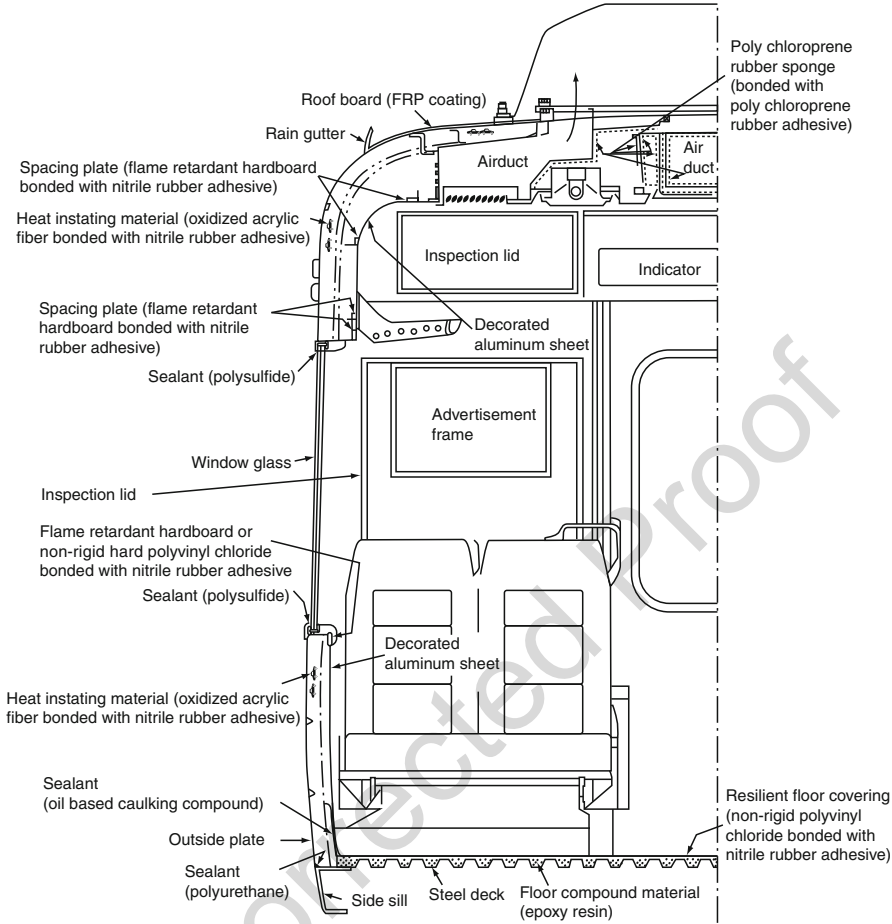

Figure 10 shows a bogie that adopted CFRP leaf springs developed by Kawasaki Heavy Industries Co. (Nishimura 2014). In this bogie, CFRP is adopted as the main structure of the bogie frame, and as shown in Fig. 11, the CFRP frame is provided with a suspension function so that the primary suspension is unnecessary.

This CFRP spring has a three-layer structure of CFRP/GFRP/CFRP using adhesive, and the upper and lower CFRP layers are designed to support the bending load and the intermediate layer GFRP supports the shear load (Nishimura 2014).

Since the CFRP springs have structures that only ride on axles, those have the feature that it is easy to absorb the irregularity of the railway, and it reduces the wheel load loss by half. This bogie has been proved to fulfill all requirements of

**Fig. 8** Cover-all hood used in N700 series Shinkansen car (Central Japan Railway 2009b)

**Fig. 9** Adhesive bonded or sealant filled parts in cross section of a railcar for private railways (Suzuki 2007)

**Fig. 10** Carbon fiber reinforced plastic (CFRP) bogie (Nishimura 2014)

**Fig. 11** CFRP spring which serves two functions of side beam and axial spring (Nishimura 2014)

regulation 49 CFR 213.333 on traveling safety of rolling stock by the Federal Department of Transportation of the United States of America.

The mass per one CFRP spring is about 50 kg, and the weight reduction of about 450 kg is achieved by one bogie (about 900 kg per one car). This bogie was first adopted as a 6000 type train of Kumamotodentetsu Co. in 2014 and was adopted as a 7200 series suburban type DC train in Shikoku Railway Company in 2016.

### 47.2.3 Use of Sealants

Sealants are widely used in railcar structures. Sealants can protect the structure and equipment from corrosion, increase the service life, and keep the airtightness of railcars in air-conditioning. For high-speed trains such as Shinkansen, airtightness is important because the outer pressure of the trains varies when they enter or exit from a tunnel. The same phenomenon can also occur when trains cross each other. In these cases, airtightness can keep passengers comfortable.

Table 2 shows examples of sealant application for railcar structures (Suzuki 2007). Figure 12 also shows some sealant applications (Japan Association of Rolling Stock 2005, 2006). Figure 13 shows the ratio of sealant types used in the structures of stainless cars for private railway and Shinkansen (Suzuki 2007). In Japan, there were a national railway owned by the government and private railways owned by companies previously. The national railway has been privatized and separated to JR companies, so that JRs are not national railways anymore and are included in the category of “private railways” in definition. However, JRs are not called “private railways” due to the convention. The word “private” indicates the railways except JRs and municipal transportations in Japan.

Generally, silicone sealants have good electric insulation, weather resistance, and good bonding strength. However, they also have disadvantages such as getting dirty due to contamination and low paint adhesion. Therefore, silicone sealants are applied to roof, equipments under the floor or around pipeworks. Since modified silicone sealants can be painted, they are applied to exteriors as waterproof or decorative sealants. Polyurethane sealants have a very good weather resistance and are, therefore, used for waterproof purposes. Although polysulfide sealants are two-part type and need primers, their water and weather resistance are good enough to apply to join and seal glass to metals. Nondrying type oil-based caulking compounds have good insulation and environmental resistance, but their bond strength is not high.

t.1 **Table 2** Use of sealants in present rolling stock (Suzuki 2007)

t.2	Position	Applied parts	Sealant
t.3	Body structure	Headlight mount End surroundings Entrance post and outside plate surroundings Outside plate seam (stainless car) Entrance threshold plate Bodyside door pocket Outside plate hem – side sill Headlight – outside plate (aluminum car)	Modified silicone Modified silicone Modified silicone Modified silicone Polyurethane Polyurethane Polyurethane Silicone
t.4	Roof top	Pantograph base Ventilator base Rain gutter (steel) – outside plate Up and down footstep	Polyurethane, silicone Silicone Polyurethane Polyurethane
t.5	Window & door	Side window unit, end window unit, and cab front window unit Train destination indicator window Sliding door window and hinged door window (outside) Sliding door window and hinged door window (inside) Polycarbonate window – outside plate (Series 100 Shinkansen passenger’s room)	Polysulfide, modified polysulfide Polysulfide, modified polysulfide Polysulfide, modified polysulfide Polysulfide Polyurethane Silicone

t.8 All the sealants are applied with caulking guns

204 Therefore, they are not suitable for air tight applications, but for equipments under  
205 the floor or around pipeworks. Joining detachable parts is one of the oil-based  
206 caulking compound applications.

207 **47.2.4 Pressure-Sensitive Adhesives**

208 Typical applications of pressure-sensitive adhesives (PSAs) are shown in Table 3  
209 and mentioned before (Suzuki 2007).

**Fig. 12** Sealant application in railcar structures (Japan Association of Rolling Stock 2005, 2006)

1. Bonding Decorating Aluminum Sheets to Spacing Plates  
As mentioned in Sect. 2.2 (5), when decorating aluminum sheets are bonded to spacing plates, double-side-coated PSA tapes are used in some cases. Nitrile rubber adhesives must be applied to the surface of the spacing plate and dried in advance.
2. Aluminum Panels Covered with Nonrigid PVC Film  
As mentioned before, Shinkansen and limited express type electric railcars have aluminum panels covered with nonrigid PVC film bonded with PSA. The panels are made with a press.
3. Name Plates  
Name plates are bonded to the structure using both double-side PSA tapes and rivets.

**Fig. 13** Ratio of sealant types used in the structures of suburban stainless cars and Shinkansen cars (Suzuki 2007)

**Table 3** Use of pressure-sensitive adhesives (PSAs) in present rolling stock (Suzuki 2007)

Position	Adherends	Supply
Decorated wall sheet	Spacing plate (incombustible hardboard, rigid PVC)/decorated aluminum plate Nonrigid polyvinyl chloride film/Al plate	Double-side PSA-coated tape Acrylic PSA(back side)
Name plate	Name plate/Outside skin, inner decorated plate, polyvinyl chloride films having PSA	Double-side PSA-coated tape
Discriminating strip	Color strip (Nonrigid polyvinyl chloride)/outside plate (Al, SUS)	Double-side acrylic PSA-coated tape

Al aluminum, SUS stainless steel, PSA pressure sensitive adhesive

4. Discriminating Strips (color strips)

In stainless cars and aluminum cars, discriminating colored PVC strips, which have PSA on one side, are pasted along the outer surface of their bodies in the longitudinal direction.

**47.3 Application of Adhesives for Prototype Railcars in Japan**

1. CFRP Body Structure

Weight saving is a very important issue, even for trains. Sophisticated lightweight materials have recently been introduced in railcar body structures. Phenol resin-based carbon fiber reinforced plastics (flame resisting CFRP), for instance, have been applied to a prototype structure shown in Fig. 14a (the outside) and (b) (the inside) (Suzuki and Sato 1993). The structure is 6 m in length and was made by Railway Technical Research Institute, Nippon Sharyo, Ltd., and Toray Industries Co., Ltd. in cooperation, using CFRP plates. The structure is made from curved outside CFRP plates and stiffeners as a unit by the pultrusion technique. The

**Fig. 14** A prototype carbon fiber reinforced plastic (CFRP) body structure for high speed trains using panels molded by pultrusion method (Suzuki and Sato 1993)

(a) Outside of CFRP body structure

(b) Inside of CFRP body structure

300-mm-width CFRP panels were joined to aluminum alloy frames with Huckbolts<sup>®</sup> (Alcoa co.) and a two-part room temperature setting epoxy adhesive. According to the results of strength tests and a finite element analysis, the structure has equal strength and stiffness as structures made only of aluminum alloy.

## 2. CFRP Roof Construction

A prototype body construction of Shinkansen was experimentally produced by Tokyu Sharyo Corporation. This had a roof construction consisting of four blocks made of phenol resin-based CFRP, as shown in Fig. 15 (Matsuoka and Aso 1992). Each block had different structures which were compared in terms of strength and weight. Block 1 and 2 had CFRP carlines and purlines crossed in a grid and bonded to a CFRP skin. The frames and skin of block 2 were thicker than those of block 1. In block 3, the structure had a sandwich panel (30 mm thick) of CFRP skins and a polyurethane foam core between carline without purline. Block 4 consisted of only a sandwich structure (50 mm thick) of CFRP skins (1 mm thick) and paper honeycomb core filled with a phenolic foam without frames. The

**Fig. 15** Carbon fiber reinforced plastic (CFRP) roof construction divided into four blocks (Matsuoka and Aso 1992 and Matsuoka 1992)

structure of block 4 was most effective to reduce the weight because ceiling boards and heat insulating materials could be omitted and air ducts were simplified due to adoption of curved sandwich structures.

The aluminum rims were bonded to the edges of each block using a heat setting epoxy adhesive. A double lap joint in which CFRP side was double with 80 mm lap length was used.

The aluminum rims of block were welded to the other of it's and aluminum side and end constructions, as shown in Fig. 16 (Matsuoka 1992). Due to the use of this structure, the weight (4.3 t) of body structure was lighter than its of the present Shinkansen. The stiffness and airtightness of this prototype body structure were satisfied usefulness.

3. Weldbonding Structures (Sasaki 1995)

East Japan Railway Company (JR-East) constructed a prototype train: TRY-Z, which consisted of carbodies of three different type structures. A front car was made of thin-wall aluminum hollow extrusions welded continuously. The other front car had a monocoque sandwich structure in which aluminum honeycomb and plates were brazed. The middle car had a skeleton body structure of aluminum alloy joined by a combined method of spot welding and adhesion by a heat setting adhesive. This method is called "weldbonding."

4. Body Structure for Maglev Trains

Japan Air Lines has developed a type of normal conduction maglev trains called High Speed Surface Transport (HSST), in which several types of sandwich panels were used as shown in Table 4 (Japan Alminium Association 1990).

5. CFRP Bogie Frame

A CFRP bogie frame shown in Fig. 17 was experimentally made by Railway Technical Research Institute. The side beams of the frame have four webs made by dry hand lay-up of carbon prepregs (Wako et al. 1992). The vertical webs had

**Fig. 16**    Joining method of a carbon fiber reinforced plastic (CFRP) roof block to the main structure (Matsuoka and Aso 1992; Matsuoka 1992)

t.1    **Table 4**    Adhesively bonded sandwich structures used in prototype HSST car (Japan Alminium Association 1990)

276    an U shape for a large bonding area. The horizontal webs of flat shape were  
277    bonded on the bonding area of the vertical webs and to the honeycomb cores with  
278    a heat setting adhesive (121 °C). The cross beams of the frame were CFRP pipes  
279    made by filament winding. The tip of the cross beam were inserted to the side  
280    beam and joined with a room temperature setting adhesive.

281    **47.4    Application of Structural Adhesive for Rolling Stock over**

282    **the World**

283    **47.4.1    Britain (Seeds 1984)**

284    **Present Use**

285    A large amount of adhesives is used in the construction of railcars, including solvent-  
286    based, anaerobic, and cyanoacrylate products, but these do not form structural  
287    adhesives. The uses of structural adhesives have been divided into three categories.

**Fig. 17** Carbon fiber reinforced plastic (CFRP) bogie frame fabricated with adhesives (Wako et al. 1992)

### 1. Simple Fastening

In this group, the normal operating stresses are quite low although high loads may occasionally have to be borne. An example of this type is the use of a two-part epoxy adhesive to bond steel kicking-strips to the base of the aluminum sliding door.

### 2. Sandwich Panel Construction

This represents a major use of structural adhesives in the industry, and a wide range of internal trim panels are produced in this way by bonding melamine to plywood or aluminum.

### 3. Structural Bonding

Two particular examples are worth noting. The first is the bonding of steel stiffening strips with acrylic adhesive to the rear surface of glass fiber reinforced plastic (GFRP) window-surround panels to prevent flexing and to provide additional stiffness under impact. The second example is the bonding of aluminum skin and honeycomb structure to make the sliding doors which are situated on the outside of the latest suburban coaches (passenger railcars without power unit).

## Development Work

### 1. Aluminum Ceiling Panel

Figure 18 shows the design of the aluminum ceiling panel intended for use on the latest inter-city coaches (Seeds 1984). The requirement is to fasten the top-hat stiffeners to the upper side of the panel without damaging the epoxy-paint finish on the underside. Two-part separate application acrylic adhesive met the requirements of the joint and a light abrasion plus a solvent wipe gave adequate preparation.

**Fig. 18** Aluminum ceiling panel bonded adhesively (Seeds 1984)

**Fig. 19** Bodyside (filter) door components of Class 58 locomotive (Seeds 1984)

2. Class 58 Locomotive Bodyside Door

The locomotive door is presently made by spot-welding a number of pressed components, as shown in Fig. 19 (Seeds 1984). The use of structural adhesive bonding has several important advantages. The surface finish can be greatly improved by eliminating the spot-weld blemishes; dimension variation in the

components can be absorbed by using a gap-filling adhesive, and therefore a smoother finish could be obtained; and finally, adhesive bonding can provide a faster process for a capital outlay of less than that for spot-welding.

Under impact conditions, joints using this steel bonded with conventional toughened epoxy and acrylic adhesives fail preferentially at the zinc/steel interface, and this leads to an unacceptable impact performance. By testing a wide range of adhesives, it was found that the shear modulus had to be less than 100 MPa to enable the adhesive in the joint to deform sufficiently under impact to prevent the over-stressing of the interface.

As an environmental durability test, measurement of lap-shear strength after exposure to 95% RH at 40 °C was carried out. The only adhesive which met all of the requirements was a two-part acrylic adhesive. That adhesive also had the desired cure characteristics (work life 5 min, de-jig time 30 min).

### 3. Coach Bodyside

The present method for constructing the coach bodyside on suburban railcars uses a spot welding process. The panel consists of 2-mm IZ steel<sup>®</sup> (zinc-coated steel) skin and top-hat section stiffeners, and Fig. 20 shows the panel components arranged horizontally on the spot-welding jig (Seeds 1984).

The advantages of doing this would be two-fold: firstly, the process could be made several times faster for a capital outlay lower than that for the present spot-welding equipment and secondly the resulting surface finish would be considerably better than the spot-welded panels, thereby saving most of the time presently taken to prepare the bodyside for painting.

Adhesive joints should be sufficiently strong and stiff for the structure to operate in 20–40 years. The determination of strength and stiffness requirements has been

**Fig. 20** The arrangement of the bodyside module components of suburban coach on the assembly jig (Seeds 1984)

tackled in two distinct ways: first, by the use of structural models of vehicles (e.g., Finite Element Method) and second, by direct comparison with spot-welds at both the joint and structural level.

Experiments indicate that in shear (the principal stress in the bodyside panel) the adhesive joints can be twice as strong as the equivalent spot-weld joint, but joint stiffness has been shown to be approximately similar.

Using toughened single-part epoxy adhesives which can be cured at 120 °C, prototype equipment, able to produce full-size bonded panels in a 2- to 3-h cycle time, will permit at least a twofold increase in production rate compared with the spot-welding process.

Several full-scale bonded panels have been prepared, and the results have proved successful in demonstrating the capabilities of structural adhesives. Assembly and service trials will be conducted within the next 15 months.

#### 47.4.2 France

Société Nationale des Chemins de fer Français (SNCF) made a full-scale prototype composite structure of Train à Grande Vitesse (TGV) double-decker trains whose maximum speed is 350 km/h (Cléon 1994). It comprises sandwich structures of glass fiber and carbon fiber reinforced epoxy resin skins and honeycomb or foam cores bonded adhesively. A half tube of the structure was integrally formed by a vacuum suction method at 120 °C. A pair of the half tubes was joined together along the longitudinal midlines at the top and bottom using adhesives, as shown in Fig. 21. The weight saving of the structure led to noise reduction, dynamic stress decrease in the lower structure, and energy saving due to the decrease of its distance for acceleration and reduction of speed.

**Fig. 21** Fabrication of Train à Grande Vitesse (TGV) double-decker prototype consisting of composite materials (Cléon 1994)

47.4.3 Germany

German high speed train: Intercity-Express (ICE) has viewing windows and blind windows, whose cross sections are shown in Fig. 22 (Rahn et al. 1991). Since these windows are bonded to the body panel making the outer surfaces of the body smooth, the aerodynamic drag of the train is minimized. The window structure is also effective to improve the airtightness and water vapor impermeability of the car. The window glasses are bonded adhesively into aluminum frames. This method is called “direct glazing.” The complete window units are screwed into the coach body, and the joint between adjacent windows and between window and coach body is plugged with an elastic filling material. This principle has already been applied to the center trailers of the ICE with very good results. The windows were subjected to a long series of fatigue tests in various environmental conditions and passed comfortably.

Such flat surfaces are very effective to reduce the running noise in the ICE train because almost all the noise is only due to aerodynamic noise at speed of 300 km/h.

Fig. 22 Cross section of Intercity-Express (ICE) trailer car windows (Rahn et al. 1991)

#### 47.4.4 Switzerland

In Switzerland, Schindler Waggon AG made a 1:2.5 scaled prototype of train cars shown in Fig. 23 (Romagna et al. 1997). The structure was fabricated by the wet filament winding method of knitted multi-axial glass fabric tape onto rigid foam cores supported by ring-shaped frames that were made by the filament winding method too. Local reinforcements, heat insulating material, wiring and air ducts, frames for door and window openings, and in situ wound ring frame were integrated into the body structure, which had enough strength, stiffness, and surface flatness. Therefore, the structure was advantageous in terms of costs and productivities.

#### 47.4.5 Indonesia

Prototype railcars consisting of multimaterials were fabricated in the Jabotabek project. For instance, the frames were mild steel, the roof construction were painted mild steel sheets, the front end construction was FRP, and the rear end construction and the side construction were stainless steel. The side constructions were bonded to the frames with a two-part room temperature setting epoxy adhesive using positioning jigs. The cars have been in service for already 4 years.

**Fig. 23** Novel construction concept for the filament wound, highly integrated carriage body of passenger coaches (Romagna et al. 1996)

## 47.5 Conclusion

To meet the demands of faster speed, weight saving, noise reduction, cost reducing in terms of production and maintenance, joining methods in train structures are increasingly diversified as well as the materials. Adhesion is a joining method having advantages such as low stress concentration, high stiffness, and large damping, so that the use of adhesion will expand in train applications as research proceeds.

## Abstract

This chapter describes the use of adhesive bonding to assemble structures in the marine industry. The marine environment is extremely aggressive, and this has resulted in the widespread use of fiber-reinforced composite materials. Adhesive

P. Davies (✉)

Materials and Structures Group, Marine Structures Laboratory, Brest Centre, IFREMER,  
(French Ocean Research Institute), Plouzané, France

e-mail: [peter.davies@ifremer.fr](mailto:peter.davies@ifremer.fr)

bonding is a lightweight and corrosion-resistant means of joining these materials. The main emphasis of this chapter will therefore be on the assembly of composites, though some examples of metal bonding will also be discussed. Three industrial applications are used to illustrate the use of adhesive bonding: small pleasure boats, high performance racing yachts, and bonded structures in the offshore industry. Each has specific design requirements, and there is no single marine adhesive suitable for all structures, but the requirement for long-term durability in a seawater environment is common to all these applications.

---

## 48.1 Introduction

The marine industry encompasses a wide range of structures, from small boats to offshore oil platforms. It covers small boatyards, large production line-based boat assembly plants, naval shipyards, and a host of subcontracting companies providing services from design through to offshore platform repair. Many of these use large quantities of adhesives and sealants, and it is not possible to provide a description of all of them. In this chapter, the role of adhesive bonding in the marine industry will be described through three examples of application areas: small pleasure boats, high performance racing yachts, and bonded structures for the offshore oil and gas industry. The materials involved are mostly fiber-reinforced composites, as these are the materials which are most frequently assembled by adhesive bonding in this industry. They range from low cost glass mat or woven roving-reinforced polyester, widely used in pleasure boats, to high performance carbon fiber-reinforced epoxy and honeycomb sandwich for racing yachts.

---

## 48.2 Specific Requirements

In this section, we will first present the particularities of adhesive bonding for this industry. There are a number of specific marine requirements, resulting from regulatory requirements, the way marine structures are assembled, and the environment they meet in service. Thus, when considering adhesive bonding of structures for marine applications, in comparison with other industrial applications, the following points need particular attention:

- Certification
- Manufacturing conditions
- The marine environment

### 48.2.1 Certification

All marine structures require certification by classification societies (Bureau Veritas, Lloyds, Det Norske Veritas (DNV), Germanischer Lloyds, American Bureau of

Shipping (ABS), etc.), so in order to obtain approval, it is necessary to take account of their requirements from the design stage. In addition to extensive recommendations, developed to ensure structural integrity, several of these societies also have requirements for the adhesive materials to be used in assembly. These are intended to ensure conformity with specified requirements, by subjecting test samples to physical, chemical, environmental, or operational stresses in a recognized laboratory. Many adhesive suppliers indicate certification authority approval for marine use in their product data sheets. Table 1 shows typical requirements. It is important to note that these tests are performed on adhesively bonded joints, usually in the form of lap shear specimens, and not bulk adhesives. The approval is therefore specified for particular substrates and includes their surface preparation and the joint manufacturing procedure.

Taking the DNV guidelines (DNV 2009) as an example, the approval procedure is based on the requirements of the DNV guidelines for classification of high speed, light craft, and naval surface craft (DNV 1991). The adhesive supplier indicates a “manufacturer’s specified minimum value” (msmv) for lap shear strength and cleavage strength. Standard tests are then performed to check these and obtain a reference value. The marine durability of approved adhesives is then taken into account by stipulating a percentage of mechanical strength retention after weathering under load. Specimens are weathered under different conditions, as shown in Table 2, and tests are performed on the aged specimens in order to determine property retention.

Here, the weathering condition involves loading according to ASTM D2919 (test method for determining durability of adhesive joints stressed in shear by tensile loading) to a constant stress and weathering according to ASTM D1183 (resistance of adhesives to cyclic laboratory aging conditions). The latter includes a cycle for exterior marine exposure:

**Table 1** Typical requirements for approval of marine adhesives

Tests type	Condition	Requirement
Lap shear testing	Control (room temperature)	Manufacturer’s values achieved
	Elevated temperatures	
	Cold temperatures	
Cleavage peel testing	Control (room temperature)	Manufacturer’s value achieved
	Elevated temperatures	
	Cold temperatures	
Fatigue testing	ASTM D3166	Target value achieved (e.g., 10 <sup>7</sup> cycles)
Immersion tests	Water	Minimum % retention achieved
	Fuel	
Glass transition temperature	ASTM E1356 (calorimetry)	Above minimum value (e.g., 70 °C for military ships)

t.1 **Table 2** Marine durability conditions for adhesive-type approval (DNV 2009)

t.2	Test	Aging condition	Requirement
t.3	Lap shear	Loaded to msmv and weathered (ASTM D1183) 28 days	Mean >90% reference
t.4	ASTM D1002 or D3163	56 days	Mean-2 standard deviations >95% 28-day value
t.5	Cleavage fracture	Loaded to msmv and weathered (ASTM D1183) 28 days	Mean >90% reference
t.6	ASTM D3433	56 days	Mean >95% 28-day value

- 90 – 48 h at 71 °C and <10% humidity
- 91 – 48 h at 23 °C immersed in artificial seawater
- 92 – 8 h at –57 °C, 100% humidity
- 93 – 64 h at 23 °C, immersed in artificial seawater

94 This 7-day cycle is to be repeated four and eight times for the 28- and 56-day  
 95 exposures. Adhesive approval thus requires considerable testing, based on proce-  
 96 dures designed to ensure long-term durability based on accelerated aging. Prediction  
 97 of long-term behavior will be discussed further below.

98 For small boats (up to 24 m long), design and scantling rules have been assembled  
 99 in a recent set of ISO (International Standards Organization) documents. Part 6 of  
 100 this set is entitled “Small Craft-Hull construction and Scantlings – Structural  
 101 arrangements and details” (ISO12215-6 2008) and includes a section on bonding.  
 102 Bonded stiffener, bulkhead, and deck-hull assemblies are considered, Fig. 1.

103 An Annex to this ISO document provides a design criterion for adhesive bonding. In  
 104 order to determine the bonded area, a simplified approach based on shear loading is  
 105 proposed. Shear stresses should be limited to 20% of the nominal bond shear strength,  
 106 i.e., a safety factor of 5. This factor is intended to account for both stress concentrations  
 107 in real joints and the viscoelastic (time and temperature dependent) nature of adhesives.  
 108 Shear data values, to be used if test values are not available, are provided, Table 3.

109 There are few guidelines for the use of adhesively bonded assemblies offshore as  
 110 currently such structures are mainly welded steel. However, UKOOA (United  
 111 Kingdom Offshore Operators Association) proposed a set of guidelines for the use  
 112 of glass-reinforced plastic (GRP) pipework offshore, Part 4 of which includes  
 113 sections on installation and assembly (UKOOA 1994). For adhesively bonded  
 114 assemblies, a quality program is proposed, which requires the recording of key  
 115 values, namely:

- 116 – Temperature and relative humidity
- 117 – Connection identification number
- 118 – Curing temperature and time
- 119 – Signature of pipe fitter and inspector

120 Formal training is required for pipe fitters, and each field bond shall be inspected  
 121 by an approved inspector.

**Fig. 1** Types of bonded marine assembly used in small boats (Figure Bostik)

	Adhesive	Nominal bond shear strength, MPa	Design shear stress in bonded joint, MPa
t.1	Cold-cured epoxy	27	5.4
t.2	Epoxy-type paste	40	8
t.3	Polyester or vinylester resin or paste	15	3

**48.2.2 Manufacturing Conditions**

In this section, various examples of adhesively bonded marine structures will be presented, in order to illustrate the type of joints used in the marine industry and show how they are manufactured.

**Pleasure Boats**

The manufacture of small boats is largely manual, and over 90% of boats smaller than 6 m long are manufactured from GRP. Hand lay-up is the principal fabrication method. However, closed mold techniques such as infusion and resin transfer molding are becoming more popular as legislation on volatile emissions becomes more strict. There are two types of bonded joint of particular importance, internal bulkheads and deck to hull joints. Adhesive bonding is increasingly being used to fix

internal structures, such as bulkheads, to the hull structure, Fig. 2. Adhesive is placed on the hull and the bulkheads are then assembled using locating jigs to maintain them in position. The bulkheads may be plywood or sandwich materials, and the traditional way of fixing them to the hull was by placing strips of fabric impregnated by resin using hand lamination (known as overlamination). This is a time-consuming operation so adhesive bonding is progressively replacing it. Methacrylate adhesives are being used today for this operation as they offer reasonable properties and simple surface preparation. The properties of marine adhesives are described in more detail later in this chapter.

Figure 3 shows an example of a marine plywood bulkhead in a small motorboat. This bulkhead/hull joint was instrumented as part of a study performed to determine the loads seen by adhesive joints in service (Bauer et al. 2004).

**Fig. 2** Placing adhesive before bonding internal motor boat structure (Photo Plexus)

**Fig. 3** Adhesively bonded marine plywood bulkhead in 6 m motor boat

Hull stiffeners may also be either overlaminated or bonded (e.g., Junhou and Sheno [1996](#)). In many small production boats, a multi-stiffener molding is produced, and bonded to the hull in one shot, rather than bonding individual stiffeners. A recent study on stiffeners for military vessels within the EUCLID RTP 3.21 project (McGeorge and Weitzenbock [2004](#)) described the design and fabrication of bonded pultruded sections to stiffen large superstructure panels (Davies et al. [2004](#)). This allowed cost savings compared to the traditional overlaminated assembly method, but infusion of the structure with the stiffeners in a single piece may prove more cost-effective.

A second operation, once the internal structure is in place, is deck to hull assembly, Fig. 4. This joint between deck and hull is critical to the structural integrity of the vessel and may be highly loaded in a motor boat. The sealant properties of flexible adhesives such as polyurethanes are used to provide a water tight bond, which may be 10 mm thick in places. Locating pins are used to align the two parts.

**Fig. 4** Hull to deck assembly using a polyurethane adhesive. (a) Adhesive placement, (b) guide pin to ensure alignment (Photos Sika), (Sika [2009](#))

Adhesive bonding is again used as an alternative to laminating with GRP, as it is faster (and hence cheaper) and more energy absorbent. Few published studies have reported on the mechanical integrity of such assemblies, but a recent study (Diez de Ulzurrun et al. 2007) evaluated different adhesive systems for this type of assembly. Mono-component and bicomponent polyurethanes and methacrylate adhesives, with different joint thicknesses from 2 to 10 mm, were tested between glass-reinforced polyester substrates. The different adhesives showed more or less ductile behavior, and the optimal adhesive changed according to the parameter considered (failure load, strain to failure, load transfer between substrates). This underlines the difficulty in optimizing the performance of such a complex joint even when the joint design is fixed. Gap-filling ability may be as important as mechanical properties in allowing lower dimensional tolerances for the two components. The aesthetic appearance of the finished joint is also very important, and there are various designs which allow the joint to be hidden, such as external profiles or rails, Fig. 5.

For both these applications, bulkhead and deck to hull assemblies, large quantities of adhesive must be applied, so adhesives must be formulated to allow sufficient working time before cure starts. Adhesives are also used in finishing operations. For example, the deck surface in large yachts is made of wooden strips adhesively bonded to the composite molding, Fig. 6. The operation involves the adhesive bonding of wooden strips, often in the form of prefabricated planking with a plywood backing and a higher quality wood surface such as teak, to the clean, primed deck. Waterproof polyurethane adhesives, with good gap-filling properties, are widely used. In a second operation known as deck caulking, the joints between the strips are filled (similar to the traditional caulking of seams between timber planks with tarred rope to waterproof sailing ship hulls). Primers are necessary to ensure a good bond to wood.

Another pleasure boat application is bonding of windows. Bonding of glass or transparent polymer (polycarbonate or acrylic) panels to the vessel superstructure, using flexible, moisture curing polyurethane adhesives, provides a waterproof connection and contributes to structural rigidity (Sika 2009). UV resistance is

**Fig. 5** Finished deck-hull bond on a small motorboat, joint hidden by elastomer profile

**Fig. 6** Deck manufacture (Photos Bostik)

particularly important for this application, and surface preparation is critical. Light abrasion is used followed by cleaning and priming before adhesive application. The adhesive thickness is calculated to minimize shear deformation and depends on the window dimensions. Deformation is the ratio of movement to thickness, so larger windows require thicker bond lines for a given deformation. Below 1 m a minimum thickness of around 3 mm is typical.

### Racing Yachts

For larger racing vessels, the materials are closer to aerospace sandwich materials, with carbon fiber-reinforced epoxy composite skins on honeycomb or foam cores widely used. In these boats, there are two types of adhesive bond. The first is within the sandwich material itself. The sandwich is manufactured by bonding the core to the skins with two layers of adhesive. This may involve multiple curing steps. For example, a first external skin is laid up and cured, the core is then bonded to this with a film adhesive and cured, and finally the second adhesive layer and second inner skin are laid up and cured. The adhesives are generally epoxy films, which wet the honeycomb and form a meniscus, Fig. 7a. This is a delicate operation; the integrity of the facing/core bond is critical to obtaining required sandwich properties. Defects may be introduced, Fig. 7b, and post-bonding nondestructive control is not simple. Some recent papers (Okada and Kortschot 2002; Ural et al. 2003) have examined the influence of interface parameters on mechanical performance. It was shown that resin fillets absorb energy so their size determines interface fracture energy. By controlling the cure conditions, it is possible to optimize this.

The second level of adhesive assembly in this application is at the structural level. Figure 8 shows a 60-ft-long (18 m) racing yacht, for which both bi-component-toughened methacrylate and epoxy paste adhesives are used to assemble the internal honeycomb sandwich structures.

The hulls of an ocean racing multihull are even larger, they may be over 30 m long. In most cases they are produced in two sections, which must then be joined together, Fig. 9. This is a very long bond line and requires great care. The substrates are abraded and degreased before bonding. A combination of adhesive bonding and

**Fig. 7** Sandwich structure. Adhesive film bonding of facing to core. (a) Meniscus on core, (b) X-ray tomography view of defects in adhesive at bonded interface (Davies et al. 2010)

**Fig. 8** Sixty-foot racing yacht (Photo Huntsman)

overlamination is used, and the entire structure is heated with a vacuum applied. For this application a high performance epoxy adhesive paste is used.

Finally, another critical application is in mast structures. In the latest racing multihulls, these may be over 40 m long and are again produced by bonding two

**Fig. 9** Racing trimaran central hull halves during assembly

half shell moldings together, though in this case an autoclave is used when one is available.

For both small boats and racing yachts, the adhesive bond line thickness is rather variable; it is not possible to maintain tight composite tolerances with this type of hand lay-up or oven manufacture, so adhesive thickness can reach several millimeters. This is much thicker than for aerospace structures, produced using film adhesives with carrier fabric in autoclaves, for which a typical bond line thickness is less than 0.2 mm. The consequences of this larger bond line thickness may be significant, resulting in:

- Defects in the adhesive
- Variable cure conditions
- Local stress concentrations

It is not straightforward to quantify the influence of bond line thickness, and the range of thicknesses of interest for marine structures has received less attention than the aerospace range. Published data from a range of different tests tend to suggest a drop in properties of epoxy and methacrylate adhesives (for the particular adhesives and conditions tested) as thickness increases (e.g., Tamblin et al. 2001; Jarry and Shenoï 2006; Davies et al. 2009). However, as tests are not easy to analyze and manufacturing and curing conditions vary between structures, it is not easy to predict the local effects and stress concentrations which will dominate joint performance, so appropriate testing is essential.

### Offshore Structures

There are few applications of adhesive bonding in the offshore industry, but this situation is evolving, and there is considerable potential for new applications. For

example, Cowling (1997) listed seven areas in which adhesive bonding could be used, in order of increasing load-bearing:

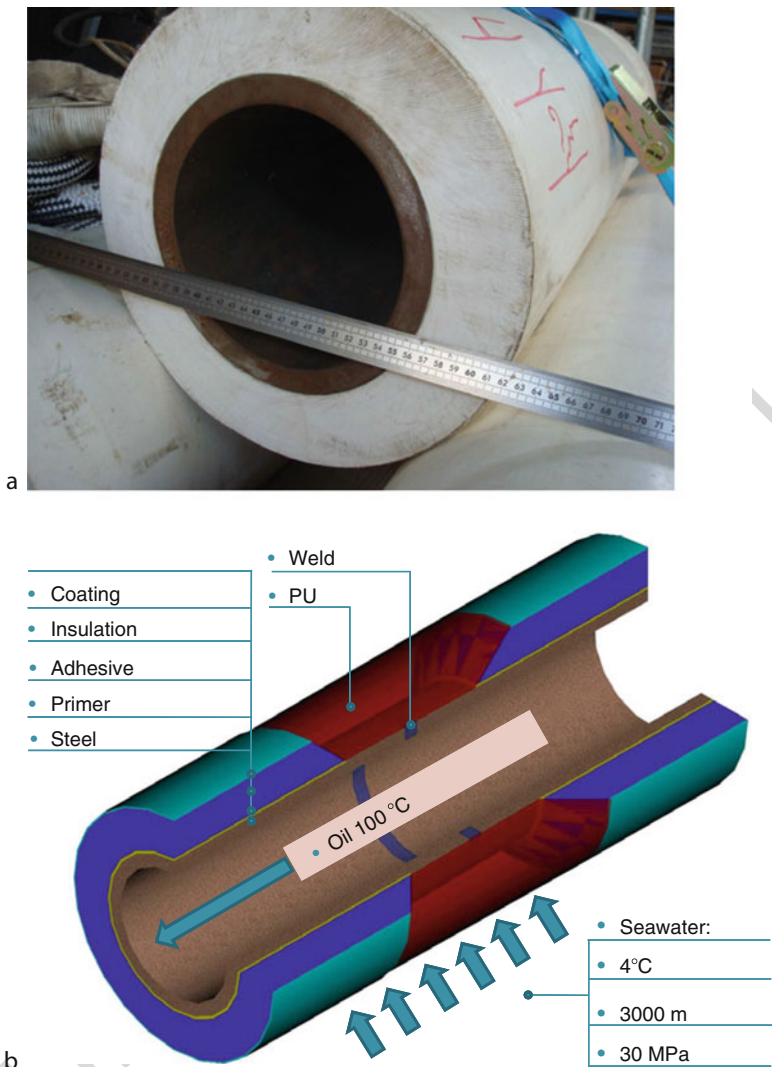

- Attachment of safety and equipment notices
- Small metal pipe support brackets (frequently retrofitted)
- Low pressure piping (for corrosion resistance)
- Stanchions and bracket supports
- Modification of deck plating
- Partition bulkhead support frames
- Plate to frame connections in accommodation and process plant areas

Some adhesive assemblies are currently used on offshore oil platforms to join tube sections in cooling and firewater pipework systems. These are filament wound glass/epoxy composite tubes produced in lengths of a few meters and assembled as required, using flanges or “tulip” joints. Assembly of the latter is shown in Fig. 10; a male tapered end is bonded inside a matched female end with an epoxy adhesive and cured with a heated mat. Such pipes are subjected to both internal pressure and axial loading (Knox et al. 2000).

A second offshore industry application which involves large quantities of adhesive for polymer/metal bonding is in the assembly of thermal insulation to flow lines (Pattee and Kopp 2000; Hansen and Rydin 2002). A thick polymer coating, which may be epoxy, polyurethane, or polypropylene, is chosen for its thermal properties. It is often filled with hollow glass spheres to make a syntactic foam to improve its thermal insulation. This coating is bonded to the steel tube which conveys the oil from the subsea wells to the platform, Fig. 11a. There may be hundreds of meters of such flow lines in a large offshore field, and maintaining the temperature of the fluid is critical if pipeline blockage is to be avoided. The insulation is bonded to the tubes in the factory. The steel is first coated with an FBE (fusion-bonded epoxy) coating. This is a corrosion protection, applied in powder form then heated to melt and cover the surface and cure. The insulation layer is then applied, and the tubes are then transported offshore, typically 12 m in lengths. Assembly of these tubes, into a

**Fig. 10** Assembly of pipework using taper/taper bonded joints (Photo Ameron)

**Fig. 11** (a) Section showing thermal insulation on steel flow line. (b) Field joint, liquid polyurethane

continuous flow line hundreds of meters long, is performed by welding at sea just prior to installation. The region close to the welds is a critical zone. In order to weld this area, there is initially no insulation, so a “field joint” is made after welding. There are various solutions, but filling the gap with a polyurethane is a popular method, Fig. 11b. This is a very demanding application; the material must adhere to the steel tube and to the insulation, polymerize very rapidly, and show good thermal and wet aging properties.

There is also currently interest in adhesives to assemble and repair steel structures on offshore platforms, where welding is not allowed for safety reasons. Robust procedures are needed, capable of ensuring a good bond in a humid environment with a simple surface preparation such as grit blasting (Bordes 2009). Repairs are discussed in a later section.

### 48.2.3 The Marine Environment

The marine environment involves a combination of high relative humidity and/or immersion in seawater, temperatures from  $-30$  to  $70$  °C ( $0$ – $35$  °C in water), and exposure to sunlight. Although the vast majority of seawater has a salinity of between  $3.1\%$  and  $3.8\%$ , seawater is not uniformly saline throughout the world. Where mixing occurs with fresh water at river mouths or near melting glaciers, seawater can be substantially less saline. The pH of seawater is alkaline, usually in the range  $7.5$ – $8.5$ .

Mechanical loads on marine structures can be extremely varied. They may be quasi-static, due to hydrostatic pressure as a result of immersion at constant depth, for example, cyclic, due to waves and currents, or dynamic, due to wind gusts, wave slamming loads, or water hammer in pipework. Finally, assemblies placed in shallow seawater for a few weeks will be colonized by biological fouling, so antifouling paints are widely employed. These must be compatible with the adhesives used.

Polymers may be sensitive to all these environmental factors and particularly to water and temperature. In addition, the influence of different parameters such as mechanical loading and water diffusion is known to be coupled, mechanical loads accelerate water ingress, and water affects the stresses developed in a joint. Adhesive formulation for marine applications is therefore critical, but, as will be discussed in more detail below, it is not yet possible to fully predict long-term marine performance of adhesive assemblies. Appropriate testing is therefore again essential to guarantee satisfactory performance.

## 48.3 Surface Preparation

There is a vast literature on surface preparation for adhesive bonding, and readers will find detailed discussions both elsewhere in this volume and in various reference books (Kinloch 1987; Adams 2005; Weitzenbock 2012). Here only some aspects specific to marine applications and the marine environment will be discussed. Modern boat structures are generally composite, mainly for cost reasons though the ability to produce complex design features and the good corrosion resistance of these materials are also important. Adhesive bonding is similar to the technology used to assemble fibers in a composite, and it has been readily adopted in boatyards. When all-metallic structures are to be assembled, then welding is still the preferred route, but adhesive bonding may be needed in hybrid joints such as those involving steel and composites. For example, in some large military vessels such as the French La Fayette-class frigates, composite superstructures are attached to metallic hulls

323 (LeLan et al. 1992; Mouritz et al. 2001; Boyd et al. 2004). Such joints require care to  
324 avoid corrosion, and surface preparation is critical (Cao and Grenestedt 2004).

### 325 48.3.1 Composite Substrates

326 Polymer matrix composite surface preparation before adhesive bonding consists of  
327 between two and five steps

- 328 (i) Cleaning/degreasing
- 329 (ii) Surface abrasion
- 330 (iii) Application of a surface activator
- 331 (iv) Application of a primer
- 332 (v) Application of the adhesive

333 In most cases in boatyards, only steps (ii) and (v) are used, but for many marine  
334 applications, “peel plies” are used to protect the surface of molded parts before  
335 bonding. These are fine polyester or nylon fabric layers, which are placed over the  
336 region to be bonded, Fig. 12. The peel ply is peeled off just before the adhesive is  
337 applied, to reveal a clean, rough surface.

338 Unfortunately, in order to remove them easily, peel plies are often coated with  
339 lubricants or other low surface energy products, which can be transferred to the  
340 surface and interfere with the bonding process. It is therefore essential to run  
341 preliminary tests for a new substrate/peel ply/adhesive combination in order to  
342 ensure compatibility. Figure 13 shows an example of results from a study of marine  
343 composites assembled by overlamination with and without peel plies (Davies et al.  
344 2005). The delamination resistance of a continuously laminated 16 woven glass fiber  
345 ply-reinforced polyester composite is compared with that of composites for which  
346 fabrication was stopped after half the layers were molded. One of these was

**Fig. 12** Peel ply (lower)  
during removal from glass  
fiber-reinforced composite  
surface. Scale in millimeters

**Fig. 13** Example of influence of peel ply on delamination resistance of woven glass-reinforced polyester

protected with a peel ply, the other was not. One week later the fabrication was continued, the remaining eight layers were laid up either onto the surface after peel ply removal or onto the unprotected surface. Delamination resistance to propagation of a mid-thickness crack was then measured on DCB (double cantilever beam) specimens. In this case, not using a peel ply provided significantly better results than when a peel ply was used, even though peel plies are sold specifically to allow manufacturers to avoid additional surface preparation. This is one example, in other cases peel plies do fulfill their function, but various problems in the aerospace industry have led to great concern over peel ply surface preparation (Hart-Smith 2002).

In some military boatyards, a sacrificial mat layer is added during manufacture when secondary bonding is required. This can then be removed by grinding, ensuring that a new surface is exposed before bonding.

### 48.3.2 Metallic Substrates

Preparation of metallic surfaces, in most cases steel or aluminum, for bonding generally includes a combination of a mechanical treatment, such as grit blasting, with a chemical cleaning procedure (Hashim 1999). It should be emphasized that the choice of surface preparation in an industrial application may be governed by practical considerations (availability of equipment used for other operations such as painting, e.g., or cost) and may not be the optimal choice based on laboratory tests. A recent study suggests that the limiting factor in steel bonding on military vessels may be the strength of the anticorrosion primer paint which is used to coat the steel substrates (Speth et al. 2010).

It is well known that aluminum alloys require special treatments in order to develop good durability, but the toxicity of the favored chromic acid anodization has led to development of alternative treatments (Armstrong 1997; Critchlow et al. 2006). Figure 14 shows a schematic set of results which illustrate the influence of this type of preparation. Short-term strength is similar with and without a chemical treatment, but long-term durability is seriously affected if the treatment is not

**Fig. 14** Schematic illustration of the influence of surface preparation on aluminum single-lap shear bond durability in water, monocomposant epoxy adhesive

performed. Titanium alloys are also sometimes used in critical marine applications, and Golaz et al. (2013) showed that a combined surface treatment of sanding, degreasing, and chemical etching showed the best durability in salt water.

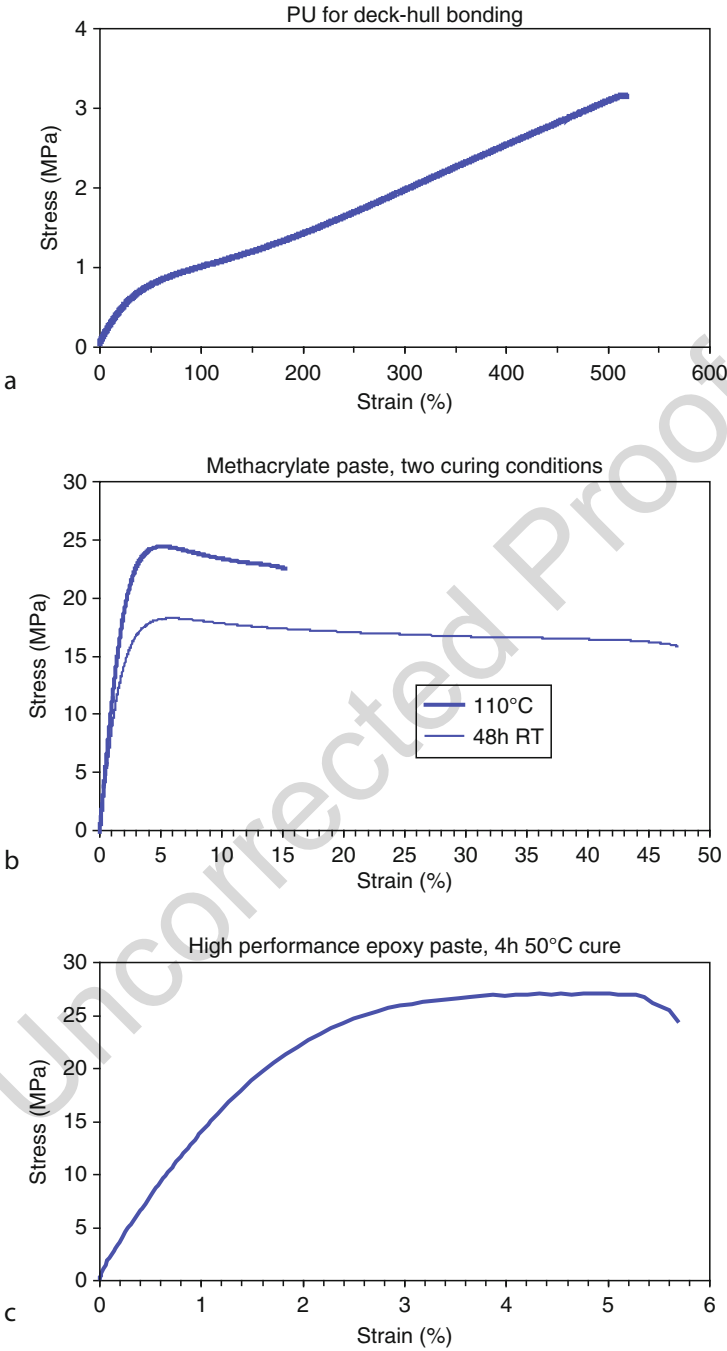

## 48.4 Mechanical Behavior

The mechanical behavior of adhesively bonded composite joints depends on the type of adhesive, the properties of the substrates, particularly in the through-thickness direction, and the care taken to guarantee the interface between the two.

### 48.4.1 Type of Adhesive

The reader will have noted from the discussion of applications above that there are three types of adhesive widely used in the marine industry. These are polyurethanes (PU), methacrylates (MA), and epoxies (EP). Each generic type includes a very large range of grades, with their advantages and disadvantages, and there is some overlap between them. Figure 15 shows examples of the tensile stress-strain properties of each. The PU is a room temperature cure low stiffness high ductility grade, of the type widely used for composite pleasure boat deck-hull assembly. The methacrylate is an intermediate solution, again with a room temperature cure. The epoxy system is a two-component paste adhesive, a high performance structural adhesive widely used in marine applications, cured for 4 h at 50 °C.

There are clearly very significant differences between these products, in terms of stiffness, strength, and ductility. Each is formulated for a specific type of assembly. As noted above, the mechanical behavior is only one element to be considered in

**Fig. 15** Typical marine adhesive tensile stress-strain plots, (a) PU, (b) methacrylate (48 h room temperature and 24 h RT then 2 h 110 °C curing), (c) epoxy (12 h RT, 4 h 50 °C cure)

material choice. For a boatbuilder, gap filling or sufficient viscosity to allow bonding onto vertical surfaces may be as or more important, while for an offshore flow line thermal properties may be critical. In addition to a range of “standard” commercial products, adhesive suppliers will therefore formulate special products designed specifically for an end user’s requirements.

#### 48.4.2 Substrates

If the adhesive is correctly chosen and a suitable surface preparation has been applied, then the resulting joint strength is limited by the through-thickness properties of the composite substrate. The majority of the GRP used for small boats is based on unsaturated polyester resins reinforced by woven glass and/or chopped strand mat. The weakest link tends to be the glass mat reinforced layer. The fracture energy of this layer may be significantly lower than that of a woven fiber-reinforced composite, so there is no point in applying very high performance adhesives to assemble these materials. This is illustrated by Fig. 16 below, which shows the fracture surface of an adhesively bonded marine composite assembly involving an epoxy adhesive and two glass rovimat (alternate layers of woven roving and random glass mat) reinforced vinylester substrates. Failure under mode I (opening) loading occurs by crack propagation in the mat layer.

#### 48.4.3 Interface

There are many factors influencing the mechanical strength of an adhesive/composite interface in a marine structure. The tests available to characterize such interfaces are relatively limited, and few studies have addressed this specific problem. Wedge tests can provide information, and a test originally proposed by Boeing (ASTM

**Fig. 16** Fracture surfaces of joint after crack propagation under mode I (opening) loading. *Upper* substrate shows mat over woven composite, *lower* substrate shows mat over epoxy adhesive. Starter crack (film insert) at *right* of photo

D3762) is often used to evaluate qualitatively the influence of environments on interface behavior in metal assemblies (Popineau and Shanahan 2006; Adams et al. 2009). This involves pushing a wedge between two adhesively bonded metallic adherends and measuring the influence of the environment on crack propagation in the stressed specimen.

---

## 48.5 Durability in a Marine Environment

### 48.5.1 Degradation Mechanisms

The entry of water into an adhesive will affect its physical and mechanical properties. Changes may be reversible (swelling, plasticization) or permanent (leaching out of additives or even hydrolysis involving chain breakage). The kinetics of these changes will depend on the exact adhesive formulation and on the environmental conditions, particularly temperature. While it is not possible today to predict with accuracy the extent of degradation of adhesives, there is much empirical data available on mechanical properties. This is a subject which has been studied extensively (see, e.g., Kinloch 1983; Bowditch 1996; Xiao and Shanahan 1997), but as there are many parameters needed to characterize an assembly completely, it is not a simple task to apply data from one to another. The very large number of adhesives on the market does not simplify this task; a major adhesive supplier may have a dozen standards in their marine catalogues, plus many more “special” formulations.

One of the conclusions of an HSE (UK Health and Safety Executive) report on the use of adhesive bonding in the offshore industry published in 1997 was that “long term durability under severe service conditions is uncertain due to a shortage of design data at present” (Cowling 1997). There has been work to remedy this since then, but for many potential users, this is still one of the reasons invoked to avoid adhesive bonding. It is important to underline certain points which put this problem in perspective. First, water ingress into a well-bonded joint is not instantaneous. A recent study (Bordes 2009) on diffusion into a 1.5-mm-thick fully immersed bulk epoxy adhesives in natural seawater at 20 °C indicated that even in this case, which is much more severe than the case of a joint between metallic adherends, the material was not saturated after 18 months. Using the diffusion rates for bulk adhesives, it is possible to estimate the time necessary to saturate even a small adhesively bonded steel joint, and this may take several years, particularly for an underwater assembly in water at 10–20 °C.

Second, the initial effect of water is very often to plasticize the adhesive, causing stiffness to drop but strain to failure to increase, Fig. 17. Subsequent degradation (after 7.5 months in this case) results in lower strain to failure.

Adhesives are designed to work in shear, and under shear loads, the strain to failure of modern structural adhesives can be very large (Cognard et al. 2005). This means that the influence of stress concentrations at joint edges may be reduced by water, though this effect must be considered relative to the local adhesive strength which may also be reduced. This initial effect is reversible, and subsequent drying

**Fig. 17** Influence of water on adhesive tensile properties, epoxy 1 h 80 °C cure

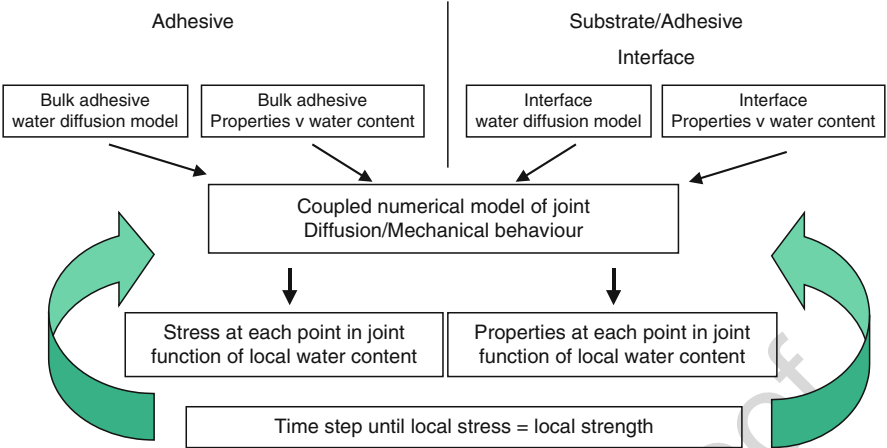

will enable initial properties to be recovered. Nevertheless, after long periods of immersion, permanent damage of the adhesive may occur, and accelerated testing is needed to establish when this will start.

Third, bonded areas may be very large, plates 250 mm square were studied in a recent offshore project, and even after several years in service, only a small edge region will be affected by water ingress. Thus, in practice, the main concern is not usually the adhesive itself but the adhesive/substrate region, which may provide a privileged path for water entry and debonding. Provided the integrity of this interface is ensured by an appropriate surface treatment and primer, then long-term durability can be achieved (Sargent 2005).

Finally, it should be noted that failures of adhesive joints in service are rare if recommended surface preparation and curing procedures have been followed.

## 48.5.2 Predicting Marine Aging Effects

With the rapid increase in numerical computing power, there have been attempts to formalize the different environmental contributions in order to provide a procedure to predict assembly durability (Crocombe 1997; Loh et al. 2002; Bordes et al. 2009). Figure 18 shows a simple scheme. This is based on an initial identification of diffusion coefficients and mechanical parameters. The relationships between water content and properties such as tensile modulus, tensile strength, and interfacial fracture energy are then established. A coupled numerical model for the joint of interest is then constructed. This allows local water content to be defined and resulting changes in adhesive and interface properties to be predicted. At present, there are various factors which prevent this rather simplified approach from providing accurate lifetime predictions, notably the viscoelastic nature of most adhesives, the difficulty in defining reliable tests to characterize interface strength, and the need to include the role of substrate corrosion. Nevertheless, it is probable that in the medium-term future, such approaches will provide a more rigorous basis to guarantee long-term performance of adhesive joints.

**Fig. 18** Simplified representation of a tool to predict the lifetime of an adhesively bonded marine assembly

**Fig. 19** Marine aging of test samples. (a) Laboratory seawater aging test facility, and (b) removal of samples by divers after aging in tidal zone at sea

### 48.5.3 Testing to Simulate the Marine Environment

Given the difficulties in predicting long-term behavior, today most estimations of durability are based on aging tests. This is reflected in the marine adhesive-type approval tests described previously, which specify a percentage strength retention after short accelerated aging tests. Figure 19 shows facilities for seawater immersion testing. In the laboratory, Fig. 19a, this consists of a set of 60 l seawater tanks maintained at different temperatures (up to 90 °C). Natural seawater is used, pumped from the sea, and renewed continuously. This is essential, as many polymers release additives during aging which can rapidly change the composition of the water in closed aging tanks and affect the degradation kinetics. Tests at elevated temperatures are used to accelerate the degradation mechanisms; an Arrhenius plot is then used to

extrapolate to longer times at lower immersion temperatures. This is a very pragmatic approach, and interpretation of the results requires some caution. Adhesives are complex polymer formulations, and raising temperature may affect certain additives disproportionately. For this reason, longer tests are also performed at sea, Fig. 19b, so that the validity of extrapolations can be checked by tests under more realistic conditions.

## 48.6 Quality Control

Quality control of adhesively bonded joints is complex. There are two issues. First, is it possible to detect the presence or absence of adhesive, and second, if the adhesive is present, will it transmit loads between the two substrates? Detecting the absence of adhesive in a joint is possible using techniques such as tapping, frequently used in boatyards, or ultrasonic C-scan. The latter can detect areas without adhesive even when 10-mm-thick steel plates are bonded. Determining whether the adhesive will fulfill its function of transferring load between the substrates is more difficult and requires some form of mechanical loading to be applied. Thus, proof loading cycles are commonly applied to test pipework systems. A complementary approach advocated in the 1997 Health and Safety Executive (HSE) report was that as inspection of adhesively bonded connections is inherently difficult, quality assurance should be built into the bonding process and post-bonding coupon testing (Cowling 1997). Thus, operator certification may be required by certification societies for critical joints. In recent years there has been some progress in instrumentation of bond lines, and this may allow in situ monitoring in the future. For example, implanted optical fibers can be used to detect moisture in epoxy adhesives (Karalekas et al. 2009; Mieloszyk and Ostachowicz 2017).

## 48.7 Repair and Recycling

Repair of composite boat structures is routine, and many boatyards have extensive experience (e.g., Biddick 2005). These repairs are usually made by hand lay-up of materials similar to the original materials and generally use scarf or chamfered joints. There is some debate over the scarf angles to use, which can vary from 6:1 up to 16:1 or more (Pfund 2007). The certification societies provide general guidelines and favor at least a 16:1 ratio which requires more material removal, usually by grinding. Germanischer Lloyd provides an expression for minimum scarf ratio (chamfer length  $l_s$ /chamfer thickness  $t_s$ ) (Germanischer Lloyd 2006):

$$\sigma_{\text{mat}}/\tau = (l_s/t_s) \cdot x$$

with  $\sigma_{\text{mat}}$  the material tensile strength,  $\tau$  the allowable shear stress (9 MPa for a shop repair, 7 MPa for a field repair), and  $x$  a factor depending on the type of repair,

1 for hand lay-up and up to 1.15 if vacuum cure is used. Ductile resins (vinylesters or epoxies) with elongation to break of at least 2.5% are recommended.

Composite patches may also be used to repair metallic structures, and recent studies have indicated the potential of such repairs for naval and offshore structures (e.g., Bowditch et al. 2004; Turton et al. 2005). These may be applied using infusion or preimpregnated materials or adhesively bonded and can be applied to repair fatigue cracks and corrosion damage or for reinforcement purposes. Advantages over metallic repair are:

- Avoid hot working
- Conform to complex surface geometry
- Reduced costs
- Rapid application
- Lightweight (easy to transport and handle)

A recent study to investigate composite repair of offshore riser tubes has been described by Alexander and Ochoa (2010). Prefabricated carbon/epoxy half shells were adhesively bonded to steel tubes and proved satisfactory during testing under internal pressure and tensile and flexural loads. There is also considerable interest in composite repair of subsea pipelines, Lieu and Green (2016) provided an overview recently, and an ISO document exists (2013).

Recycling and end-of-life management of marine structures are topical issues. Adhesively bonded joints assembled using thermosetting adhesives are, like welding, not easy to disassemble, and alternative thermoplastic adhesives may become more popular. There are also some bio-sourced adhesives available, but to date their properties, particularly after immersion, are considerably lower than those of conventional adhesives. It should be noted that the quantities of adhesives used in marine structures such as boats are significantly smaller than the amounts of composites, and the recycling of the latter is currently the main priority.

---

## 48.8 Conclusions

Adhesive bonding is very widely employed to assemble and repair marine structures. New markets are appearing, the renewable marine energy sector (offshore wind, wave, and tidal energy) will require adhesives for structures such as turbine blades, and long-term durability in a marine environment will remain a key issue for these applications. This chapter has presented some current applications, and it is clear that considerable experience is already available to guide future projects. Certification societies are making efforts to provide a framework for marine use of adhesives which is closer to that of the aircraft industry, and this should result in improved joint quality. In parallel, several academic groups have recognized the importance of durability and are developing numerical tools to aid the designer and end user in predicting the lifetime of adhesive joints.

**Fig. 20** Data recorder adhesively bonded to Galapagos sea lion (Photo Huntsman) using modified epoxy adhesive

Challenges remain, and very specific marine bonding problems have been addressed. Figure 20 shows one example, in which time-depth recorders are attached to Galapagos sea lions in order to study their behavior. The adhesive has to withstand the heavy impact of 100 kg sea lions rolling, scratching, hitting rocks, as well as the salt water of the Pacific Ocean and the strong sun radiation. A modified epoxy adhesive was used successfully, enabling unique results to be obtained. These indicated that these sea lions dive to more than 500 m depths.

must fulfill criteria other than simple wall and brick building. Topics like freedom in design, energy efficiency, repair, and lightweight construction are continuously addressed. In particular, bonding of dissimilar materials requires the improvement of joining technologies, and thus adhesion technology is equally evolving.

This chapter aims to introduce applications of adhesive bonding in civil construction. For this purpose, four fields of application (concrete construction, glass construction, timber construction, and steel construction) are considered with regard to already established and novel joining techniques. Particularities of the individual substrate materials are described as well as commonly used and suitable adhesive systems and the specific requirements of their applications.

---

## 49.1 Introduction

Today's engineers are faced with a wide variety of constructive and design-related tasks which require a great understanding of joining processes and material combinations.

Adhesive bonding has been employed for centuries. However, modern adhesive technology in civil construction is still a niche application, especially compared to other industrial sectors like the automotive industry. The field of civil construction is still cautious with this innovative joining technique and also has been historically very conservative.

One reason for this fact may be found in the Codex Hammurabi, a comprehensive set of Babylonian rules, which dates back to about 1750 BC. In that time, the builder had to compensate the owner's loss in case of damage. He was even sentenced to death if the owner of the house was killed because of a collapse of the building.

Above all, the main reason for the restrained use is the high demands on the predictability of the long-term behavior of the connections. Compared to other bonding methods such as welding or screwing, predictions for adhesive joints are more complex. Moreover, the manufacturing of adhesive bonds is a sensitive process, whereby the control on the construction site is just possible to a very limited extent. Thus, merely technically mature and proven methods are used, and new techniques must first prove their reliability.

However, adhesives have proven their efficiency and among others are established nowadays in the fastening and strengthening technology with concrete as substrate, in structural glazing, in timber construction, and to a small extent in steel construction.

---

## 49.2 Concrete Construction

### 49.2.1 Introduction

The development of concrete and mortar dates back to around 6500 BC when the Nabataeans used concrete-like materials in northern Jordan. The Babylonians used pitch or lime as mortar for constructions of baked bricks.

A forerunner to modern concrete and mortar is *opus caementicium* (Roman concrete). The Romans used volcanic ash (natural pozzolans) as a component of the mixture, which enabled underwater curing, and, more importantly, made long-lasting structures possible, which stand the test of time (e.g., the dome of the Pantheon in Rome, completed around AD 125).

Actually, any mortar or concrete, as it is used today, is an adhesive. Binders that exclusively harden under air are referred to as non-hydraulic, whereas lime and especially cement are hydraulic binders since these require water for their setting process.

Concrete is widely used in civil construction for buildings, bridges, road surfaces, and further components which have to meet the demands of long-term durability in combination with high compressive strength. The versatility of concrete is based upon the fact that both a prefabrication of cast components as well as direct processing on the construction site is possible. As long as prefabricated parts are utilized, quality control can be integrated into the general production process of standard industrial fabrication. However, the manufacturing of security-relevant parts or bonds directly on construction site is difficult to supervise, and hence high requirements regarding quality assurance and strict guidelines are necessary. Nevertheless, adhesive bonding of structures to concrete components is successfully carried out in the fields of anchoring systems and strengthening.

## 49.2.2 Concrete as Substrate Material for Adhesive Bonding

Concrete is one of the most durable materials and is commonly employed in civil engineering. However, the adhesion between newly hardened and old concrete is very poor. It can be improved though by surface roughening and latex emulsions or epoxy resins serving as an intermediate layer on which the repair mortar or concrete is applied (Mailvaganam 1997).

In general, special requirements must be placed on adhesives when bonding to concrete. A sufficient adhesion of epoxy resins to dry concrete is achieved if the surface is clean and slightly roughened, e.g., by means of sandblasting or a needle hammer, so that the cement skin is removed and the grain is partially exposed. For economic reasons, bonding cannot be limited to dry summer weather, and thus adhesives must also stick to wet concrete. Furthermore, the curing has to be ensured even in cold, damp weather. Due to the concrete's porosity and its vulnerable surface, reagents such as acids, salts, and water may harm the concrete or the bond. The influence of the corrosive media is especially severe when alternating cycles of wetting and drying or freezing and thawing occur. Coatings (based on silicones, epoxy resins, urethanes, bitumes, oil-based paints, acrylics, styrene butadienes, chlorinated rubber, vinylesters, polyesters, or linseed oil) can decrease the extent of deterioration because of a reduced water absorption and chloride ion penetration.

The alkalinity ( $\text{pH} = 12$ ) of concrete may also pose a problem for the adhesive's polymeric structure and the long-term behavior of the adhesion. If a quick repair of

components is required, acrylates prove beneficial instead of epoxy resins since the curing of the former is fast and even readily achieved at low temperatures. Nevertheless, the alkaline concrete demands the use of special acrylic systems that are insensitive to alkaline hydrolysis.

It is advisable to verify the properties of the adhesive bond by means of preliminary tests that are suited to the specific application and its requirements (Zilch and Mühlbauer 2007; Krelaus et al. 2008).

### 49.2.3 Applications

#### Tiles and Floors

##### Tiles

Besides the use of reactive resins or dispersion adhesives, in 90% of the respective applications, ceramic tiles are laid with *cement-based systems*. These are provided as dry mortar blends; thus, they have to be mixed with water and other liquid additives prior to application to ensure hydraulic setting. The final product is water resistant. Cement-based mortars contain cement binder as the main part, quartz sand or powdered limestone as filler, and special additives such as defoamers, wetting agents, and thickeners.

Although these mortars harden rapidly, in most cases the process is finished not before 24 h (Grimm 2013). In recent years, fast-curing adhesive mortars based on special cements have been developed to take the need for short-term construction into account. Tiles fastened by these adhesive mortars may already be grouted just hours after the laying of the tiles (Geiß 2006).

For the application of mortars on “moving” grounds, special blends have been developed which contain polymeric components, e.g., ethylene-vinyl acetate copolymer, or waterborne latex dispersions that are admixed to the basic mortar. Besides the increase of adhesion, these mortars dampen vibrations and take up stresses more effectively than systems without elastic inclusions.

*Reaction resin tile adhesives* set by a chemical curing process and are usually based on polyurethane or epoxy. The filled resin and the unfilled curing agent are mixed at the construction site prior to use. Since these adhesives are highly developed products, they are used far more often in professional construction than in do-it-yourself applications (Grimm 2013). For instance, they are utilized in highly loaded areas, for industrial flooring, for wet or otherwise chemically contaminated outdoor terraces, and for tiling cantilevered balconies which are submitted to high-temperature changes (Geiß 2006).

*Dispersion tile adhesives* are based on finely dispersed polymeric particles in water (e.g., styrene acrylate dispersions). Therefore, they can be directly applied at the construction site without the need of further mixing or adding other components. Because these systems are set physically by evaporation, hardening takes more time compared to chemically reactive adhesives. Furthermore, these systems are not

suitable for outdoor applications since they are, in most cases, frost sensitive. However, for renovation work, for the installation of skirtings, borders or similar, dispersion-based adhesives are particularly convenient.

## Flooring

For bonding parquet, the following types of adhesives are mainly used:

- Dispersion parquet adhesives
- Solvent-based resin flooring adhesives
- Reactive resin flooring adhesives

Although waterborne dispersions, for instance, on the basis of polyvinyl acetate, are the most environmental friendly adhesives for parquet on the market, their use may be critical because excessive swelling of the timber may lead to parquet distortion. Apart from timber-based floor covers, other materials, e.g., linoleum, rubber, cork, and polyvinyl chloride, are almost exclusively fixed with dispersion-based adhesives.

Solvent-based flooring adhesives possess excellent processing characteristics. The amount of parquet swelling is reduced due to the absence of water. Therefore, despite their relative high concentration of volatile organic compounds (20–25%), they are still the most used systems in the market with a share of approximately 65–70%. Common solvents are acetates, alcohols, or ketones like acetone or mixtures thereof in which a thermoplastic resin like polyvinyl acetate is dissolved. Also, mineral fillers such as chalk are admixed. Furthermore, solvent-based contact adhesives are used predominantly for bonding flooring to shape-giving substrates like stairs or skirting boards because of their higher initial adhesion in processing (Geiß 2006).

Bright timber like maple and beech which is highly sensible to swelling even requires the application of both water- and solvent-free adhesives, that is, reactive polyurethane and epoxy-based systems.

## Pavement Marking Tapes

Pressure-sensitive adhesives (PSA) are applied for the installation of pavement marking tapes onto the driving surface. A typical tape consists of a waffle-like rubber support layer, equipped with a polyurethane coating and attached ceramic particles. This combination achieves a high flexibility with a good visibility/reflective power and an optimum tire grip (see Fig. 1). The PSA is located on the bottom side of the rubber. For a good adhesion, the application of a primer after a thorough cleaning of the road surface might be necessary depending on the surface type (concrete, asphalt, bitumen). As a function of the field of application, several types of marking tapes are available, e.g., systems that outlive a perennial stress by traffic as well as tapes which are only temporarily used for building site markings (3M 2013, 2016).

**Fig. 1** Schematic structure of a pavement marking tape (Source: tff)

## Fastening Technology

Fastening in the construction industry is often achieved with anchors in masonry or hardened concrete. Besides systems that feature fixation by mechanical interlock (deformation-controlled anchors, torque-controlled anchors, undercut anchors), bonded anchors effectively transmit forces from the body into cracked or non-cracked concrete by a hardened binder (Carroll 2014; Götz et al. 2010).

The binder consists of synthetic resin, cement, or even of a mixture of both. The operating principle of bonded anchors is based on a material closure; the hardened resin fills the gap between the anchor or threaded rod and the borehole wall and transfers external loads.

The bond strength largely depends on the nature and extent of the hole cleanliness (Geiß 2006). Although recently bonded anchors have been developed which require virtually no hole cleaning, systems generally show significantly reduced bond strengths, when a certain amount of drilling dust remains at the borehole wall. Thus, special care must be taken in cleaning the drill hole. This is especially the case when the anchor rod is inserted only by hammering without a turning motion. The latter removes adhered drilling dust from the borehole wall more effectively and ensures a better distribution and inclusion of dust within the mortar or adhesive. For a complete dust removal, most often a sequence of repeated blowing out of the bore dust and cleaning of hole wall with a brush is carried out.

Expansion forces do not occur before prestressing and loading of the anchor. During the setting, no spreading forces are generated. Since bonded anchors create much lower expansion forces as compared to metal expansion anchors, the former are more suitable for components with small thicknesses and fixtures with a low edge distance (Geiß 2006).

To evaluate the expectable structural strength of these systems, a destructive pullout test is commonly performed. However, the long-term behavior is in general not well understood. This clearly shows that the development of *in situ* nondestructive monitoring methods for structural components is of utmost importance (Rizzo et al. 2010).

Chemically bonded anchors are prone to different failure modes (Rizzo et al. 2010):

**Fig. 2** Partly destroyed glass capsule for bonding anchors. The small glass tube contains the curing agent (Source: tff)

- 216 (a) Failure of the anchor material
- 217 (b) Concrete cone failure
- 218 (c) Bond failure of the interphase (anchor/resin or resin/concrete)
- 219 (d) Combination of failure modes (b) and (c)

220 Bonded anchors can be subdivided into four categories (Carroll 2014; Götz et al.  
221 2010):

- 222 • Capsule-type systems
- 223 • Prepacked injection-type systems
- 224 • Post-installed rebar connections
- 225 • Expansion anchors

### 226 Capsule-Type Systems

227 Capsule-type bonded anchors make use of reactive polymeric resins which are  
228 encapsulated in soft-skin walls (plastic foil bags) or glass vials. In these containers,  
229 the resin and curing agents are separated from each other and thus cannot react prior  
230 to cartridge destruction (see Fig. 2).

231 Since styrene-containing resins are classified as hazardous to health and environ-  
232 ment in many countries, styrene-free systems are increasingly available (Geiß 2006).  
233 Most often, the resin is based on vinylester or unsaturated polyester, which is cured  
234 with dibenzoyl peroxide. Additional components are fillers (quartz), catalysts, and  
235 stabilizers.

236 Prepacked capsules ensure an optimal mixing ratio and therefore enable, assum-  
237 ing homogeneous mixing, a thorough curing of the resin. The cartridge size and  
238 hence the amount of resin are adapted to the required borehole diameter and the hole  
239 depth which directly relate to the dimension of the anchor itself. Since the gap  
240 between the anchor rod and the borehole wall has to be filled completely, dimension  
241 tolerances of the drill holes also have to be considered.

242 For fixation, the glass vial or foil bag is inserted into the borehole. Subsequently,  
243 the reservoir is destroyed by the anchor stud. A chisel at the stud end can support  
244 effective mixing of the components. The accomplishable load capacity is generally

lower for systems which make solely use of opening the cartridges by striking without any additional rotatory motion because of insufficient mixing of the components.

Compared to glass cartridges, foil bags have the advantage of a lower damage sensitivity during transport and handling. Furthermore, in overhead applications, foil bags prove beneficial as they remain in the borehole without the need of further fixation.

### **Prepacked Injection-Type Systems**

Injection systems are provided either in cartridges or as bulk material. Bulk material components have to be properly mixed in stoichiometric amounts before filling the cavity. In cartridges, resin and hardener are stored in separate chambers that are side by side (shuttle) or coaxial (cartridge inside cartridge) (Carroll 2014). The adhesive is blended in a static mixer prior to injection. The amount of resin injected is dependent on the drill hole depth. After filling, the anchor bar is pushed into the cavity. Leaking resin at the well mouth indicates a complete filling of the drill hole.

Although their curing via a polyaddition generally takes much longer compared to radical polymerization systems, epoxy resins are widely used in civil engineering to anchor both threaded rods and reinforcing bars in hardened concrete. In addition, they are advantageous for larger hole tolerances and anchorage lengths (Geiß 2006). Common applications include bridge widening, structure-mounted signs, luminaries and light poles, concrete repair and rehabilitation, and tunnel finishing. Other adhesives applied are vinylester systems and unsaturated polyesters. The curing cycles of the injected resins are commonly chemically prolonged to ensure sufficient processing times for hole filling and the subsequent setting of the anchor rod.

### **Post-installed Rebar Connection**

Rebars (Carroll 2014) are commonly used for the reinforcement of concrete. Anchors can be divided into two groups: cast-in-place and post-installed. A typical cast-in-place anchor consists of a rebar which is set before the concrete is placed. The rebar may require a protective coating to avoid corrosion and is finally fixed by the hardening of the surrounding concrete.

Instead, a post-installed rebar is set in a borehole filled with resin in order to facilitate the concrete reinforcement. This system features higher limit stress as compared to the cast-in-place anchors and is often used for starter bars.

### **Expansion Anchor**

Concrete is highly prone to cracking. This is due to shrinkage during hardening and because of loading in the tensile zone of the material. As the building component is loaded and unloaded, these cracks open and close (Rizzo et al. 2010). Bonded anchors as described above (e.g., for setting at the bottom side of a dynamically loaded ceiling) are not suitable for load transmission with predominant tensile amplitude in cracked concrete. Thus, expansion anchors have to be applied which generate spreading forces (form closure) by means of cones. The setting of the anchor rod is the same as in conventional bonded anchors (hitting and turning the rod

into a cylindrical hole). Due to a tension load induced into the fastening element, the adhesive bond between the anchor rod and the adhesive partly dissolves and the cones are pushed into the mortar. The resulting expansion forces and therefore the cottering between the mortar shell and the borehole wall are essential for the transition of tensile forces into the ground (Geiß 2006).

## Structural Reinforcement

Nowadays, civil building engineers are increasingly faced with the challenge of strengthening existing buildings and thus ensuring the durability or even increasing it because of altered circumstances. The reasons are (Bergmeister 2001):

- Changing the purpose of the building (e.g., due to higher loads or damage)
- Rebuilding and thus change in the supporting structure
- Reduction of structural safety due to concrete and steel corrosion
- Reduction of bending by a stiffness increase
- Design errors

The so-called surface-bonded reinforcement is a readily available method that strengthens concrete structures quickly, economically, and usually without further intervention in the building (Gao et al. 2004; Ferrier et al. 2001; Oehlers 2001; Wu et al. 2005; Dutta et al. 2001; Meier 1994; Meier and Munger 1995). For this method, steel and carbon fiber-reinforced polymers (CFRP) are commonly applied. Methods of attachment range from solely adhesive bonding to hybrid jointing techniques, e.g., adhesive bonding in combination with bolting.

This external reinforcement increases the flexural stiffness and load-carrying capacity of the previously deficient beams, provided that the attachment method enables a reliable transfer of stress between the concrete surface and the reinforcement element.

Thus, special attention must be paid to the interaction of concrete and adhesive which can only be achieved by clean (oil-free) and dry substrates. Besides wet-chemical methods (degreasing, primer treatment), mechanical methods are widely used for adhesion enhancement. For joining concrete and/or steel, sandblasting and grinding have proven beneficial. These methods effectively remove loose particles and contaminations, that is, oxide layers on metals and the weak top layer of cement stones (laitance) that is generated during the hardening of the fresh concrete (Hollaway 2008). In addition, these methods beneficially modify the surface texture and thus increase the bond strength. Sandblasting is carried out by a transportable sandblasting unit, whereas grinding is often conducted by using special grinding attachments on drilling machines.

The ability to built up adhesion to wet surfaces only plays a subordinate role because the application of the bonded reinforcement is usually done on the underside of the component and is therefore protected from rain. However, reliable curing at high humidity levels and low temperature is a prerequisite for this application. Epoxy resins have proven extremely effective. Furthermore, the process of carbonation and the chloride exposure must not be harmful to a great extent during the lifespan.

### Strengthening by Steel

A large number of techniques currently exist for strengthening of concrete structures and enhancing the flexural strength like external post-tensioning systems or the attachment of plates to the tension site of concrete beams (McKenna and Erki 1994; Shayan et al. 2003).

The latter method was first established in Paris, France, in 1964 where due to a static calculation error, a bridge had to be reinforced. In the late 1960s, engineers at Swiss Laboratories for Materials Testing and Research (EMPA) in cooperation with construction firms began to post-strengthen structures by means of bonded steel plates, based on the work of L'Hermite and Bresson. Comprehensive research effort was also conducted to establish an appropriate design basis. In Germany, similar work was carried out at the University of Braunschweig – Institute of Technology (Meier 1994).

Corrosion at the steel-epoxy interface can adversely affect bond durability with premature failure/collapse being the result (Karbhari et al. 1997; Keller and Gürtler 2006). A high degree of adhesion between steel and concrete is accomplished by compressed air jets or sandblasting to remove rust from the metal to prepare a suitable surface for coatings and bonds. Afterward, the lamellae are coated with a primer for corrosion protection which enhances the long-term efficiency of the strengthening capability (Brunner 1996; Kleist 1998).

Considerable effort has been conducted to understand the method of surface-bonded reinforcements, and engineers have also reported on the results of field implementation ranging from use in apartments to that in arched and prestressed bridge decks. Although extensively used in Europe for over a decade, this method suffers from a number of disadvantages ranging from difficulty in placement to concerns related to overall durability. Steel plates are heavy and hence hard to handle during erection and may be limited in length due to weight and size restrictions where utility lines and other obstructions exist. At the minimum, jacks, extensive scaffolding, and winches or cranes are needed for buildup. The length restriction necessitates the use of joints that need special attention since on-site welding is not possible due to the destructive effect of heat from the welding process on the adhesive. In addition, corrosion of the steel plates or at the steel-resin interface still plays a major role despite protective actions like sealings. Due to water seepage through concrete and resin, a reduction in failure load may occur. Furthermore, if the steel is loaded in compression, a detachment of the bonded sheet might occur at or near a cap beam. Beyond that, the steel enhances the overall self-weight of the buildings, and the structure gauge might be affected negatively. Due to the high weight, stripping of the steel plates can be executed not less than 24 h after the joining process.

Therefore, over the past years, strengthening by CFRP evolved which does not feature such drawbacks (Hollaway 2008).

### Strengthening by CFRP

CFRP as externally bonded reinforcement elements are increasingly used in the rehabilitation of deteriorating and deficient concrete structures (Stahlton 2011). The

method was first applied in 1991, when the Ibach Bridge near Lucerne was supported by bonded CFRP strips (Meier and Munger 1995). This technique was also employed at the town hall in Gossau SG and at an office building in Flims, Switzerland. The roof of the garage which had been insufficiently designed showed cracks and had to be rehabilitated. By bonding CFRP plates, the building could be quickly and safely reconditioned.

The strengthening procedure based on CFRP is dependent on the particular purpose and can be divided into four execution methods (Grunewald 2012; Zilch 2013; StoCretec 2016):

- (a) Adhesive bonding of CFRP plates/lamellae onto concrete
- (b) Adhesive bonding of CFRP strips into slots within concrete
- (c) Laminating of carbon fiber layings directly onto concrete
- (d) Pretensioned CFRP lamellae

A CFRP surface preparation may consist of a solvent treatment for removing adhesion-lowering substances, but usually, CFRP plates are sanded prior to their application to ensure sufficient adhesion. Water condensation on the CFRP should be avoided as a durable bond cannot be guaranteed under damp circumstances.

Since the respective composite element is bonded directly onto the concrete substrate, the efficiency of the rehabilitation scheme depends on the combined effect of the entire system with emphasis on the integrity and durability of the bond between CFRP and concrete. Premature debonding or loss of force transfer of the CFRP reinforcement due to degradation of bond strength can result in failure of the strengthened structural component, even at lower load levels than the strengthening can theoretically resist. The performance characteristics of the substrate, CFRP, adhesives, as well as the interfaces are all prone to deterioration by environmental exposure. Hence, there is a need to assess its effect on these materials and on the bond itself.

The use of CFRP techniques does not require closure of traffic lanes or a major disturbance of existing traffic patterns since extensive scaffolding, barriers, and heavy equipment are unnecessary. Strengthening by CFRP can be achieved in very close quarters and in areas where access is limited. This not only increases the ease of retrofit but also results in lower overall systems cost. It must be kept in mind that although the material cost attributed to composites is higher than that of steel, it is the total systems cost, which includes equipment, time, and detour costs, that needs to be considered when comparing the application of both reinforcement materials.

### **Adhesive Bonding of CFRP Plates/Lamellae onto Concrete**

The method of bonding CFRP onto concrete is especially suited for flexural strength enhancement of even concrete or round structures with a large diameter. A crosswise sheet bonding enables a biaxial strengthening (see Fig. 3). In addition, the level of shear force can be increased by application of CFRP angle elements.

**Fig. 3** Ceiling strengthened with CFRP plates (Source: Stahlton AG)

CFRP plates possess a high specific stiffness and strength ratios, outstanding fatigue behavior, and a negligible thermal expansion and are corrosion resistant. Furthermore, in comparison to steel, they are lighter and hence easier to handle. Thus, they can simply be positioned at the concrete substrate on the construction site without the need of extensive scaffolding and jacks. In addition, support is obsolete during the curing process of the epoxy resin since the initial adhesion strength is sufficient for holding the CFRP in position. Special care must be taken to attach the CFRP strips rapidly to the substrate without bulges occurring.

Due to the low rigidity of the lamellae with a thickness of 1–1.5 mm, they are often delivered as coils (Hollaway 2008; StoCretec 2016). The material is supplied in different dimensions and can be easily cut into necessary proportions on the construction site.

### **Adhesive Bonding of CFRP Strips into Slots Within Concrete**

Prior to bonding, slots with a width of 3–6 mm and a depth of 15–30 mm are milled into the concrete substrate. The recess is filled with epoxy resin and the preformed strips are pressed into the mold. Afterward, excessive adhesive is removed (see Fig. 4). The free ends of the rods may require further anchoring (Hollaway 2008).

The method highly increases the load capacity and bending strength of the construction to a high extent. The procedure is especially suited for systems where combined shear forces and moments occur and in areas with high stress gradients. Since the strips line up precisely with the surface level, they are effectively protected against mechanical damage (Mihala 2008). A further benefit is the visual appearance of the strengthening structure. Besides the advantages cited above, the procedure is also suitable for crack width limitation. In general, large cracks diminish the durability of structures. However, injection of reactive resins into cracks is not ideal for components where crack motion due to repetitive strain or variable forces can occur. The integration of glued CFRP into slots is a promising alternative for solving this issue (Meier 1994).

**Fig. 4** Strengthened concrete structure achieved by bonding CFRP strips into slots  
(Source: StoCretec GmbH)

**Fig. 5** Strengthening of a column by a direct laminating approach (Source: StoCretec GmbH)

#### Laminating of Carbon Fiber Layings Directly onto Concrete

Carbon fibers can also be attached on-site using a wet lay-up technique. Because the strengthening effect is dependent on the fiber orientation, the procedure is especially versatile and can easily be adapted to the conditions on the construction site for reinforcing different building structures.

The bonded layings enhance the flexural strength when laminated on flat substrates or result in high transversal forces when applied to the outside of concrete beams (Corradi et al. 2007). The procedure is often utilized for round elements, e.g., supporting pillars (see Fig. 5).

The laminating resin is applied onto the concrete surface; an impregnation of the latter with a primer is optional. A surface treatment is not required (Hollaway 2008). Afterward, the layings are deposited, followed by a second resin impregnation and a final coating which meets the required visual appearance.

### **Pretensioned CFRP Lamellae**

In critical areas which are particularly susceptible to tensile stresses, a high degree of reinforcement can be achieved by introducing compressive forces into the basic structure. An enhancement in this way is conducted, for example, by prestressing systems (Suter and Jungo 2001; Berset et al. 2002). These comprise an anchor fixed to the concrete substrate, which holds a CFRP lamella and a connected stress head in place. Alternatively, the CFRP is directly glued onto the steel end anchorage which in turn is fixed with screws and dowels. The lamella is tensioned hydraulically or with means of a manually adjustable tensioning head and is afterward fixed in the tensioned position. The prestressing force is introduced into the concrete exclusively through the anchors at the lamella ends. Adhesive bonding of lamellae to the concrete surface is not necessary to achieve a reinforcing effect. However, often the CFRP is glued to the substrate for protective purposes (Berset et al. 2002).

---

## **49.3 Glass Construction**

### **49.3.1 Introduction**

Glass, being a versatile construction material, possesses a high compressive strength and modulus besides its excellent long term durability. However, its brittleness and the high notch sensitivity exhibit major challenges when connecting glasses for construction applications. Nonetheless, direct contact between glasses and other hard materials like metals must be prevented. Thus, intermediate layers are necessary.

For this reason, adhesive bonding is predestined as a joining technique, allowing a homogeneous stress distribution over a large area and avoiding penetration of the glass by mechanical fasteners and clamping devices, which leads to reduced local stress peaks. Traditionally, glass in buildings is mainly used for windows as separating feature, but laminated safety glass (LSG) can also act as a load-carrying support element for large-size glazing. Recently, structural glass elements, such as beams, columns, and floors, are realized despite an absence of technical standards and/or practical recommendations as reference for design and construction (Biolzi et al. 2010; Haldimann et al. 2008).

However, due to rapidly advancing research and development in construction with glass, more highly transparent building envelopes and other structural elements are to be expected in the future (Weller and Schadow 2007).

### **49.3.2 Glass as Substrate Material for Adhesive Bonding**

Silicate glass is used almost exclusively in the construction sector. The most common is soda-lime silicate glass, which consists mainly of quartz sand, lime, and soda. The liquid state consists of  $\text{SiO}_2$  (about 70%),  $\text{CaO}$  and  $\text{MgO}$  (about 12%),

and  $\text{Na}_2\text{O}$  (about 15%). During the solidification, silicon oxides form a network of  $\text{SiO}_4$  tetrahedra into which the alkalis are embedded (Wörner and Freitag 2012).

Glass possesses a theoretical strength in the range of 1–100 GPa; the real (tensile bending) strength of annealed float glass is limited to 20–110 MPa. This mismatch results from small defects in the glass surface, which especially may be caused by cutting and grinding processes at the edge of a pane. A common method for increasing the strength of glass is prestressing by thermal treatment, leading to an inhomogeneous stress distribution across the section. Depending on the prestress level, several categories can be differentiated. Annealed float glass exhibits reduced internal prestresses; it breaks into large shards at relatively low forces. Heat-strengthened glass features medium tensile and compressive stresses, whereas fully tempered glass shows a more extensive crack branching because of increased energy release (Louter 2007).

The surface energy of glass in the solid state is in the range of 300–500 mJ/m<sup>2</sup>. Hence, the thermodynamic prerequisite for sufficient wetting with organic adhesives is theoretically given. Nevertheless, the hydrophilic surface of glass absorbs water from the environment, which results in a thin water layer. In particular, in the case of glasses with high alkali content, hydrolysis and the formation of  $\text{SiOH}$  groups on the surface lead to a reduction in surface energy, so that no ideal, purely oxidic surface is to be expected. Moreover, it must be taken into account that other corrosive media (neutral, alkaline, and acidic) also affect the surface characteristics. Also, the relatively low thermal expansion coefficient of  $5\text{--}10 \cdot 10^{-6} \text{ K}^{-1}$  must be taken into consideration, because this may cause stresses in the adhesive bond, e.g., for structural glazing facades, where large metallic and glass substrates are joined (Habenicht 2009). Pretreatments for achieving long-term stable bonding of glass are the application of silane coupling agents by wet-chemical processes, flame pyrolytic deposition of silicate layers (Pyrosil<sup>®</sup>), activation of the surface with atmospheric pressure plasma, and layer deposition by plasma polymerization (Wagner 2009).

### 49.3.3 Applications

#### Laminated Glasses

Laminated glass is a composite material consisting of one or more sheets of glass or synthetic polymers like acrylic glass joined together with one or more interlayers, simultaneously acting as adhesive and separator. Laminated safety glass (LSG) meets special safety requirements according to EN ISO 12543. To avoid a shattering into sharp pieces and to enhance the mechanical properties, LSG combines the unique characteristics of glass with the benefits of a tough but highly elastic organic material (Keller and Mortelmans 1999; Haldimann et al. 2008). For many structural applications, it is required to guarantee residual carrying capacity and to avoid dropping out after breakage. For this reason, LSG often consists of two or more prestressed glasses with an interlayer of polyvinyl butyral (PVB) or ethylene-vinyl acetate (EVA). The mechanical behavior of the composite is influenced by the

thickness of the glasses as well as the thickness and condition of the interlayer (Headley 2014; Jalham and Alsaed 2011; Biolzi et al. 2010). Moreover, the adhesion between the organic interlayer and the glass is relevant for the performance. A high adhesion of the polymeric foil ensures that glass fragments stick to the foil even after break, whereas a low adhesion improves the impact resistance because the interlayer retains its mobility and can be pulled from between the glass panes (Keller and Mortelmans 1999). For the production of LSG, a prelamination is carried out by heated pressure rollers, and subsequently the final product is formed in an autoclave at higher temperatures for expelling air pockets and, in case of thermoset EVA foils, for cross-linking (Headley 2014; Jalham and Alsaed 2011).

## Glass Facades

Structural glazing is a term used for several methods of attaching a curtain wall of glass to a support structure. Common technologies of attachment are spider fittings, clamps, structural silicone adhesives, as well as structural adhesive tapes. Built in 1903, the Margarete Steiff Toy Factory in Giengen, Germany, featured one of the earliest examples of glazed curtain walls in Europe and the first double-skin facade ever built. One major field of adhesive bonding in the construction industry is structural sealant glazing, especially structural silicone glazing (SSG), a technique for bonding glass to the frame of a building by silicone adhesives, which mainly must withstand live loads, such as wind, and in some cases the self-weight of the panel (dead load). By the late 1960s, the total vision system was developed, where glass panes were structurally bonded to glass mullions by silicones. In 1983, the construction of the 37-story-high Park Avenue Tower in New York City laid the foundation for SSG facades. The transparent architectural design, enabled by the use of a medium-modulus silicone, became so popular that today SSG is one of the most versatile forms of curtain wall construction in the commercial facade business and enhances the artistic appeal of buildings (see Fig. 6) (Klosowski and Wolf 2016; White et al. 2010; Giesecke 2007).

To support dead loads and to resist live loads while being able to compensate different thermal elongations, medium-modulus adhesives with elastomeric properties, low creep behavior, and high durable adhesion are required. Because the interface between structural adhesives and glasses is usually directly exposed to sunlight, the adhesive must resist UV light at least for an expected service life of 30–50 years. Besides, in particular for protective, safety, and security glazing systems, the joint must withstand high load rates (hurricane, bomb blast, earthquake) over a short impact time. For many structural glazing applications, silicones are predestined because of their special properties caused by their different chemical backbone compared to other, purely organic-based adhesives. They display a very low glass transition temperature ( $T_g$ ) owing to the flexibility of their siloxane polymer backbone. The time-temperature superposition principle implies that a low  $T_g$  stands for a high flexibility of the polymer chains at high temperatures within very short time scales. Thus, the theory predicts particularly good performance for silicone adhesives when submitted to sudden load conditions. Moreover, they remain highly elastic and allow a tension equalization over a large temperature

**Fig. 6** Examples of structural sealant glazing constructions (*left* adhesively bonded all-glass facade edge of the Alea 101 office building, Berlin; *right* hybrid glass facade with inserted mechanically fastened toggle spacers and bonded glass panes of the Jewish Museum Berlin) (Source: Verrotec GmbH)

range, are nearly inert to chemicals, and exhibit excellent resistance to moisture and weathering. These properties mark silicones as perfect adhesives for long durable bonds (Giesecke 2007; White et al. 2010).

Commonly, structural loads are transferred from the panel to the framing via a linear structural adhesive fixation along the panel's perimeter. The number of adhesive bonds per panel leads to the division into two- or four-sided SSG structures. Two-sided SSG are either vertically or horizontally bonded to the substructure on mutually opposing panel edges. Four-sided SSG is achieved by applying adhesive in all four edges of each pane. Because in case of two-sided bonding two edges are captured by conventional glazing channels, the functional reliability is higher compared to the four-sided variants. Nevertheless, the importance of the sealant is obvious in both versions. Besides the number of adhesive joints, the construction of SSG facades is different in regard to the dead load support and mechanical restrains. The guideline for European technical approval for structural sealant glazing (ETAG 002) differentiates four basic types of SSG construction (cf. Table 1). National regulations lay down the need for restraint systems for various applications (Kłosowski and Wolf 2016).

Moreover, it is important to ensure a reproducible bonding process. Ideally, the production of structurally glazed curtain wall modules, especially four-sided variants, should be carried out as factory production to guarantee a controlled environment with proper surface preparation and quality assurance programs. But, especially in case of maintenance or repair, the structural bonding operation must

**Table 1** Basic types of SSG (ETAG 002)

Type	Mechanical dead load support	Mechanical safety retention device
I	Yes	Yes
II	Yes	No
III	No	Yes
IV	No	No

be executed on the construction site, and temporary mechanical fasteners may be required to firmly hold the panes in place until a sufficient cross-linking density is reached.

Besides linear bond lines, technologies have been developed that allow adhesive point fixations of curtain wall elements near the corners. These point-fixing elements can lead to frameless and visually appealing glass facades (Dow Corning 2011). In case of LSG panes, the fastening can be achieved by bonding on the outer glass surface. Alternatively, the outer glass layer of the pane can be penetrated by the point holder and the joint is thus glued to an inner layer of the LSG pane.

While in SSG a metallic substructure forms the building to which the facade elements are glued, glass can also act as a structural element itself. In Amsterdam, the entrance of a Chanel store was designed by replacing the old brickwork by glass bricks and door and window frames. For the realization of this facade, more than 7.000 handmade glass elements were joined by a tension equalizing UV-curing adhesive (Delo 2016).

**Other Glass Construction Elements**

Further construction elements made of glass are divided into overhead glazing, accessible glazing, as well as railings and balustrades. Flexible adhesives such as silicones with limited strength but high elasticity are not always suitable for these applications. Even though SSG necessitates the use of elastic adhesives, structural silicones are neither stiff nor strong enough and unsuitable for small adherend surfaces in many applications. Although annealed glass is a relatively flat product, heat treating causes roller wave distortions, so that assembly tolerances must be taken into account for the selection of the adhesive. For tolerances of more than 1 mm, it is recommended to use epoxy-based systems with sufficient gap-filling properties, whereas the use of contact adhesives such as acrylic-based systems is possible for smaller spacings. Especially for transparent substrates like glasses, UV-curing acrylics, as used for the previously described Crystal House in Amsterdam, should also be considered. Nevertheless, for many applications, the limited absorption of deformation and compensation of thermal elongations of these rigid systems must be considered already in the design phase (Haldimann et al. 2008).

Due to the brittleness and unpredictable failure behavior, glass is considered as a structurally unsafe material. To reduce the risk of a spontaneous failure of load-bearing structures, research was carried out to obtain ductile failure behavior by the combination of glass with other materials like CFRP, stainless steel, concrete, or

even timber. Moreover, the exclusive use of adhesives to obtain a ductile fracture behavior was examined. Glass beams, composed of multiple overlapping glass segments being adhesively bonded by acrylic adhesives, lead to transparent construction elements with a ductile failure behavior (Louter 2007).

The potential of glass elements in construction engineering can be seen on a record-breaking construction in China. A 430 m long suspension bridge in the Chinese province Hunan, opened in summer 2016, consisting of a structural glass deck and banisters with side hanging stay cables. With a width of 6 m, the bridge spans a canyon between two cliffs and hovers over a vertical drop of 300 m. The bridge consists of 99 panes of three-layer safety glass (Yiin 2016).

## 49.4 Timber Construction

### 49.4.1 Introduction

Timber from well-managed forests is one of the most sustainable and oldest materials used in the construction industry. The key advantages of timber are the very high strength-to-weight ratio, the ability to transfer tension and compression forces, and its suitability as a flexural member. The excellent durability, performance, and insulating properties against heat and sound make timber a versatile working material. It can be easily shaped and connected by screws, nails, bolts, and dowels. Furthermore, there have been significant advances in adhesive technology.

Connections achieved by adhesive bonding can result in a better appearance, are often stiffer, and require less timber. Examples of structural timber connections include finger joints, scarf joints, glued gusset joints, and splice joints, which can reach better mechanical properties compared to butt or lap joints (see Fig. 7) (Porteous and Kermani 2012; Serrano 2000).

In case of thermosetting adhesives, the joints perform better than mechanical connectors with regard to fire resistance. The main disadvantages of adhesively bonded timber parts are the necessity of quality control during manufacture and the risk of degradation in conditions of fluctuating moisture content, especially in case of joints between dissimilar materials. However, the developments in adhesive technology have led to an increase of glued joints for structural timber construction as well as for engineered wood products (EWP) (Porteous and Kermani 2012).

### 49.4.2 Timber as Substrate Material for Adhesive Bonding

Due to the fibrous and porous structure of almost all types of timber, the adhesion of wood-based materials is predominantly caused by form closure. In addition, intermediate molecular binding forces between the polar wood surface and adhesives can support the strength of the joint. In some cases, even covalent bonds form, for instance, in the reaction of isocyanate or epoxy containing adhesives and hydroxyl groups of the cellulose molecules. Besides this, the polarity of wood results in

**Fig. 7** Examples of structural timber connections which can be realized by adhesive bonding (Source: tff)

hygroscopy that must be taken into account since the presence of water influences the setting process of many adhesives as well as the performance of both adhesive and adherent (Habenicht 2009; Custódio et al. 2009).

Although adhesive bonding of wood does not pose much of a problem, an adequate surface pretreatment is appropriate for:

- Reproducing long-term durable bonds
- Establishing a close fit between the adherents
- Creating freshly cut or planned surfaces free of irregularities and contaminants
- Enabling a sufficient wetting and penetration by the adhesive

Immediately after surface preparation, the surface undergoes an inactivation process by external contamination (airborne chemical contaminants, oxidation, and pyrolysis), as well as self-contamination, that is the migration of hydrophobic wood extractives to the surface leading to a reduction of surface energy. To achieve optimal adhesion conditions, the inactivation process of a prepared surface must be taken into account. For this reason, for an appropriate bond the bonding process should be carried out immediately after cutting and activation (Custódio et al. 2009).

Especially in case of timber constructions, adhesives should be selected with regard to the expected exposures. It is required that adhesives are resistant against relevant chemicals, temperatures, and microorganisms and insects that may influence the adhesive bond. The resistance to humidity is of greatest importance (Rug and Mönck 2015). Phenolic and aminoplastic polycondensation adhesives for load-bearing timber structures can be divided into two categories with regard to the expected climatic exposure conditions (Porteous and Kermani 2012).

- I. Suitable for indoor and outdoor applications – adhesives should withstand full outdoor exposure and temperatures up to 50 °C.
  - II. Primary suitable for indoor applications – adhesives may not be able to withstand prolonged exposure to weather or temperatures above 50 °C.
- Suitable structural wood adhesives recommended for several service environments are listed in Table 2.

49.4.3 Applications

Engineered Wood Products

In order to add value to the raw material and to overcome the limitations of sawn timber, several EWP have been developed which often involve the use of adhesive joints. As a natural product, wood is a material with a strong anisotropic behavior and an inhomogeneous, porous structure. It mainly consists of cellulose fibers, hemicellulose, and lignin. Characteristics are the large property variation in the processed state, such as swelling and shrinkage due to moisture absorption and release, leading to the development of EWP (Habenicht 2009). Many of these products use the same approach: cutting solid wood into small pieces (sheets, laminations, or even fibers) and joining them to gain a more homogeneous material (Serrano 2000). Glued laminated timber (glulam) is an example of an EWP, which consists of dried thin planks of wood with parallel grain to the longitudinal axis in each layer. Durable and moisture-resistant structural adhesives are used for their interlaminar bonding. Glulam laminate is commonly used for columns, trusses, bridges, portal frames, post, and beam systems (Porteous and Kermani 2012). Further EWP products like laminated lumber, plywood, and particleboards and their applications are described in the literature.

Glued-In Rods

Glued-in rods (GiR) are an effective way for both constructing new and strengthening existing timber structures. Most applications have used GiR reinforcements with

Table 2 Adhesives for structural timber engineering (Levy 2012)

Primary service environment	Main types of adhesives
Fully exterior use	(Phenol)-resorcinol-formaldehyde
(Withstands long-term water and drying)	Emulsion polymer/isocyanate
	Melamine-formaldehyde
Semi-exterior use	Melamine-urea formaldehyde
(Withstands short-term water soaking)	Isocyanate
	Epoxy
Interior use	Urea-formaldehyde
(Withstands short-time high humidity)	Casein

metal bars for repair, strengthening of solid timber beams and for joining concrete slabs and floor beams. Requirements like limited weight or resistance to corrosion can be fulfilled by the use of pultruded fiber-reinforced plastic (FRP) rods instead. To realize GiR, a hole with defined diameter is drilled into a wood block (usually softwood or glulam). After cleaning the hole, e.g., by compressed air, a certain amount of adhesive is filled in followed by the insertion of the rod. Different variants of GiR were developed to enhance the quality control of this process and to allow a better performance (Steiger et al. 2015).

A large number of adhesives have already been investigated for this application. Epoxy-based systems have been able to achieve high adhesion on both the metal rod and the wood surface. They showed excellent pullout strengths, so in the end the wood itself became the weakest link. Other commonly used adhesives are phenol-resorcinol adhesives and polyurethanes. Besides shrinkage during initial hardening, gap-filling qualities, viscosity, moisture, temperature-dependent properties like creeping as well as loads and geometrical conditions must be considered during the selection process for optimum GiR applications (Steiger et al. 2015).

### Reinforcement of Timber Structures

For strengthening and repair of timber structures, the use of FRP has been shown to be an effective and economical method as compared to traditional techniques. The selection of adhesives has to be undertaken with great care. Five categories of adhesives for FRP reinforcement of timber are available: epoxies, polyurethanes, polyesters, phenolic resins, and aminoplastics. Similar to GiR, two-part, cold-curing epoxy adhesives are particularly appropriate, not least because of their good gap-filling properties and their low curing shrinkage. External reinforcements utilize almost exclusively plane products whereas internal reinforcement use pultruded rods and plates. These are inserted into timber slots or grooves (Schober et al. 2015).

Four different applications of reinforced timber structures can be divided. Beam-end reinforcements are commonly used variants for repair and support of wood structures only at the edges. Therefore, holes or grooves are inserted into locally prepared beams followed by the insertion of adhesives and reinforcement elements like FRP. Furthermore, a tension reinforcement perpendicular to the grain can be useful to increase or maintain the load-carrying capacity of structures. Since notches, holes, curved beams, and beams with variable height result in high tensile stresses perpendicular to the grain, which is an unsuitable load type for wood as an anisotropic material, FRP reinforcement with defined fiber orientation can be used to enhance the performance locally. Other variants for structural elements, loaded by shearing or bending, can also be enhanced by FRP, either internally or externally. In some cases, a prestressing of FRP elements can be beneficial on the tension side of beams, which presents the most effective utilization of FRP reinforcement (Schober et al. 2015; Triantafillou and Deskovic 1992).

## 49.5 Steel Construction

### 49.5.1 Introduction

Adhesive-bonded steel joints are nowadays not only used in automotive and airplane industry (Pasternak and Mainz 2006). However, although adhesive bonding has significant benefits in comparison to other joining techniques, constructions in civil engineering which are completely made of steel (or metal in general) are not commonly achieved by the use of adhesion technology. Usually, these connections are established by welds, screws, bolts, or rivets.

One main reason for this fact is that adhesive bonding processes are often lacking in order to ensure the process reliability and long-term stability of the bonds.

In the classical steel body, forces are absorbed by individual beams and struts. However, this local load concentration is unfavorable for glued joints (Geiß et al. 2012; Geiß 2008). This situation could be remedied by a modified design. Yet, there is a lack of experience in adhesive construction. In addition, dimensional tolerances of the components are unavoidable in construction. Gap thicknesses of several millimeters to centimeters are generally difficult to compensate by adhesives if at all (KIT 2016a). More often, adhesives are applied for joining steel with other materials, such as glass in the structural-facings sector. In this case, mostly silicone-based adhesives, urethanes, and epoxy resins are used.

### 49.5.2 Steel as Substrate Material for Adhesive Bonding

Since the surface energy of steel is sufficiently high, gluing to steel is generally not an issue. In order to produce long-term resistant, high-strength adhesive bonds, grinding or sandblasting is necessary when layers like rust or scale adhere to the surface which does not have sufficient adhesion to the base material. Due to production processes before the bonding and the necessity of corrosion protection, steel surfaces are usually oiled. Several adhesives are capable of achieving good bonds even at high levels of oiling ( $>3 \text{ g/m}^2$ ), such as, for example, acrylates or some epoxy resins. As a rule, however, these surface contaminations have to be removed prior to bonding (Henning and Moeller 2011).

Special attention must be paid to the type of steel used. Stainless steels are passivated by their chromium content in such a way that the reactivity toward corrosive media is reduced. Due to this passivation, the strength of intermolecular bonds between the adhesive and the steel necessary to achieve a good adhesion may also be reduced (Habenicht 2009). However, this statement has not been demonstrated in general (Geiß et al. 2012), and the bond strength needs to be evaluated for any combination of adhesive and steel grades.

The bonding to galvanized steels can be problematic in that the zinc layer has a different adhesion to the steel substrate, depending on the type of deposition

(hot-dip or electrolytic galvanizing). Furthermore, the adhesive strength is influenced by the different orientations of larger zinc crystallites, as a heterogeneous stress distribution is thereby generated within the adhesive layer (Habenicht 2009).

Today, in steel construction, polyesters, vinylesters, acrylates, epoxy resins, polyurethanes, or hybrid systems are employed (Dilger 2011). Especially the polymerizing systems (acrylates, esters) prove beneficial, since these readily cure at low temperatures and are more insensitive to mixing errors (Feldmann et al. 2006).

Structural thermosetting adhesives, which have been successfully used in car body shops for several years like one-component epoxy-based systems, are not suitable for many steel structure applications because of the required high curing temperatures (between 175 °C and 190 °C) and the resulting difficulties on construction site.

### 49.5.3 Applications

As mentioned above, gluing in steel construction (as in the construction industry in general) only has a very limited range of use, even though in the past initial attempts have been made to increase its application. Therefore, the examples listed here are rather of an academic nature or part of basic research and are not routinely used in steel construction.

#### Bridge Building

In 1955, a bridge based on hybrid bonding technology (adhesive bonding backed up with screws) was raised over a side channel of the river Lippe in Marl, Germany (Brockmann and Neeb 2001). In this case, rods were adhesively bonded with the lower and upper belt with a polyester-phenolic resin via a flange connection.

Besides other examples (Brockmann and Neeb 2001; Piekarczyk and Grec 2012), further developments at the time were scarce due to the limited properties of the adhesives and experiences compared to contemporary joining techniques. However, even today, gluing in bridge construction remains a niche application. This is mainly due to the progressive development of welding technology with regard to the realization of complex structures. In addition, statements about the long-term stability of adhesive bonds under environmental influences can only be made inadequately.

A common method for strengthening decks in ship construction is the application of sandwich structures where an elastomeric adhesive fills the gap between two steel sheets. These steel-polymer-steel structures (SPS) possess a promising torsion rigidity. Furthermore, the elastic core is able to relieve stress peaks. Feldmann et al. were investigating such laminates for the post-strengthening of road bridges (Feldmann et al. 2006). They achieved a reduced cover plate bending and thus a higher load capacity.

### **Metal Framework Facades**

Recent glass facades demand a highly stiff supporting structure with a maximum bearing capacity which effectively takes up the occurring loads (e.g., wind loads) but which at the same time makes light-flooded architectural design and construction possible (Pasternak and Mainz 2007). Mullion and transom facades which use profiles with a rectangular hollow cross section are a suitable construction variant for this kind of task. However, an additional strengthening in terms of an increased load-bearing capacity and improved stiffness can be achieved by glued-in steel sheets. The effectiveness of this method could be evaluated by means of a four-point bending test at the Brandenburg Technical University (Pasternak and Mainz 2007).

Especially for industrial halls, facades made of trapezoidal profiles are employed which in general are attached to the support structure by means of nails, rivets, or screws. However, the fastening methods possess several disadvantages like the possibility of rust formation or the local occurrence of dents (Pasternak and Mainz 2007). Thus, Pasternak and Mainz developed a fastening method that makes use of a hook profile adhesively bonded to the trapezoidal sheets. They determined the optimal construction parameters in terms of normal stresses in dependence of hook length or type of the adhesive system used.

### **Hybrid Bonding**

As already mentioned, adhesives are often not able to compensate larger bonding gaps in the range of several millimeters to centimeters. However, these gaps are unavoidable due to high tolerances in building construction. Scientists at the Karlsruhe Institute of Technology have developed a method that can solve this discrepancy (KIT 2016a, b). For this purpose, inorganic granules are adhered to the steel surface with an organic structural adhesive. The steel surface is simultaneously sealed by the adhesive and protected against corrosion. The components thus treated are subsequently connected by means of a grouting mortar.

---

## **49.6 Conclusions and Outlook**

In structural engineering, two connection techniques are currently employed. On the one hand, mechanical fixing elements are used. These transfer forces only locally and, in addition, may partially damage the adherends. On the other hand, welding is a widely spread joining technology that results in stiff and resilient structures. However, welding is only suitable for certain material combinations. Thus, many novel design concepts cannot be realized.

Adhesive technology leads to a high material utilization and freedom of design and is therefore nowadays already established in some sectors of the construction industry. This includes not only maintenance and repair but also the realization of novel building structures.

Since concrete itself can be referred to as an (inorganic) adhesive, in concrete construction all processes are basically bonding processes. In addition, the use of organic systems can be beneficial for further applications, e.g., for anchor systems and reinforcement elements.

The glass industry best illustrates the high potential of adhesive bonds. SSG facades play an increasing role due to their excellent design possibilities. The development of suitable silicones and acrylic systems as well as special types of glass (prestressed glasses, laminated glasses) are likely to lead to further construction projects that will benefit from the advantages of glued joints.

In timber construction, the use of adhesives is also quite common. By the use of adhesion technology, new material combinations could be achieved, which feature many advantages. In addition adhesives are employed for structural bonding as well as for reinforcement applications.

In steel construction, adhesive bonding is less common. Nevertheless, several research projects demonstrate its benefits even in this sector. This results not least from the vast diversity of materials and the resultant difficulty of joining by well-established techniques.

Even if adhesive bonding is already established in many areas of construction, its potential is not yet fully exploited. The reasons for this are the relatively low level of trust in this technology, the lack of knowledge in the use of adhesives, as well as the limited process control. Future developments should address these current deficits in order to successfully expand the application of adhesive technology in the civil construction sector.

## Abstract

Electrically conductive adhesives (ECAs) are used for the joining of electrical and electronic components in the electrical industry. ECAs are composites consisting of a polymeric matrix and electrically conductive fillers. The mechanical properties are provided by the polymeric matrix, while the electrical conductivity is supplied by the conductive fillers. Typically, there are three types of conductive adhesives, viz., isotropic, anisotropic, and non-conductive adhesives. These adhesives are classified according to their conductivity, which is controlled by the conductive filler content in the polymer matrix. For their application in the electrical industry, there are two main specific requirements for these adhesives, i.e., electrical conductivity and thermomechanical properties. In this chapter, the mechanism underlying the electrical conduction in adhesive joints is derived, while the thermal and mechanical parameters that should be measured are introduced. Some recent advances related to the improvement of ECAs are also addressed. In terms of the evaluation of the reliability of adhesives in electronics, the basic test procedures, including several specific test methods and analysis techniques, are explained. Recommendations are also given to select a suitable test method.

## 50.1 Introduction

Conventionally, the joining of components in the electrical and electronic industries was mainly achieved by employing metallic materials, such as low melting point Sn-Pb solders. Sn-Pb solders are generally used to join similar or dissimilar metallic materials, such as Cu to Cu or Cu to Ni, etc., which are used as interconnect materials in electrical/electronic systems. When using Sn-Pb solders for joining, Sn plays the major role in the joining process, while Pb is included to lower the melting temperature and increase the ductility, thereby enhancing the thermomechanical reliability, preventing whisker formation, and decreasing the thickness of the inter-metallic compound layers which could be formed between the solder and other metallic materials.

Although Sn-Pb solder alloys provide a low melting point and good mechanical reliability, the toxicity and environmental incompatibility of the lead contained therein are forcing changes in the world market for electronic products which will dramatically reduce and possibly even eliminate their use altogether. As a consequence, the industry is changing its primary interconnect technology from Pb-based solder alloys to Pb-free alloys and electrically conductive adhesives (ECAs) (Liu and Lin 2005; Kim et al. 2005; Yin et al. 2006; Zhang et al. 2006; Plumbridge 2004). Although various Pb-free solders have already been developed, most current commercial Pb-free solders, such as Sn-Ag and Sn-Ag-Cu, have higher melting temperatures than that of Sn-37Pb solder, which raises the soldering temperature and, thus, reduces the integrity, reliability, and functionality of the printed circuit boards, components, and other attachments. On the other hand, ECAs generally have a lower processing temperature, which minimizes the thermal damage of the

packaging components, as well as many other distinct advantages that solder alloys cannot offer. They are flexible, capable of fine pitch interconnections, environmentally friendly, and cheaper to manufacture (Kim et al. 2008a).

The first employment of ECAs in the electrical and electronic industries was realized in the early 1970s for attaching semiconductor chips and other passive devices onto ceramic substrates in the fabrication of hybrid microcircuits. Epoxy technology pioneered the use of isotropic conductive adhesives for die attach applications in 1966. These early adhesives were filled with gold and silver powders and flakes which provided electrical and thermal pathways for the bonded devices (Lau 1995). However, those rare metal fillers must be reduced to allow their application in ECAs from the aspect of cost. Researchers are recently focusing on high aspect ratio and highly conductive fillers such as metallic nanowires and carbon-based nanomaterials instead of excess weight loading of rare metal fillers.

Nowadays, ECAs are mainly employed in advanced electronic packaging technologies, such as chips on flex (COFs), chips on glass (COGs), and flip chip attachment on printed circuit boards (PCBs). Figure 1 shows schematic images of these electronic packages. Before proceeding to the discussion on the concept and applications of ECAs, a brief introduction to electronic components and packaging technologies is helpful.

**Fig. 1** Schematic description of various electronic packages with adhesives: (a) chip on flexible substrate, (b) chip on glass substrate, (c) chip on rigid board

The technical developments realized in the industry in the last two decades of the twentieth century were enabled by the enormous progress made in microelectronic and semiconductor technology, due to the miniaturization of integrated circuits (ICs). Reducing the circuit dimensions reduces the transmission distances and increases the achievable speed of operation, and, in this way, the performance of the chips could be enhanced dramatically. The chips in the circuit communicate with each other through an input/output (I/O) system of interconnects, and these delicate chips and their embedded circuitry are dependent on the package for support and protection. At this time, the major functions of the electronic package are to provide a path for the electrical current that powers the circuits on the chip, distribute the signals onto and off of the silicon chip, or remove the heat generated by the circuit and support and protect the chip from hostile environments.

In the microelectronic packaging industry, flip chip technology, which was introduced for ceramic substrates by IBM in 1962, provides the highest packaging density and performance and the lowest packaging profile. Flip chip technology involves the connection of a chip to a substrate with the active face of the chip facing toward the substrate. Generally, flip chip technology can provide a cost-effective packaging method in various applications, such as telecommunication, computers, display products, and automobiles. The interconnection in flip chip packages that was firstly suggested by IBM was achieved by solder bonding. Flip chip interconnects formed by solder bonding are called solder-bumped flip chip interconnects, and they consist of essentially three basic elements. These include the chip, the solder bump, and the substrate. An underfill is often used to improve the reliability of the interconnect system. Figure 2 shows a brief schematic diagram showing the flip chip packaging structure with a ball grid array bonding. Each of these elements and the processes used to assemble them together affect the performance and cost of the interconnect system. Therefore, the performance and cost must be compared on the

**Fig. 2** Package structure for flip chip ball grid array

basis of the interconnect system as a whole, and not merely on the basis of any single element of the interconnect assembly.

Eutectic Sn-Pb alloys are widely used as interconnects in solder-bumped flip chip packages. However, as indicated above, there are increasing concerns about the use of Sn-Pb alloy solders, because Pb, a major component in the solder, has long been recognized as a health threat to human beings. With the phasing out of Pb-bearing solders, various ECAs have been identified as environmentally friendly alternatives to Sn-Pb solders in flip chip applications. There are three leading ECA flip chip methodologies: isotropic conductive adhesives (ICAs), anisotropic conductive adhesives (ACAs), and non-conductive adhesives (NCAs). ICAs consist of an insulating adhesive polymer matrix with a high loading of conductive particles. The conduction mechanism is based on the percolation theory of electrical conduction afforded by the physical contact of the conductive particles. ACAs are similar to ICAs, except that they have a lower conductive filler content and thus provide unidirectional conductivity in the vertical or z-direction (perpendicular to the plane of the substrate). This means that the controlled conductive filler loading provides a higher resistance interconnect through the thickness of the adhesive than those of the ICA or solder-bumped interconnects. NCAs, on the other hand, do not consist of conductive particles but rather maintain a pure mechanical contact between the bumps and pads due to the application of a compressive force, and it is this that ensures the electrical connectivity between them. Nowadays, NCAs are being considered as an alternative to ACAs, because they can achieve a finer pitch of input/outputs (I/Os) due to the absence of any dispersion of conductive particles between I/Os and their better electrical performances. However, some issues concerning their performance and long-term reliability have recently been raised, so that a technical review of each material is essential. Figure 3 provides a comparison of the three ECA technologies, and a more detailed description of them will be provided in the next chapter.

---

## 50.2 Classification of Electrically Conductive Adhesives

Adhesives are basically organic materials containing a small amount of additive materials such as conductive or dielectric materials. The organic materials in adhesives can be separated into two different types depending on their structure and thermal behavior: thermoplastics and duromers (Aschenbrenner et al. 1997; Habenicht 1990). While thermoplastics are hot melting and can be plasticized and reshaped at temperatures above their glass transition temperature ( $T_g$ ), duromers are thermosetting and can be modeled during the curing process only (Aschenbrenner et al. 1997). Today, most adhesives are thermosetting ones based on epoxy resins, which provide high heat resistance and excellent adhesion to a variety of substrates. However, they are not thermally reversible and cannot be dissolved in common organic solvents, because they are cross-linked after bonding. In addition, thermosetting adhesives provide a low interconnection resistance, because they are easy to exclude between the bonding electrodes during the bonding process. There are various kinds of conductive particles that can be used to endow the adhesives with

**Fig. 3** Schematic descriptions of three ECA technologies: (a) isotropic conductive adhesive (ICA), (b) anisotropic conductive adhesive (ACA), (c) non-conductive adhesive (NCA)

electrical conductivity. Ag is by far the most common conductive material for ECAs, but most of the recent ACAs employ polymer particles coated with various metals. Polymer particles are more elastic and, therefore, have the potential to compensate for the strains within the adhesive interlayer induced by thermal expansion (Aschenbrenner et al. 1997). Here, we will briefly introduce the various adhesives, starting with ICAs.

## 50.2.1 Isotropic Conductive Adhesives

ICAs are generally fabricated using adhesive and metallic conductive fillers that impart the desired adhesive and electrical properties, respectively. Typically, silver flakes and powders are utilized, because of their high electrical conductivity, chemical stability, and low cost. Processed Ag fillers must have suitable properties in order to fabricate compatible ICAs. For example, several micron-sized Ag flakes with a loading of 25–30% by volume in ICAs can give good conductive and adhesive properties (Markley et al. 1999). The particle size, particle size distribution, and other important characteristics can be controlled by the manufacturer by manipulating the various processing conditions, e.g., the lubricant concentration used during the formation of the neutral Ag particles. Only slight variations in the concentration of the lubricant, such as oleic acid, can cause significant changes in the application properties, such as the adhesive conductivity and stability (Markley et al. 1999). Therefore, it is important to understand how Ag fillers impact the properties of ICAs.

**Fig. 4** Bonding and packaging procedure with ICAs

The general form of ICAs is a viscous paste statistically filled with a sufficient content of metal flakes to provide conductivity in all directions (up to 30 vol.%). The conductivity between the particles is based on their touching each other. The process flow can be divided into five steps, as shown in Fig. 4 (Aschenbrenner et al. 1997):

- Application of the isotropic conductive paste (ICP) precisely onto the points to be electrically connected
- Alignment of the bumps to the electrodes on the substrate
- Bonding the chip by curing the adhesive typically at over 150 °C for several minutes
- Applying an underfill material to compensate for the thermal mismatch
- Curing of the underfill material

Generally, the electrical conductivity of ICAs increases with increasing filler content, which means that they are transformed from an insulator to a conductor. This can be explained by percolation theory. Percolation theory was developed to mathematically deal with disordered media, in which the disorder is defined by a random variation in the degree of connectivity (Zallen 1983). The main concept of the percolation theory is the existence of a percolation threshold, which is a critical

filler concentration at which the resistivity drops dramatically. At the percolation threshold, it is believed that all of the conductive filler particles come into contact with each other and form a three-dimensional network. The resistivity decreases only slightly as the filler concentration is further increased (Lau et al. 2003). Figure 5 schematically describes the decrease in the resistivity with increasing filler content based on percolation theory.

The ICAs used in flip chip technologies serve not only to provide electrical continuity but also to support the mechanical load experienced during chip operation. Therefore, the mechanical strength of ICA joints has been another major reliability concern in electronic assembly technology. The electrical conductivity is proportional to the filler content; however, a too high filler concentration can deteriorate the mechanical integrity. The electrical continuity is achieved by the contact of the metal fillers, but the mechanical integrity is provided by the curing of the polymer resin. Therefore, the challenge in an ICA formulation is to use as much conductive filler as possible to achieve high electrical conductivity without affecting the mechanical properties adversely (Lau et al. 2003).

## 50.2.2 Anisotropic Conductive Adhesives

From the viewpoint of their conduction and mechanical joining, ACAs are similar to ICAs, except that they have lower concentrations of conductive particles. This lower concentration provides unidirectional conductivity in the vertical or z-direction (perpendicular to the plane of the substrate), which is why they are called anisotropic conductive adhesives. In the same way, ACA materials are prepared by dispersing electrically conductive particles in an adhesive matrix at a concentration far below the percolation threshold. The concentration of particles is controlled, so that sufficient particles are present to ensure reliable electrical conductivity between the assembled parts in the z-direction, while insufficient particles are present to achieve percolation conduction in the X-Y plane (Kim

**Fig. 5** Resistivity with volume fraction of a conductive filler according to the percolation theory

**Fig. 6** Schematic description of flip chip structure with ACA

**Fig. 7** Structure comparison between solder and ACA joints: (a) flip chip with solder bumps, (b) flip chip with ACAs

et al. 2008b). Figure 6 shows a schematic description of an ACA interconnect, showing the electrical conductivity in the joint. The volume loading of conductive filler in ACAs is 5–20 vol.%, which is much lower than that of ICAs. This low volume loading is insufficient for interparticle contact and prevents conductivity in the X-Y plane of the adhesives. The Z-axis adhesive, in film or paste form, is interposed between the surfaces to be connected (Li and Wong 2006). However, the controlled conductive filler loading still provides a higher resistance interconnect through the thickness of the adhesive than that of the solder-bumped interconnect. A comparison between the solder-bumped and ACA joint structures is shown in Fig. 7.

From Fig. 7, it can also be seen that the area of the pad used for joining with the solder should be much larger than that used for ACAs. When we employ solder for the interconnect, the smallest pitch, which means the distance between the center point of a solder bump and that of the next one, is more than 50  $\mu\text{m}$ , but it can be decreased to less than 30  $\mu\text{m}$  by using ACAs. This limitation of solders based on ECAs is mainly caused by the difficulty involved in the bumping technology of solder, e.g., the screen printing of the solder paste, the evaporation of the solder materials, and the electroplating process. Using these processes, aligning the mask opening before the deposition of the solder is essential and requires high accuracy, so

the extent to which the pitch and joining area can be reduced is limited. However, ultrafine pitch interconnections can be achieved when employing ACAs for joining. The fine pitch capability of ACAs is limited by the particle size of the conductive filler, which is only a few microns or a few nanometers in diameter. Therefore, a finer pitch is easily achieved these days by using smaller particles.

Heat and pressure are simultaneously applied to this stack-up until the particles bridge the two conductor surfaces. ACAs utilize both a thermosetting polymer and a thermoplastic polymer for their adhesive matrix. The thermosetting type is hardened by the thermally initiated chemical reaction during heating, while the thermoplastic matrix is hardened by cooling after heating. Many recently commercialized ACAs employ a thermosetting polymer based on epoxy resin, which provides a high heat resistance and excellent adhesion to a variety of substrates, although they are not thermally reversible and cannot be dissolved in common organic solvents, because they are cross-linked after bonding. In addition, thermosetting adhesives provide a low interconnection resistance, because they are easy to exclude between the bonding electrodes during the bonding process. The main advantage of thermoplastic adhesives is the relative ease with which the interconnection can be disassembled for repair operations, because they are rigid materials at temperatures below the  $T_g$  of the polymer, but exhibit flow characteristics above their  $T_g$  (Li and Wong 2006). Conductive fillers are generally metal microparticles or polymer cores coated with some high conductivity metals. Their basic particle shape is spherical. Ag is the most frequently used material for metal particles, due to its moderate cost, high electrical conductivity, high current-carrying capacity, and low chemical reactivity. Au is another widely employed filler material, but its cost prohibits large volume applications. An alternative to these noble metal fillers is polymer particles coated with conductive metals, such as Au, Ag, and Cu. The size of the polymer cores generally ranges from 1 to 5  $\mu\text{m}$ , and they are coated with a Cu, Ni, or Au layer a few nanometers in thickness. Polymers generally have viscoplastic properties, so that they allow the external compressive stresses applied to the package to be easily released. Figure 8 shows the two different deformation behaviors of the particles when external forces are applied to the ACA joint. However, most importantly, they are much cheaper to make than metal-only fillers, so that they are the most commonly used conductive fillers in industry.

**Fig. 8** Schematic description of two deformation behaviors in ACA joints: (a) soft conductive fillers, (b) rigid conductive fillers

50.2.3 Non-conductive Adhesives

In contrast to ICAs and ACAs, NCAs do not consist of conductive particles but rather maintain a pure mechanical contact between the bumps and pads due to the application of a compressive force, and it is this that ensures the electrical connectivity between them. The quality of the electrical contact depends solely on the magnitude of the mechanical contact pressure. A high mechanical contact pressure is critical in providing a low electrical connection resistance, which is induced by the cross-linking shrinkage and thermal strain during the curing and cooling processes. The formation of contact spots depends on the surface roughness of the contact partners. Bringing the two surfaces close to each other enables a small number of contact spots to form, which allows the electric current to flow. When the parts are pressed together during the sealing process, the number and area of these single contact spots are increased according to the macroscopic elasticity or flexibility of the parts and the microhardness and plasticity of the surfaces, respectively (Li and Wong 2006). Nowadays, NCAs are being considered as an alternative to ACAs, because they can achieve a finer pitch of input/outputs (I/Os), due to the absence of any dispersion of conductive particles between the I/Os and better electrical properties. NCA joints avoid short-circuiting and are not limited by the particle size or percolation phenomena, leading to a reduction of the connector pitch. Another important advantage of NCAs is their cost-effectiveness, which is achieved by the exclusion of conductive fillers. Figure 9 compares the shape of ACA and NCA joints enlarging electrical contact area.

50.3 Conductive Filler Materials for ECAs

The conductive filler in the conventional ECAs is metallic particles or flakes. These filler materials have some critical limitations in terms of lower electrical conductivity and inferior impact performance induced by unstable network formation of particle fillers. Considering these challenges of traditional filler materials, there are three

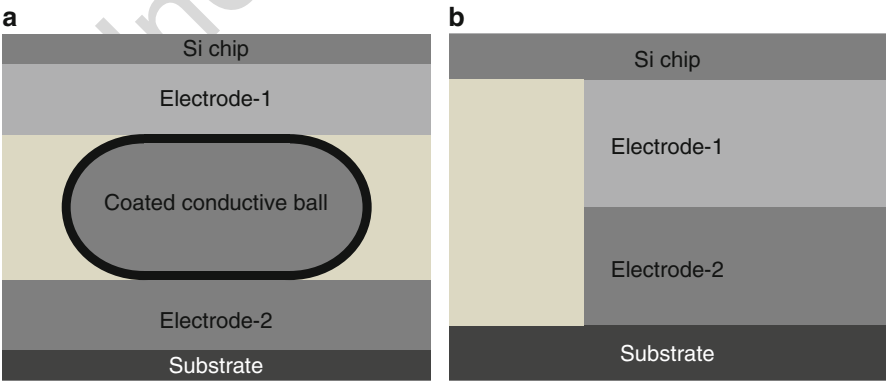

Fig. 9 Comparison of contact areas between ACA and NCA joints: (a) ACA joint, (b) NCA joint

major approaches to enhance the electrical conductivity of ECAs, which include (i) hybrid metallic fillers, (ii) carbon-based nanomaterials, and (iii) hybrid nonmetallic fillers: conductive polymers and poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS).

### 50.3.1 Hybrid Metallic Fillers

Metallic fillers are widely used in the field of printed electronics due to their high conductivity and excellent compatibility with metal electrodes. Printed components using ink or paste with the metallic fillers have been used in fabrications of various applications such as flexible radio frequency identification (RFID) tags, flexible heaters, and organic light-emitting diodes. In general, printed components are thermally treated in high temperature in order to decrease contact resistance formed among metal fillers or induce interparticle necking by atomic interdiffusion. Recently, highly conductive interconnects can also be established via some other technical approaches, e.g., plasma, microwave, and intense pulsed light (IPL) treatment, instead of thermal heating (Kim et al. 2013, 2015; Song et al. 2015). Figure 10 shows a schematic of IPL sintering and its commercial system which provide the selective sintering at lower temperatures within several microseconds.

Hybrid metallic fillers mean the incorporation of one-dimensional metallic nanowires into metal particle or flake fillers to improve electrical conductivity through an increase of metallurgical connections between each individual metallic filler. The metallic nanowires prefer to establish conductive networks rather than metallic particle or flake fillers because one-dimensional metallic structures are capable of forming a continuous network at lower loading level of the filler than spherical or platelet fillers (Grujicic et al. 2004). In particular, at lower temperatures, sintering process is controlled by surface diffusion due to mass flow to minimized Gibbs free energy (Mayo 1996), resulting in weak contacts between conventional metallic fillers. Since the

**Fig. 10** (a) A schematic of IPL sintering and (b) its system (PSFL-4021-PC, [www.pstek.co.kr](http://www.pstek.co.kr))

metallic nanowires are also likely to sinter at a low temperature, the large longitudinal size of nanowires makes it easy for fillers contacted weakly to sinter each other and bond. As shown in Fig. 11, the increased number of conductive pathways and the better quality of conductive linkage are obtained by mixing metallic nanowires with metal particles or flakes. Since the nanowires act as bridges among the spherical metal fillers, electrical conductivity of ECAs is dramatically improved (Chen et al. 2007).

The dimension of metal fillers in ECAs critically determines their electrical conductivity. As explained above, the conventional filler is metal particles (0 dimensional), and different dimensional fillers such as nanowires and nanorods (1 dimensional) are regarded as promising conductive fillers, since they can provide electrical percolation at relatively low concentrations (Wu et al. 2007). Figure 12 shows the examples of different dimensional silver fillers.

Chen et al. reported the incorporation of silver nanowires into ECAs (Chen et al. 2010). It was found that the electrical conductivity of the system composed with silver nanowires and nanoparticles is higher than that with either one of the two co-fillers (Chen et al. 2010). Zhang et al. reported the sintering characteristics of ECAs filled with surface-modified silver nanowires (Zhang et al. 2011). The sintering of silver nanowires can form high electrical conductivity of the ECAs although the high temperature of heat treatment is not suitable for most epoxy adhesives (Zhang et al. 2011). Yang et al. described a novel formulation method for a high-performance ECA which consisted of silver nanorods, nanoparticles, and modified epoxy matrix (Yang et al. 2012). The ECA film was able to achieve low resistivity of  $3\text{--}4 \times 10^{-5} \Omega \text{ cm}$ .

### 50.3.2 Carbon-Based Nanomaterials

To meet the requirements for high-performance electronic devices, ECAs are required to achieve high electrical conductivity at lower filler contents. Recently,

**Fig. 11** Illustration of conductive paths for ECAs filled with (a) silver nanoparticles and (b) silver nanowires

**Fig. 12** Field-emission scanning electron microscope images of (a) silver nanoparticles and (b) silver nanowires

**Fig. 13** Transmission electron microscopy images of (a) the graphene flakes and (b) multi-walled carbon nanotubes

many efforts have been devoted to obtaining high conductivity of ECAs with low silver loading by introducing the carbon-based nanomaterials such as carbon nanotubes (CNTs) and graphene into the conventional formulation of ECAs. Figure 13 shows examples of representative carbon-based nanomaterials.

CNTs are one of the ideal reinforcing carbon-based nanomaterials for enhancement of polymer composites because of their intrinsic marvelous physical, electrical, and thermal properties. Addition of CNTs can improve the mechanical properties as well as the electrical conductivity. However, the introduction of CNTs into ECAs has significant challenges in processing, dispersion control, and their high cost (Yim et al. 2016). Graphene is also one of the promising conductive fillers which can provide more stable electrical networks for ECAs' application. It is confirmed that graphene is much more effective than other carbon-based filler materials. However, the agglomeration problem of carbon-based filler materials including CNTs and

graphene leads to other problems such as increase in viscosity and poor dispersion, which cause the outstanding properties to be suppressed, resulting in the ECAs with minimal performance improvement (Amoli et al. 2015). To overcome these problems, (1) surface modification of graphene using organic materials (to exfoliate graphene in which the interaction occurs via either covalent bonding or via  $\pi$ - $\pi$  stacking) (Kim et al. 2012) and (2) surface decoration of graphene with inorganic nanoparticles (incorporation of silver nanoparticle-decorated graphene to reduce the tunneling resistance) (Amoli et al. 2015) have been suggested.

### 50.3.3 Hybrid Nonmetallic Fillers (Conductive Polymers and PEDOT:PSS)

This approach to improve the electrical conductivity of ECAs is mixing with conventional ECAs with conductive polymers such as polypyrrole (PPy) (Mir and Kumar 2010), polyaniline (PANI) (Desvergne et al. 2011), and polypoly (3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) (Chueh et al. 2015). The electrical conductivity of conductive polymers are determined by the loading, dispersion, and geometry (shape and diameter) of conductive fillers, degree of resin curing, and cross-link density, and so forth (Lilei et al. 1999; Kim and Shi 2001; Lee et al. 2005). Chemical structures of the representative electrically conductive polymers are shown in Fig. 14.

PPy is one of the promising conductive polymers for ECAs due to ease of synthesis, stability, and low cost (Mir and Kumar 2010). PPy has been modified with other polymers to form composites and improve its processing properties which

**Fig. 14** Schematic of the representative electrically conductive polymers: PPy, PEDOT, PSS, and PANI

enable to provide better electrical performance such as smooth percolation curves. Mir et al. reported the composite manufactured by blending PPy with epoxy was utilized as ICAs, and their electrical conductivity, impact properties, and thermal and morphological characteristics were demonstrated with various concentrations of PPy in the epoxy matrix (Mir and Kumar 2010).

PANI is also a suitable conductive polymer for improving the properties of the conventional ECAs owing to its high polymerization yield, good environmental stability combined with moderate electrical conductivity, and low cost. Mir et al. presented the composite of PANI in an epoxy/anhydride matrix, which is suitable as ICAs with enhanced impact properties and conductivity (Mir and Kumar 2010). Gumfekar et al. reported the reduced percolation threshold and enhanced conductivity of the silver-PANI-epoxy system via improved dispersion of silver fillers (Gumfekar et al. 2011).

PEDOT:PSS has recently been studied and is emerging as a major attraction for next commercial ECAs. Chueh et al. reported ECAs comprising of the silver-plated graphite powder, PEDOT:PSS, and organic additives improved the electrical conductivity by at least two orders of magnitude compared with those filled with graphite powders only (Chueh et al. 2015).

---

## 50.4 Specific Requirements

There are at least three important requirements for the application of conductive adhesives in the electrical industry. The first one is the electrical resistance. Because of the typical low electrical conductivity of the polymer materials, a high electrical conductivity or low resistivity is definitely the most important factor for the conductive adhesive. Secondly, we should carefully consider the thermal properties of the adhesive. The bonding process with the adhesives is optimized by their thermal properties, e.g., their  $T_g$  and curing behavior. Finally, we would like to discuss in this chapter the thermomechanical properties of the adhesives. The thermomechanical properties determine the long-term reliability of the adhesive interconnect, so it is necessary to review how the thermomechanical properties can be measured and the results analyzed.

### 50.4.1 Electrical Conductivity

When two metallic conductive pads are electrically interconnected by an adhesive, there is a large difference in their electrical conductivity in comparison with solder-bumped interconnects. The solder-bumped joint is based on the melting of the solder and chemical reaction between the solder and metallic pad. In this case, some chemical compounds such as intermetallic compound layers form at the interface, which makes it possible to fill the interface without any large gap remaining.

Therefore, the electrical resistance of the solder joint largely depends on the bulk resistance of the constituent components, e.g., the metal pad used for bonding, intermetallic compounds, and solder. However, in the case of adhesive interconnects, the joining process is essentially based on the mere physical contact between the pad and pad or pad and conductive fillers included in the electrically conductive adhesives. When two conductors are connected by a mere physical contact, the interfacial resistance, i.e., the contact resistance, is much larger than the bulk resistance when a current is flowing through the joint pathway. Therefore, the calculation or exact measurement of the contact resistance is a key point to evaluate the electrical conductivity of each adhesive interconnect. There are three main types of electrically conductive adhesive interconnects, all of which include bulk resistance and contact resistance components. Here, we will discuss the electrical conductivity of the adhesive joint with a simple derivation of the total resistance of the ACA interconnect.

When a spherical particle meets a metallic pad, there are three separate contributions to the resistance: the intrinsic conductive resistance of each particle, the constriction resistance at the contacts, and the tunneling resistance at the contacts (Holm 1979; Ruschau et al. 1992). Therefore, the connection resistance through the conductive particles,  $R_c$ , is expressed by

$$R_C = R_i + R_{CR} + R_f \quad (1)$$

where  $R_i$  is the intrinsic resistance of an individual particle,  $R_{CR}$  is the constriction resistance caused by the bending of the current flow paths, and  $R_f$  is the tunneling or film resistance associated with any insulating film which may be covering each metallic surface. At the point of contact between the conducting particles and the metallic bumps or pads, the majority of the current will flow through the areas of metal-to-metal contact. Thus, the current is constricted to flow through these areas, and the resistance will therefore be higher than if the current were passing directly through a straight path with no constriction. The resistance increase caused by this structure is called the constriction resistance. Some examples of insulating films in which tunneling behavior is observed are oxidation layers, residues of resin in the adhesives, and contaminants on the metal films. The electrical conduction must then proceed across these gaps, which represent electrical potential barriers to conduction. Therefore, tunneling is needed to allow conduction between the electrodes. Tunneling is a process by which electrons on one side of the barrier jump to the other side without any energy input, in which case the resistance increase caused by the potential barriers is called the tunneling resistance.

Among the contributions to the connection resistance described above, the intrinsic resistance of an individual conductive particle can be estimated with respect to its deformation. Since the metal-coated conductive particles are deformed plastically during the bonding process of an ACF, the numerical model for the calculation of the connection resistance should consider the plastic deformation of the conductive particles. Yim and Paik (1998) derived the connection resistance of an ACF joint

**Fig. 15** Deformation model of the conductive particle: (a) before deformation and (b) after deformation

from Holm's electrical contact theory, and the derived model described the connection resistance of the ACF in terms of the sample geometry, particle size, applied pressure, and the intrinsic properties of the conductive particles. However, this model is valid only for the elastic deformation of the conductive particles; therefore, it cannot reflect their plastic deformation. For a more exact prediction of the connection resistance, the plastic deformation of the conductive particles should be considered. Maattanen (2003) derived the connection resistance of metal-coated polymer particles using the degree of deformation during the bonding process of an ACF. He described the degree of deformation as

$$\text{Degree of deformation} = 1 - \left( \frac{h}{2R} \right) \quad (2)$$

where  $h$  is the distance between the electrodes and  $R$  is the radius of the undeformed conductive particles which are shown in Fig. 15. The area of the spherical cap forms the metal contact area, and, therefore, the metal contact area,  $A$ , and the length of the conductor,  $l$ , are given as

$$A = 2\pi R^2 \left( 1 - \frac{h}{2R} \right) \quad (3)$$

$$l = \frac{\pi h}{2} \quad (4)$$

However, since the current would flow only through the thin metal layer of the conductive particles, the average area of the metal film should be calculated. The average area can be derived as follows:

$$\begin{aligned}
\left(\frac{1}{A}\right) &= \frac{\int_0^{\pi h/4} \frac{dS}{2\pi t R \cos \alpha}}{\int_0^{\pi h/4R} dS} \\
&= \frac{\int_0^{\pi h/4R} \frac{d\alpha}{2\pi t R \cos \alpha}}{\int_0^{\pi h/4R} d\alpha} \\
&= \frac{4R}{\pi h} \frac{1}{2\pi t R} \int_0^{\pi h/4R} \frac{d\alpha}{\cos \alpha} \\
&= \frac{2}{\pi^2 h t} \int_0^{\pi h/4R} \left[ \ln \tan \left( \frac{\pi}{4} + \frac{\alpha}{2} \right) \right] \\
&= \frac{2}{\pi^2 h t} \ln \tan \left[ \frac{\pi}{4} \left( 1 + \frac{h}{2R} \right) \right]
\end{aligned} \tag{5}$$

476

477 where  $r = R \cos(\alpha)$ ,  $S = R\alpha$ ,  $dS = R d\alpha$ , and  $t$  is the thickness of the metal layer on  
 478 the particle. For  $\alpha$ , see Fig. 15.

479 Since there is spherical symmetry, an approximation can be made, and the  
 480 problem is solved using Ohm's law, and the formula for the intrinsic resistance of  
 481 the deformed particle,  $R_i$ , is written as follows:

$$R_i = \rho \frac{l}{A} = \rho \frac{\pi h}{2} \left( \frac{1}{A} \right) = \frac{\rho}{\pi t} \ln \tan \left[ \frac{\pi}{4} \left( 1 + \frac{h}{2R} \right) \right] \tag{6}$$

482 where  $\rho$  is the resistivity of the metal coating.

483 In electrical interconnects made using ACAs, electrical conduction is provided by  
 484 the conducting particles trapped within the interconnection area. At the point of  
 485 contact between the conducting particles and the metallic bumps or pads, the  
 486 majority of the current will flow through the areas of metal-to-metal contact. Thus,  
 487 the current is constricted to flow through these areas, and the resistance will,  
 488 therefore, be higher than if the current were passing directly along a straight path  
 489 with no constriction. This resistance is called the constriction resistance. According  
 490 to Holm (1979), the constriction resistance,  $R_{CR}$ , can be written as

$$R_{CR} = \frac{(\rho_1 + \rho_2)}{2d} \tag{7}$$

491 where  $\rho_1$  and  $\rho_2$  are the intrinsic resistivities of the conductive particles and  
 492 substrate, respectively, and  $d$  is the diameter of the metal contact area. Looking  
 493 closer at the diameter of the contact area in different compression situations, it  
 494 is possible to derive a formula for it in the case of metal-coated polymer  
 495 particles. The area is a spherical cap of the conductive particle where the size  
 496 is a variable depending on the degree of deformation. The formula for the metal  
 497 contact area is

$$\pi \left( \frac{d}{2} \right)^2 = 2\pi R^2 \left( 1 - \frac{h}{2R} \right) \quad (8)$$

Therefore,

$$d = R \sqrt{8 \left( 1 - \frac{h}{2R} \right)} \quad (9)$$

Substituting Eq. 9 into (7) yields

$$R_{CR} = \frac{(\rho_1 + \rho_2)}{2R \sqrt{8 \left( 1 - \frac{h}{2R} \right)}} \quad (10)$$

For contacting materials that form metal-to-metal contacts and that do not oxidize, the tunneling resistance,  $R_f$ , is zero. This oxidation problem is considered a special case, and, therefore, we can neglect the oxidation term in this simple derivation. Finally, according to the schematic of an ACF interconnection, the connection resistance,  $R_c$ , considering the plastic deformation of a metal-coated polymer sphere is described by

$$R_c = R_{CR-1} + R_{CR-2} + R_i = \frac{(\rho_1 + \rho_2)}{2R \sqrt{8 \left( 1 - \frac{h}{2R} \right)}} + \frac{(\rho_1 + \rho_3)}{2R \sqrt{8 \left( 1 - \frac{h}{2R} \right)}} + \frac{\rho_1}{\pi t} \ln \tan \left[ \frac{\pi}{4} \left( 1 + \frac{h}{2R} \right) \right] \quad (11)$$

where  $R_{CR-1}$  and  $R_{CR-2}$  are the constriction resistances generated between the conductive particle and the two electrodes,  $\rho_1$  is the resistivity of the conductive particles, and  $\rho_2$  and  $\rho_3$  are the resistivities of the electrodes.

Using this derivation, the connection resistance of the ACA interconnect can be easily calculated by the simple investigation of the physical shape of the connected pathway. This derivation is based solely on the physical contact of the two unmelted metals, so it could be applied to the other two types of adhesives, i.e., ICAs and NCAs. In the case of ICAs, the shape of the current flowing path is more complex, which means that the contact resistance might also be more complex than that in the ACA case. However, the resistance components of an ICA interconnect are completely identical to those of an ACA interconnect, so the derivation and calculation of the components are also easy to perform. In the case of an NCA, there are no conductive fillers and, therefore,  $R_{CR}$  and  $R_i$  can be excluded from the derivation. This means that the connection resistance for an NCA joint consists only of  $R_f$ , so that the resistance should also be lower than that of an ACA joint.

In summary, the electrical conductivity of adhesive joints is dominated by the physical contact between the two unmelted conductive materials, and, therefore, the

resistance of the joint seems to be nearly equal to the contact resistance. Among the various adhesives, ACAs are considered to be the least conductive materials, and the resistance is controlled by the joint structure and constituent materials.

## 50.4.2 Thermomechanical Properties

According to various previous studies concerning the bonding process for the joining of adhesive electronic components, it was reported that the electrical properties of the ACF flip chip package are highly affected by the bonding temperature and pressure. Especially, the contact resistance of the adhesive joints is highly correlated with the deformation of the metal bump or conductive fillers induced by the pressure applied during the bonding process. This is because if the conductive fillers are too spread out between adjacent bumps or pads, due to too much pressure being applied, they may end up contacting each other, creating the same effect as short-circuiting; whereas if the bonding pressure is too low, the particles may not be able to make contact between the connecting bumps and pads. After the complete bonding process, the adhesive joints are established by the compressive forces generated by the shrinkage stress in the adhesive matrix. The shrinkage stresses originate from the thermomechanical properties of the adhesives, such as the thermal shrinkage and thermal stiffness generated during or after the thermal reaction (Kwon and Paik 2004; Yu et al. 2013). This shrinkage stress, influenced by the thermal shrinkage and buildup stiffness, is responsible for the contact integrity in an adhesive joint, and, therefore, the evaluation of the shrinkage behavior is very important for the optimization of the bonding process. Generally, the shrinkage stress is generated by the curing reaction of the adhesives, which means that the thermal and thermomechanical behavior of the adhesives during heating and cooling should be evaluated before the application of the adhesives in electronics.

The first parameter we should examine is the degree of curing of the adhesives containing  $T_g$  and the reaction ratio during heating and cooling. Kwon and Paik (2004) described the evaluation of the degree of curing of an ACF joint with a differential scanning calorimeter (DSC). They defined the term, degree of curing, as follows:

$$\text{Degree of cure} = \frac{\Delta H(\text{uncured adhesives}) - \Delta H(\text{heated adhesives})}{\Delta H(\text{uncured adhesives})} \times 100 \quad (12)$$

Figures 16 and 17 present an example of the DSC measurement curves for an ACF and NCF. From Fig. 16, we can obtain the  $T_g$  information of the ACF and NCF employed, while the degree of curing is calculated using Fig. 17. Generally, for electronic applications, faster curing with a lower  $T_g$  is favorable for various reasons, such as the impact of a high temperature on other nearby components, the deviation of the process temperature from the conventional reflow profile for solder joining, and the manufacturing efficiency. Especially, from the viewpoint of the impact on nearby components, the  $T_g$  of the adhesive is highly correlated with its applicable

**Fig. 16** Comparison of heat flow with temperature between ACF and NCF

**Fig. 17** Comparison of curing degree with time between ACF and NCF

561 areas in electronics. That is, the bonding temperature is determined by the thermal  
562 stability of the nearby components, e.g., the substrate. For example, in display  
563 applications, a glass panel is used as a substrate, which means that the bonding  
564 temperature can be as high as 400 °C. However, polymer-based plastic substrates are  
565 typically used in printed circuit board (PCB) applications, where the bonding

temperature must be less than the  $T_g$  of the substrate, which is generally less than 200 °C. Therefore, adhesives with a lower  $T_g$  would be more favorable due to their wider range of applications.

As shown in Fig. 17, the degree of curing might also be different between adhesives consisting of different materials. The degree of curing determines the bonding time for adhesive joining, so that the manufacturing efficiency is highly related to this factor. For flip chip joining with adhesives, a chip with numerous metal bumps should be aligned on a substrate, e.g., glass, printed circuit board (PCB), or flexible polyimide-based one. After aligning the chip, a certain bonding force is applied to the chip to generate a compressive force in the adhesive area. At this time, the temperature is raised to that required for curing, which is typically 30–50 °C higher than the  $T_g$ . At this stage, the adhesive resin starts to undergo the curing reaction, which increases its viscosity and modulus, due to the development of a cross-linking structure. Both the bonding force and temperature are continuously applied in order for the adhesive to be fully cured. After the adhesive resin is fully cured, the bonding force is removed, and the assembly is cooled to room temperature. During the cooling process, shrinkage stress can develop, due to the thermal shrinkage and buildup of stiffness of the ACFs. Although the external bonding force is removed after the bonding process, the electrical conduction of the ACF joint is mechanically maintained by the compressive force due to the thermal shrinkage of the ACF (Kwon and Paik 2004). Referring to Fig. 17, it can be seen that a shorter time for full curing is favorable for the efficient joining of electronic components.

Next, we should examine the thermomechanical properties through the measurement of the coefficient of thermal expansion (CTE) of the adhesives. The CTE values can be obtained by the measurement of the length deformation with temperature (Noh et al. 2008). The length deformation can be measured by using a thermomechanical analyzer (TMA). Generally, the smaller the length deformation with temperature, the higher the CTE value. It is anticipated that the CTE value of an adhesive will determine the thermomechanical reliability of the electronic interconnect with the adhesive, that is, the similarity of the CTE values of the adhesive and the substrate and other nearby components is favorable for its long-term reliability. If the CTE of the adhesive is significantly different from those of the nearby components, the resulting mismatch of the CTE values may give rise to certain kinds of reliability problems, such as the thermomechanical fatigue cracking of the material, delamination of a layer, and unstable electrical contact between the metals. Therefore, for the design of a new adhesive material, the CTE values of its constituent materials should be carefully considered, and reliability testing with a fully fabricated sample or a computer simulation is essential to verify its acceptability for the application.

---

## 50.5 Reliability

The short-term quality and long-term reliability are always the most important considerations to determine the value of materials. Typically, it is considered that the best method of evaluating the reliability of an electronic component is an actual

application (Lau 1995). However, this is not always practical, especially during process development and optimization. Therefore, the reliability behavior of an interconnection is characterized by performing accelerated environmental tests, such as temperature cycling, thermal shock, high and low temperature storage, and high temperature and humidity testing. According to some previous studies, the main degradation mechanisms include the oxidation of the metal surfaces in the joint, stress concentration at a certain area during temperature fluctuations, and so on (Li and Wong 2006). Here, we will review the various reliability testing methods for adhesive interconnects, beginning with an introduction to test vehicle design for adhesive interconnects.

### 50.5.1 Test Vehicle Design

Basically, the test vehicle for the accelerated testing should resemble the real components or interconnect systems. That is, the test vehicle design must be such that it can be processed using all the technologies of interest. In addition, the ability to change the wafer layout, such that the user has flexibility in selecting an appropriate chip size for the application, is sometimes desirable to evaluate its technological capability (Lau 1995). Adhesives are used to join various systems in electronic manufacturing, e.g., Si die bonding to rigid printed circuit board (flip chip application), Si die bonding to flexible substrate (COF, chip on flexible substrate), Si die bonding to glass substrate (COG, chip on glass), rigid printed circuit board to flexible substrate, and so on. Therefore, proper test vehicle design is possible only after the consideration of the real application of the adhesives developed. After considering the application, the materials used for the chip, substrate, metal bump for joining, the number of bumps on a die, pitch of bump array, and bump array specification can be easily determined in the case where the target application is definite. Then, we should design conductive metal circuits of the test vehicle, in order to measure the total resistance of the circuits or a single bump interconnect.

Figure 18 shows an example of the test vehicle used for the reliability testing of the adhesives. As can be seen in the figure, the test vehicle is fabricated by joining an Si die to a flexible substrate that is typically made from polyimide. An adhesive film, ACF, was used for the joining process. This design is called the COF, and it is widely used in the manufacture of display modules such as liquid crystal displays (LCDs). Enlarged views of the test circuits are shown in Fig. 19. In the design of conductive circuits for electrical evaluation, it is important that we measure or calculate the resistance of only the adhesive interconnects, which consist of a metal bump on a die, adhesive, and metal pad on a substrate, excluding the resistance of any conductive traces on the Si die or substrate. This is possible if we apply the four-point electrical resistance measurement system with a proper design using the so-called Kelvin structure.

Figure 20 shows a schematic description of the Kelvin structure for the selective electrical characterization. This structure contains four metal bumps and pads for adhesive joining. The traces used as the voltage sense and current sense can be interchanged. The principle of operation of this structure is fully described in the

**Fig. 18** Test vehicle sample for reliability testing of adhesive interconnects

**Fig. 19** Scanning electron microscope image for surface of flip chip test vehicle

literature (Lau 1995) and is briefly introduced here as follows. Let us assume that the current flows through trace A, through bump 1, over the trace on the die, down bump 2, and out of trace B. It should be noted that traces C and D have no current flowing through them. Furthermore, trace C and bump 3 are at the same potential as the bottom of bump 2. Also, trace D and bump 4 are at the same potential as the top of bump 2. Therefore, any potential difference measured across traces C and D would represent the potential drop across bump 2. Given the current flowing through bump 2 and the measured potential difference across traces C and D, the bump resistance may be readily estimated.

**Fig. 20** Schematic description of four-point measurement for Kelvin structure design

**50.5.2 Storage Test in Harsh Environments**

The past few years have witnessed explosive growth in the research and development efforts devoted to the improvement of adhesive joint reliability for mobile electronics. In the evaluation of the reliability, it is emphasized that the following must be noted in order to obtain a full understanding of the adhesive technology. To investigate the reliability of adhesives in an electronic component, the stability of the connection resistance of a single interconnect in the specific electrical system under environmental stress should be evaluated. Therefore, the design and fabrication of the test vehicle are essential prerequisites. Then, the environmental conditions to use for the reliability testing should be selected. Various testing methods are generally selected for the evaluation of adhesive interconnects, ranging from the reflow test to the pressure cooker test (PCT). Here, we will review the various environmental test methods and their failure analysis techniques.

The reflow test is typically conducted to evaluate the thermal stability of adhesive interconnects. Reflow is the process of melting and cooling of the solder placed on a substrate for joining various component electrodes to metal pads. Today, adhesive interconnection technology is also applied to join ICs to a PCB, and, therefore, these kinds of products are packaged with adhesive technologies together with the conventional reflow process. In these soldering processes, the package needs to be heated up to above 200 °C, which is much higher than the final bonding temperature of the adhesive interconnection. Therefore, the development of adhesives which can withstand multiple solder reflows was a major milestone in the process of its acceptance within the semiconductor packaging industry (Kim et al. 2008a). Figure 21 shows a reflow machine for soldering, and Fig. 22 shows a typical temperature profile for the reflow of Sn-based Pb-free solders.

Thermal shock and temperature cycling tests are typically employed to evaluate the ability of the adhesive interconnect to resist the temperature variation during the operation of the electrical system. The adhesives in an electronic package serve as a mechanical mechanism for resisting the thermal deformation induced by the CTE mismatch between the upper chip and lower substrate. The thermally induced

**Fig. 21** Reflow machine (RF-430-N2, Japan Pulse Laboratory Ltd. Co., Japan)

**Fig. 22** Reflow temperature profile for Sn-based Pb-free solders

fatigue cracking through a constituent material and the delamination of the adhesive from the attached area, resulting from the mismatch in the CTE of the chip and substrate, are the major wear-out failure modes in adhesive joints. The thermal fatigue process involves microcrack initiation and coalescence followed by crack propagation. Figure 23 shows an example of a catastrophic failure mode of adhesive interconnect after thermal shock testing. The thermal shock test is an accelerated test form of the temperature cycling test. The thermal shock test controls only the highest and lowest temperatures in the testing zones, and then moves the position of the test samples from the first zone to the other, which means that the samples experience a very abrupt temperature variation during the testing. Meanwhile, the temperature cycling test controls the total temperature profile, so that the test samples can experience milder temperature variations. The detailed test methods for the test of electronic components are provided by the Joint Electron Device Engineering Council (JEDEC) standards. Figure 24 shows an example of a thermal shock testing chamber.

**Fig. 23** Failure mode for ACA interconnect after thermal shock testing

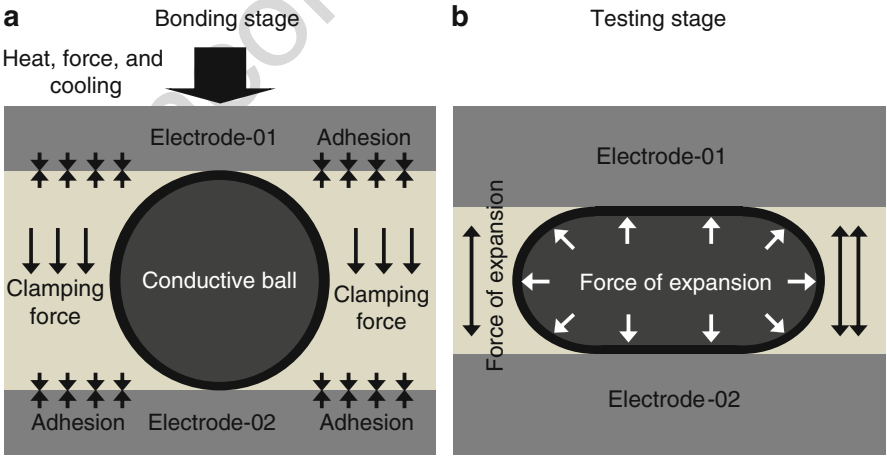

**Fig. 24** Thermal shock testing chamber (TSA-101S, Espec, Japan)

The high and low temperature storage test is also typically used to evaluate the ability of the adhesives to resist a harsh environment. In this case, the temperature variation is not included in the testing profile, so the test evaluates the effects of a fixed environmental temperature on the stability of the electrical system. Conventionally, this test was widely conducted to investigate the effects of a certain

temperature on the growth behavior of an intermetallic compound layer, which is a reaction layer formed between a solder and a metal substrate during a reflow process. However, it is also employed to evaluate the impact of long-term storage at a rigorously stabilized temperature on the electrical quality of the adhesive interconnect. The high temperature and humidity test is considered to be one of the most important test methods for the evaluation of adhesive joints, because of their high absorption of humidity. When a sample with an adhesive joint is placed in an environment having high humidity, the swelling of the polymeric conductive fillers in the ACA and z-directional expansion of the adhesive matrix occur. Figure 25 shows this behavior for the example of an ACA joint before and after the high temperature and humidity test (85 °C and 85% relative humidity for 500 h). After the test, no significant defects such as delamination or cracking of the adhesive matrix were evident, but initially the deformed conductive particles swelled upward due to the release of the residual z-directional shrinkage stress and the expansion of the polymeric cores of the conductive particles and adhesive matrix. After the joining process with the adhesives at room temperature, the z-directional stress in the adhesive areas was mainly compressive stress, but it decreased with increasing temperature and humidity. A small compressive stress induces the swelling of the polymer particles and adhesive matrix layer, and ultimately electric disconnection may occur in the worst case. The swollen conductive particles decrease the contact area, and, thus, the electrical connection resistance should increase during the testing.

For the failure analysis of the test samples after the harsh environmental tests, various analysis tools are employed, e.g., scanning electron microscopy (SEM) with a cross-sectional analyzing technique; X-ray microscopy; A-, B-, and C-mode scanning acoustic microscopy (A-SAM, B-SAM, and C-SAM, respectively); and

**Fig. 25** Schematics of stress field around the conductive particle: (a) after bonding, (b) during testing at high temperature and humidity

tomographic acoustic microimaging (TAMI), to analyze the failure samples. The continuous measurement of the electrical resistance should consequently be conducted during all of the environmental tests mentioned above.

### 50.5.3 Mechanical Reliability

The adhesives used in the electronic industry serve not only to provide electronic continuity but also to support the mechanical load experienced during service. Therefore, the mechanical stability of the adhesive joints has been one of the major reliability concerns in electronic assembly technology. The mechanical peeling and shear test of the adhesive joints are typically performed to characterize the bonding strength at the adhesive-substrate interface. These two methods are very simple to implement. That is, the test procedure consists of the detachment of a component bonded with an adhesive on a substrate. During the detachment process, mechanical stress such as shearing or peeling is applied to the component, while the loading applied to a stress sensor is recorded for the characterization of the mechanical stability.

Owing to the increasing demand for portable electronic devices, which are affected by low-frequency and random vibrations, the reliability of electronic packages subjected to repetitive mechanical loads has recently become an important issue in the electronic industry (Noh et al. 2009). In this case, assembly warpage has been recognized as an important factor for determining the package reliability, as it can lead to IC failure, due to the delamination of a layer and cracking through a specific material in the subsequent process caused by dimensional instability and non-coplanarity. In particular, the cyclic bending reliability testing of various packages under different test conditions is widely conducted at the board or system level (Noh et al. 2009). The three-point or four-point bending test is one of the most frequently employed test methods, due to its suitability for testing large package samples under similar loading conditions (bending moments) within the inner load span. Here, we will review the four-point bending test for the evaluation of the mechanical reliability of adhesive joints.

Figure 26 shows a four-point bending tester used for testing a sample with an ACF. The tip of each support consists of a roller to ensure line contact with the test board, as shown in the figure. In this case, the in situ electrical resistance should also be measured, in order to identify the failure of the package during bending testing. The bottom supports are fixed, while the top supports move downward repetitively with the displacement profile prescribed by the sinusoidal movement of the actuator. The top and bottom support spans are fixed at a certain distance apart. For the measurement of the electrical resistance, a current is flowed through the metal circuits and adhesive joints. An event detector is generally used to determine when the overall electrical resistance exceeds a specific value. The experiments are typically performed at room temperature, but could also be done at higher ones. The bending fatigue test can be conducted using the load-control or displacement-control method.

**Fig. 26** Four-point bending tester for adhesive joint

## 50.6 Conclusions

This chapter describes the adhesive technologies used in the electrical industry with an introduction to the conduction mechanisms in adhesive joints, the specific requirements for the application of adhesives in electronics, and reliability evaluation methods. We will summarize this chapter with the following conclusions:

1. There are three types of electrically conductive adhesives typically used in the electrical industry, e.g., isotropic conductive, anisotropic conductive, and non-conductive adhesives.
2. Isotropic conductive adhesives have a large amount of conductive fillers (25–30 vol.%) with the electrical conductivity provided by the contact between the conductive fillers.
3. Anisotropic conductive adhesives are similar to isotropic conductive adhesives, except that they have a lower conductive filler content (5–20 vol.%) and thus provide unidirectional conductivity in the vertical or z-direction (perpendicular to the plane of the substrate).
4. Non-conductive adhesives have no conductive fillers but rather maintain a pure mechanical contact between the bumps and pads, due to the application of a compressive force, and it is this that ensures the electrical connectivity between them.
5. Considering the drawbacks of conductive filler materials in conventional ECAs, there are three major approaches to enhance the electrical conductivity and thermomechanical properties, which include (i) hybrid metallic fillers, (ii) carbon-based nanomaterials, and (iii) hybrid nonmetallic fillers: conductive polymers and PEDOT:PSS.
6. The conductivity of electrically conductive adhesives is described by percolation theory, which explains that the resistivity of an adhesive drops dramatically at a certain vol.% of conductive fillers.

7. The connection resistance at the interface between the adhesives and metal bumps is composed of three resistance components, i.e., the intrinsic resistance of the constituent materials, constriction resistance, and tunneling resistance.
8. Shrinkage stress is generated by the curing reaction of the adhesives, which means that the thermal and thermomechanical behavior of the adhesives during the bonding process should be evaluated before their use in electronics.
9. For the reliability testing of adhesives in electronics, a test vehicle for accelerated testing should be fabricated, which resembles the real components or interconnect systems. This means that the design of the test vehicle must be such that it can be processed using all of the technologies of interest.
10. Various testing methods are employed to evaluate the reliability of adhesives in electronics, such as temperature cycling, thermal shock, high and low temperature storage, and high temperature and humidity testing.
11. The mechanical peeling and shear tests of the adhesive joints are typically performed to characterize the bonding strength at the adhesive-substrate interface.

**Abstract**

This chapter constitutes one of the very few reviews in the existing literature on shoe bonding, and it gives an updated overview of the upper-to-sole bonding by using adhesives. The surface preparation of rubber soles and the formulations of the solvent-borne and waterborne polyurethane and polychloroprene adhesives are described in more detail. The preparation of the adhesive joints and the specific adhesion tests in shoe bonding are also revised. Finally, the most recent developments dealing with shoe bonding are described.

## 51.1 Introduction

The attachment of the upper to the sole by means of adhesives in shoe manufacturing is one of the most exigent bonding technologies. Several different types of materials are used in shoe manufacturing most of them varying in nature and composition from year to year because of fashion requirements. Furthermore, the geometrical shape and the design of the upper and the sole change often in male and female shoes, and several models and kinds of shoes can be manufactured (casual shoes, sport shoes, boots, safety shoes, sanitary and orthopedic shoes). For each shoe, bonding must be specifically designed, and this situation happens twice a year (spring and fall seasons in shoe industry). This is one of the reasons for the difficulty in establishing unified methodologies for shoe bonding as there is no time for shoe manufacturers to react once debonding appears, i.e., the upper and the sole separate during use (Fig. 1).

Another particular feature in shoe industry is the lack of quality control of the materials and the adhesives used for bonding. Shoe manufacturers have extensive knowledge on the technology of making shoes, but their knowledge on bonding comes mainly from the experience and the advice of the adhesive manufacturers. Certainly, the bonding of the shoe parts is more of an art than a technology, and the shoe manufacturers are always worried and even scared when they have to attach the upper to the sole in the new models of shoes in the season. In fact, it is a common practice in several famous shoe brands to sew the upper to the sole simply because they do not trust in the quality of the adhesive bonding!

The above given arguments justify the writing of a review on the bonding of shoe industry based mainly on the experience of the author in the field acquired during more than 25 years.

The bonding with adhesives has been introduced in the footwear industry as an alternative to sewing or the use of nails, staples, or tacks to bond several parts of the

**Fig. 1** Upper-to-sole detachment in a shoe

shoes, the most critical part being the upper-to-sole bonding. The introduction of adhesive technology in shoe manufacturing provided several advantages: (i) More flexible and homogeneous joints were obtained; (ii) the stresses during use were similarly distributed all along the joints; (iii) improved aesthetic properties were obtained, and new design and fashion shoes were possible; and (iv) automation was feasible. However, as a limitation, the bonding with adhesives in shoe industry needs a severe control of all steps involved in the formation of the joints to avoid adhesion problems, mainly the separation of the sole from the upper. Although several parts of a shoe are bonded with adhesives (mounting, heel covering, box toe bonding, sticking of the soft lining, lift attachment, shank and cushion bonding, etc.), this chapter will be devoted only to the upper-to-sole attachment because it is the most critical bonding operation in shoe manufacturing.

Depending on the type of shoe, different bonding performance is required. Due to fashion issues, the bonding of the casual and the free-time shoes is relatively low exigent as the requested durability is not too high (3 years maximum). However, the sport shoes are extremely exigent in bonding as low weight, high performance under impact and flexural stresses, high comfort, and high durability are mandatory requirements. Safety shoes are the most exigent in terms of bonding because they have to work in the presence of solvents, high or low temperature, high-impact resistance, and all these should last for a long time.

There are not many reviews in the existing literature dealing with the adhesive bonding in shoe industry. Some Spanish books (Diputación de Alicante 1974; Amat-Amer 1999) devoted to shoe industry include some basic technical chapters dealing with the use of the adhesives for bonding operation, but they have not been translated to English. In the 1960s and 1970s, the Prüf- und Forschungsinstitut Pirmasens (PFI) in Pirmasens (Germany) (Fisher and Meuser 1964; Fisher 1971) and the Shoe Allied Trade Research Association (SATRA) in Kettering (England) (Pettit and Carter 1973) published excellent reports dealing with several specific aspects of the adhesive joints in shoe industry. More extensive literature dealing with the solvent- and waterborne polyurethane adhesives used in shoe industry has been published (some to be cited are Pettit and Carter 1973; Schollenberger 1977; Dollhausen 1985; Kozakiewicz 1991; Sultan Nasar et al. 1998; Frisch 2002), but minor attention has been paid to polychloroprene adhesives (some to be cited are Whitehouse 1986; Kelly and McDonald 1963; Harrington 1990; Guggenberger 1990; Lyons and Christell 1997; Martín-Martínez 2002). On the other hand, the surface preparation procedures of the upper and sole materials for shoe bonding have been widely considered in the literature (some to be cited are Oldfield and Symes 1983; Extrand and Gent 1987; Hace et al. 1990; Fernández-García et al. 1991; Lawson et al. 1996; Cepeda-Jiménez et al. 2002).

Most of the books devoted to footwear consider only a chapter devoted to adhesives or surface preparation of materials before bond formation, but rarely both aspects are described in the existing literature, and the understanding of the complex nature of the bonding process in shoe manufacturing is almost absent. A previous chapter written by the author dealing with shoe bonding was published in 2005 (Adams 2005), and the present chapter is an update of that chapter in which the

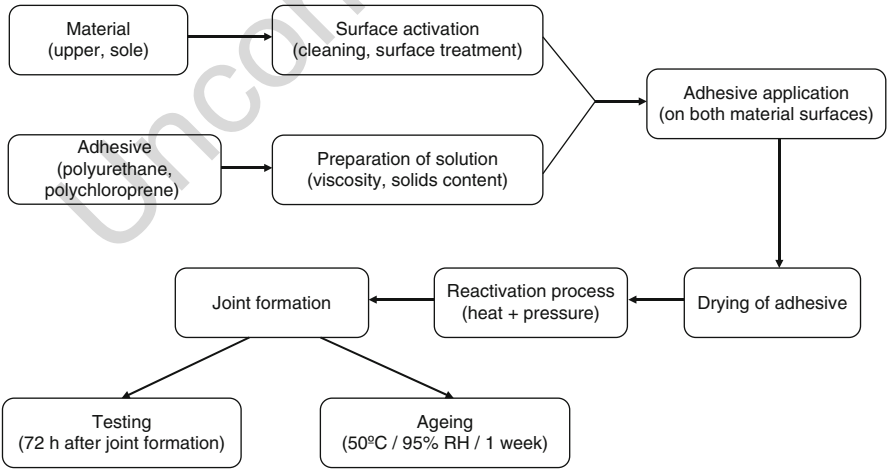

most recent scientific contributions have been addressed. Recently, a review dealing with the use of adhesives in the footwear industry has been published (Paiva et al. 2016). Obviously, the reader will find some similarities between the two chapters written by the author, but as a comprehensive updated view on shoe bonding is given, the reading of this chapter will certainly compensate for it.

This chapter is divided into four sections. The first section provides an overview of the bonding in the shoe industry. Conventional surface preparation of different sole and upper materials is described in section two, with special attention to the chlorination of rubber soles by using organic solvent solutions of trichloroisocyanuric acid. Both solvent-borne and waterborne polyurethane and polychloroprene adhesives are described in detail in section three with special reference to their formulations. Finally, the testing, the quality control, and the durability of the adhesive joints in shoe bonding are considered in section four.

## 51.2 Overview of the Shoe Bonding Process

Although each shoe may be constituted by materials of different nature with different shapes and the adhesives commonly used are polyurethane or polychloroprene adhesives, to produce an adequate bonding, the different operations/steps given in Fig. 2 must be followed.

The first operation consists in the surface preparation of the materials to be bonded (upper and sole). Irrespective of the inherent difficulty of bonding these materials, solvent cleaning and roughening are generally carried out. For difficult-to-bond materials, more aggressive chemical surface treatments and/or primer application are mandatory. Once the materials are ready for bonding, the adhesive is

**Fig. 2** Schematic overview of the bonding process in shoe manufacturing (upper-to-sole attachment)

prepared by adjusting its viscosity and by adding isocyanate hardener, mainly for improving the durability of the adhesive joints. The application of the adhesive is a critical step to reach good bonding as the method of application (brush, roller, etc.), and the amount of adhesive determine the success of the joint; the adhesive is usually applied to both materials to be bonded, and, therefore, contact adhesives are used (reactive polyurethane hot melts are an exception because of they are applied on the sole only). The next step in the joint formation consists in the evaporation of the most solvent of the adhesive on the surfaces to be bonded, and because of the absence of tack, reactivation (i.e., sudden heating with infrared or halogen lamps) of the adhesive layers is carried out followed by immediate joining of the melted adhesive films applied on the two materials to be bonded followed by the application of pressure for a given time. Finally, the joints are cooling down before placing the shoe in the box.

Interestingly, green adhesion is a critical issue for shoe manufacturers. It is a general practice to place the thumb nail at the shoe front and try to separate the adhesive joint. If the joint resists the press of the thumb nail, the joint is considered acceptable. If it is not the case, sewing is a common practice!

In terms of the mechanisms of adhesion (see ► [Chap. 2, “Theories of Fundamental Adhesion”](#)) involved in upper-to-sole bonding, mechanical interlocking is important. Considering that most of the upper materials are porous and the adhesives used in shoe bonding are applied as liquids, an acceptable penetration of the adhesive into the upper is expected, and then the mechanical adhesion is generally favored. However, because several synthetic sole materials are nonporous and have in general a relatively low surface energy, both mechanical (e.g., roughening) and chemical (e.g., halogenation) surface preparations are necessary, and enhanced chemical adhesion is required. Therefore, the main mechanisms of adhesion involved in shoe bonding are mechanical interlocking and chemical. Furthermore, in the bonding of some rubber soles, the weak boundary layers produced by surface contaminants and/or by migration of antiadherend moieties to the interface during joint formation must be removed before joint formation.

In the following sections, the materials and their surface preparation prior to be bonded, the adhesives used, and the manufacture and testing of the upper-to-sole joints will be separately discussed. Each section will consider an overview of the current state of the art in shoe industry, and future trends will be highlighted too.

---

### 51.3 Surface Preparation of Upper and Sole Materials for Bonding

Depending on fashion, each year different materials have been and are currently used in the manufacturing of shoes, including the rubber soles (vulcanized styrene–butadiene rubber (SBR), thermoplastic rubber, ethylene propylene diene monomer (M-class) rubber (EPDM)) and different polymeric materials (leather; polyurethanes; ethylene–vinyl acetate copolymers, EVA; polyvinyl chloride, PVC; polyethylene, *Phylon*). In order to produce adequate adhesive joints, the surface

preparation of those materials is required (see part related to Surface Treatments). Surface preparation procedures for these materials must be quickly developed, and the validity of these treatments is generally too short because of fashion constrictions. Several procedures have been established to optimize the upper-to-sole bonding; the most of them are based in the use of organic solvents. Due to environmental and health issues, the solvents should be removed from the surface preparation procedure, and several environmental-friendly procedures for the surface preparation of different materials have been proposed.

Most of the upper and sole materials used in shoe industry cannot be directly joined by using the current adhesives (polyurethane and polychloroprene adhesives) due to their intrinsic low surface energy, the presence of contaminants and release agents, and antiadherend moieties on the surface. Therefore, the surface preparation of upper and sole must remove contaminants and weak boundary layers, and roughness and chemical functionalities able to produce adequate bond strength should be created.

A review on the formulation and characteristics of the main materials used in shoe manufacturing (except adhesives) was published by Guidetti et al. 1992. To the author's best knowledge, no additional reviews on the subject have been published later.

In this section, a short review of the main materials used in shoe bonding as well as their current surface preparation procedures will be considered. In the last part of this section, the current and alternative surface treatments for upper and sole materials are described.

### 51.3.1 Upper Materials

#### Leather

Full-chrome, semi-chrome, and vegetable-tanned leathers are still the main source and most common upper material in shoe manufacturing. In general, the porous nature of the leather facilitates its bonding with adhesives in solution, mainly solvent-borne polychloroprene adhesives. To obtain good adhesion, the weak grain layer of the leather must be removed by using rotating wire brushes (roughening) to expose the corium (the part of the leather with higher cohesion of the collagen fibers) to the adhesive (SATRA 1963). In general, deeper roughening of upper leather produces a stronger bond than light roughening. Furthermore, two consecutive adhesive layers are generally applied on the roughened leather. First, a low-viscosity adhesive solution (incorrectly called *primer*) is applied to fill the pore entrances of the corium fibers and to facilitate the wettability of the leather surface. At least 5 min later (or alternatively when the adhesive layer becomes dried), a second high-viscosity adhesive solution of the same nature than the previous one is applied; diffusion of the polymer chains between the two adhesive layers is produced, and a homogeneous adhesive layer with high cohesion is created on the upper leather surface.

The main issues that make difficult the bonding of upper leather are the existence of finishing on the surface to be bonded and the presence of high grease content. Deep or slight scouring or roughening is sufficient to remove the finishing and the weak grain leather. However, in thin leathers (such as buffalo or calf leathers), mild surface scouring followed by application of a primer is necessary to avoid leather tearing; the primer must increase the cohesion of the collagen fibers, and also it has to be compatible with the adhesive. Several primers for thin leathers have been proposed (Ferrandiz-Gómez et al. 1994), but they generally require the application of moderate temperature for being effective. Furthermore, different low-viscosity reactive solvent-based polyurethane primers containing about 10 wt% free isocyanate groups have been developed for improving the adhesion of difficult-to-bond leather (Vélez-Pagés 2003).

Depending on the amount (more than 11 wt% is critical) and type of grease (mainly unsaturated fatty acids) in the leather, poor adhesive bond can be produced. The fat may diffuse through to the surface of the polyurethane adhesive film (possibly while the adhesive still wet, with the solvent acting as the vehicle) and interfere with its subsequent coalescence with the adhesive or the sole. When polychloroprene adhesive is used, the reaction of the fatty acids with some components in the adhesive formulation (zinc oxide, magnesium oxide) forms insoluble metal soaps (salts of fatty acids) at the interface that impart antiadherent properties. Polyurethane adhesives are more tolerant to greasy leather than polychloroprene adhesives. The roughening of the leather is always necessary, and the addition of 5 wt% isocyanate hardener to the adhesive just before application helps to reach good adhesive joints.

Solvent-borne polychloroprene adhesives are excellent for bonding leather because of their high wettability and permanent tack (heat activation is not needed). However, these adhesives have poor performance with most of the rubber soles and with several synthetic upper materials. In these cases, polyurethane adhesives provide better performance.

### Synthetic Upper Materials

Several synthetic upper materials such as canvas, textiles, nylon, PVC on woven or nonwoven, and poromerics are used in shoe manufacturing. As for leather, most of these materials need roughening (to remove finishing) and/or solvent wiping, followed by application of two consecutive adhesive layers, to produce good adhesive joints.

*PVC uppers* may cause lack of adhesion due to the migration of plasticizer into any material with which the PVC comes in contact. Light roughening is necessary, or alternatively methyl ethyl ketone (MEK) wiping can be applied followed by the application of polyurethane adhesive containing 5 wt% isocyanate hardener. Alternatively, the application of a primer based on nitrile rubber followed by application of two-component polychloroprene adhesive may perform adequately. *PVC-coated fabrics* may have acrylic or urethane coatings on top. Acrylic coatings are readily soluble by MEK wiping, whereas the urethane coatings need tetrahydrofuran wiping.

*Polyurethane-coated fabrics* can be bonded by using polyurethane adhesives. Mild scouring using a fine rotary wire brush must be used to completely remove the coating before applying the adhesive.

*Poromerics* (nonwoven fabric supporting a microporous urethane layer) also need to be roughened with extreme care. When nylon, polyester, or cellulose interlayers are present, the application of isocyanate-based primers promotes the adhesion.

*Nylon fabric* uppers show serious adhesion problems. The best bonding is obtained by mild roughening followed by applying 2 wt% isocyanate-based primer; the application of two-component polyurethane adhesive is also necessary.

### 51.3.2 Sole Materials

Several kinds of sole materials are currently used in shoe manufacturing, the rubber soles are the most common. Few soles are made of natural products, such as leather or cork. The *leather soles* are not difficult to bond because they are porous and easily wetted by adhesive solutions. A primer is required to produce good bond with solvent-borne polychloroprene adhesives. The use of polyurethane adhesives is also feasible but not so effective, and there is the need of the previous application of low-viscosity polyurethane primer to which 2.5 wt% isocyanate hardener must be added. On the other hand, the *cork soles* are widely used for sandals, and they are joined with polychloroprene adhesives. In some cases, a thin EVA midsole is attached to the cork to improve its abrasion resistance and comfortability by using two-component polychloroprene adhesive (Martin 1971).

#### Rubber Sole Materials

Rubber soles are by far the most common in shoe industry. Vulcanized or unvulcanized (thermoplastic) rubber soles are generally used. In general, the bonding is produced with one- or two-component polyurethane adhesives, and a surface treatment is always required to produce good adhesive joints.

#### Thermoplastic Rubber (TR) Soles

Styrene-butadiene-styrene (SBS) block copolymers are adequate raw materials to produce *thermoplastic rubber (TR) soles*. SBS block copolymers contain butadiene domains – soft and elastic – and styrene domains – hard and tough. Because the styrene domains act as virtual cross-linking in the SBS structure, the vulcanization is not necessary to provide dimensional stability. The TR soles generally contain polystyrene (to impart hardness), plasticizers, fillers, and antioxidants, and processing oils can also be added. The TR soles have low surface energy, so a surface modification is needed to reach proper adhesion to polyurethane adhesive. Special adhesives for the TR soles have been developed to avoid surface preparation, but they have poor creep resistance.

Due to their softness, the TR soles cannot be roughened. The TR soles tend to swell by application of adequate solvents, and the mechanical interlocking of the adhesive is favored; however, vigorous rubbing must be avoided to maintain the mechanical integrity of the sole. Chemical treatments are necessary to improve the

adhesion of the TR to polyurethane adhesive, mainly cyclization (treatment with sulfuric acid) and halogenation.

The TR can be treated with concentrated sulfuric acid to yield a cyclized layer on the surface (Cepeda-Jiménez et al. 2001). This layer is quite brittle, and when it is flexed and stretched, microcracks are developed which help in the subsequent bonding by favoring the mechanical interlocking of the polyurethane adhesive with the TR. The thickness of the cyclized layer depends on the length of the treatment with sulfuric acid. On the other hand, the treatment with sulfuric acid mainly produces the creation of highly conjugated C–C bonds and the sulfonation of the butadiene units of the TR material. The immersion of TR for less than 1 min, the neutralization with ammonium hydroxide (it extracts the hydrogen from the sulfonic acid and leaves stabilized  $\text{SO}_3^- \text{NH}_4^+$  ion pair), and the high concentration of the sulfuric acid (95 wt%) are essential to produce an adequate surface treatment. The treatment with  $\text{H}_2\text{SO}_4$  increases the T-peel strength of surface-treated TR/polyurethane adhesive joints (Fig. 3). On the other hand, the styrene content in the TR determines the effectiveness of the treatment with sulfuric acid. The lower is the styrene content in the TR, the more noticeable are the modifications produced on the surface. Furthermore, the styrene content in the TR affects the extent but not the nature of the surface modifications produced by treatment with sulfuric acid.

Halogenation is the most common surface treatment for TR. The use of the chlorination surface treatment in improving the adhesion of several types and formulations of rubbers has been extensively demonstrated, and it is cheap and easy to apply. Furthermore, the chlorination surface treatment removes contaminants and antiadherend moieties from the rubber surface and imparts improved durability and aging resistance to the upper-to-sole joints, and the treated surfaces remain

**Fig. 3** T-peel strength values (15 min and 72 h after joint formation) of sulfuric acid-treated TR rubber/polyurethane adhesive joints as a function of the immersion time (Cepeda-Jiménez et al. 2001)

**Fig. 4** Chemical structures of DCI (sodium dichloroisocyanurate) and TCI (trichloroisocyanuric acid)

**Fig. 5** Chemical structure of chloramine T

reactive with the polyurethane adhesive for at least 3 months after surface preparation. Immersion in aqueous chlorine or in sodium hypochlorite aqueous solution is a very effective surface preparation for TR soles although fast evolution of chlorine is produced. Therefore, the organic chlorine donors for the treatment of the TR have been proposed alternatively for allowing moderate evolution of chlorinated species during surface treatment. The most commonly used chlorinating agent is an organic solvent (ketone or ester) solution of trichloroisocyanuric acid (TCI) – 1,3,5-trichloro-1,3,5-triazin-2,4,6-trione – (Fig. 4) which is very cheap and common (it is generally used as chlorinating agent in swimming pools). The organic solvent in the TCI solutions determines the degree of rubber wetting, and furthermore, the actual chlorinating species are produced by reaction of the TCI with the organic solvent. The use of the TCI solutions is quite satisfactory for the TR surface preparation although it should be applied with a soft brush and left to dry during moderate time to avoid degradation of the TR surface by the solvent (Carter 1971).

For avoiding the use of organic solvents in the chlorination agents, *acidified sodium hypochlorite aqueous solutions* containing 1-octyl-2-pyrrolidone as wetting agent have been successfully used for the treatment of the TR soles (Cepeda-Jiménez et al. 2003a). The treatment is restricted to about 1  $\mu\text{m}$  depth surface of the TR, and the enhanced adhesion is due to the improved wettability and the creation of chlorine moieties on the rubber surface. Furthermore, *aqueous solutions of sodium dichloroisocyanurate* (DCI) (Fig. 4) have been used to increase the adhesion of the TR soles (Cepeda-Jiménez et al. 2002). The chemical structure of DCI is somewhat similar to that of TCI, and relatively concentrated DCI water solutions are necessary to obtain good peel strength values. On the other hand, successful surface chlorination treatment of the TR has been obtained by using aqueous *N-chloro-p-toluenesulfonamide solutions* (obtained by acidifying chloramine T solutions) (Cepeda-Jiménez et al. 2003a) – Fig. 5. The actual chlorinating species is  $\text{SO}_2\text{-C}_6\text{H}_4\text{-NCl-Cl}$ . The surface treatment is carried out by immersion of the TR in

the aqueous chlorinating solution at 20–80 °C for about 1 min. The effectiveness of this treatment was ascribed to the introduction of chlorine and oxygen moieties on the rubber surface.

*Electrochemical treatments* have also been successfully proposed to improve the adhesion of the TR (Brewis et al. 1997). The treatment consists in the immersion of the TR in an electrochemical cell of silver nitrate in 3.25 M nitric acid. After treatment, the rubbers have to be washed with nitric acid and then with bidistilled deionized water until neutral pH is reached.

Several environmental-friendly surface preparations of the TR sole materials by means of radiations have been more recently proposed. These treatments are clean (no chemical or reaction by-products are produced) and fast, and furthermore online bonding at shoe factory can be produced, so the future trend in the surface modification of the rubber soles will be likely directed to the industrial application of those treatments. Corona discharge, low-pressure radio-frequency (RF) gas plasma, and ultraviolet (UV) enriched in ozone – UV-ozone – treatments have been successfully used at laboratory scale to improve the adhesion of several TR sole materials.

*Corona discharge* has been used to improve the adhesion of the TR to polyurethane adhesives (Romero-Sánchez et al. 2003a). Although the treatment with corona discharge improved the wettability of the TR due to the formation of polar moieties on the surface, and surface cleaning and removal of contaminants (mainly demolding silicone moieties) were produced, the peel strength values moderately increased.

*Low-pressure RF gas plasma* has been shown effective to enhance the adhesion of the TR to different polyurethane adhesives (Ortiz-Magán et al. 2001). Different gases (oxygen, nitrogen, and oxygen–nitrogen mixtures) were used to generate the RF plasma. The treatment produced the partial removal of hydrocarbon moieties from the TR surface, and the formation of oxygen moieties and surface roughness was also produced. On the other hand, the treatment of SBS rubber with low-pressure RF plasma in CCl<sub>4</sub> has also been proposed for improving its adhesion to polyurethane adhesive, and a drastic increase in the peel strength was observed after only a few seconds of treatment which was ascribed to the chemical bonding between the carbon–oxygen moiety species on the SBS surface and the isocyanate groups of the polyurethane adhesive (Tyczkowski et al. 2009). Water molecules strongly attached to the SBS surface were also found, and they reduced the adhesion by partial blocking of the functional groups against the action of isocyanates. On the other hand, because no correlation between the peel strength and the surface free energy was observed, the thermodynamic adhesion was unimportant, and the dominant role of the chemical adhesion was confirmed.

The surface treatment of the TR with *UV–ozone* produced with low-pressure mercury vapor lamp enriched in 175 nm wavelength has been shown to successfully increase its adhesion to polyurethane adhesive (Romero-Sánchez et al. 2003b). The UV–ozone treatment produced important surface modifications (improved wettability, roughness) incorporating oxygen and nitrogen moieties at the TR surface. The peel strength values increased after UV–ozone treatment of the TR, in a greater extent by increasing the treatment time (Fig. 6). More recently, several SBS rubbers

**Fig. 6** T-peel strength values of UV-ozone treated TR/polyurethane adhesive joints as a function of the UV treatment time (Romero-Sánchez et al. 2003)

containing different amounts of calcium carbonate and/or silica fillers were surface treated with UV-ozone to improve their adhesion to polyurethane adhesive (Romero-Sánchez and Martín-Martínez 2008). The nature and content of fillers determined the extent of surface modification and adhesion of SBS rubber treated with UV-ozone. The UV-ozone treatment improved the wettability of all rubber surfaces, and chemical (oxidation) and morphological modifications (roughness, ablation, surface melting) were produced. The increase of the UV-ozone treatment to 30 min led to surface cleaning due to ablation and/or melting of the most external rubber layers, and also incorporation of more oxidized moieties was produced. As a consequence of these surface modifications, the UV-ozone treatment increased the adhesive strength in all joints made with polyurethane adhesive, more noticeably in the joints made with the SBS rubbers containing silica filler. On the other hand, although the chemical modifications were produced earlier in unfilled rubber for short time of treatment with UV-ozone, they were more noticeable in silica-filled rubbers with low silica content for extended length of treatment. However, the oxidation process seemed to be inhibited for the SBS rubbers containing calcium carbonate filler.

### Vulcanized NR and SBR Soles

Although natural rubber (*crepe*) and nitrile rubber soles (common in the manufacturing of safety shoes due to its chemical inertness) are used, *sulfur-vulcanized natural rubbers* and *styrene-butadiene rubbers (SBR)* are the most common sole materials. The vulcanization system contains sulfur and activators (*N*-cyclohexyl-2-benzothiazole sulfenamide, dibenzothiazyl disulfide, hexamethylenetetramine, zinc oxide), and fillers (silica and/or carbon black, calcium carbonate) are added to control hardness and abrasion resistance. Antioxidants (zinc stearate, phenolic

antioxidant) and antiozonant (microcrystalline paraffin wax) are also necessary to avoid degradation processes and early aging. In general, vulcanization is carried out in a metal mold placed in hot plate press at about 180 °C for allowing the reaction of the zinc oxide and the stearic acid to produce zinc stearate, which is combined with hexamethylenetetramine to form an unstable complex. After vulcanization, the contact with moisture or different solvents apparently causes the breakdown of this complex with the appearance of the zinc stearate that migrates to the vulcanized NR or SBR sole which acts as an antiadherend material to polyurethane adhesive (Pettit and Carter 1964). On the other hand, during cooling after vulcanization, the paraffin wax migrates to the rubber surface also producing adhesion problems.

The causes of poor adhesion in vulcanized NR and SBR soles are quite diverse. Over-vulcanized external rubber layer is too stiff to support peel strength stresses. The presence of silicone release agents may reduce the bond strength of the vulcanized SBR sole joints. The presence of antiadherend moieties on their surfaces, their low surface energy, and the migration of low-molecular moieties (antiozonant wax, processing oils) to the interface once the adhesive joint is produced are other causes for the poor adhesion in vulcanized NR and SBR. The paraffin wax and zinc stearate are concentrated in a layer covering the vulcanized rubber surface with a thickness of about 2.0 µm. The factors favoring or inhibiting the migration of antiozonant wax to the vulcanized NR and SBR surfaces have not been fully understood. The temperature is one key factor that determines the migration of the antiozonant paraffin wax to the rubber surface. The antiozonant migration with the temperature in vulcanized rubber has been recently studied (Torregrosa-Coque et al. 2012) by heating at 40–90 °C for 15 h in an oven. The heating of vulcanized SBR at different temperatures caused a partial removal of paraffin wax from the surface, and at a temperature close to the paraffin wax melting point, the crystals of paraffin wax on the vulcanized SBR surface were melted, causing a decrease in the thickness of the paraffin wax film on the surface. Furthermore, the migration of zinc stearate to the paraffin wax layer on the vulcanized SBR surface occurred by heating at 90 °C, and even after heating at 90 °C, a thin film of paraffin wax always remained on the vulcanized SBR surface.

Time is another key factor that determines the migration of the antiozonant paraffin wax to the rubber surface causing the formation of a weak boundary layer of nonrubber contaminants which is deleterious for adhesion of rubber to polyurethane adhesives (Torregrosa-Coque et al. 2011a). Figure 7 shows the ATR-IR spectra of polyurethane coating on MEK surface cleaned vulcanized SBR just after application and after 2 weeks. The increase of the time favored the migration of paraffin wax which is noticed by the appearance of the methylene bands in the ATR-IR spectra of the vulcanized SBR at 2848, 2915, and 2950 cm<sup>-1</sup> on the polyurethane coating.

One of the key steps in the manufacturing of rubber/adhesive joints is reactivation, i.e., sudden heating of the thin adhesive layers on the substrates to be joined under infrared (IR) radiation to 80–90 °C for a few seconds to allow diffusion of the polymeric chains under pressure. This reactivation may cause the migration of low-molecular-weight additives to the rubber surface causing a lack of adhesion. The influence of the reactivation temperature (40–90 °C) on the surface properties of sulfur-vulcanized styrene–butadiene rubber on the extent of the diffusion of the

**Fig. 7** ATR-IR spectra obtained with ZnSe prism of polyurethane coating on MEK surface cleaned vulcanized SBR for different time after polyurethane coating deposition. 3100–2700  $\text{cm}^{-1}$  region (Torregrosa-Coque et al. 2011b)

paraffin wax and zinc stearate to the rubber surface has been studied (Torregrosa-Coque et al. 2011a). The reactivation of the rubber at different temperatures produced changes in the morphology and thickness of the paraffin wax layer on the surface. By increasing the reactivation temperature, a partial removal of paraffin wax was produced, and the thickness of the paraffin wax film on the rubber surface was reduced. On the other hand, the increase in the reactivation temperature increased the surface area of the melted paraffin wax layer that prevented migration from the rubber bulk, but a critical reactivation temperature at 90–100 °C existed at which the migration of zinc stearate to the paraffin wax layer on the rubber surface was favored. Furthermore, it has been demonstrated that the paraffin wax migrated from the vulcanized rubber bulk to the polyurethane–rubber interface, and, then, it diffused across the polyurethane coating and migrated later to the polyurethane coating surface (Torregrosa-Coque et al. 2011b). On the other hand, the extent of migration of the paraffin wax depended on the time after polyurethane adhesive deposition, and the faster migration was produced 1 h after applying the polyurethane adhesive.

The application of surface treatments to NR and SBR soles should produce improved wettability; creation of polar moieties able to react with the polyurethane adhesive, cracks, and heterogeneities should be formed to facilitate the mechanical

interlocking with the adhesive; and an efficient removal of antiadherend moieties (zinc stearate, paraffin wax, processing oils) has to be reached. Several types of surface preparation involving solvent wiping, mechanical and chemical treatments, and primers have been proposed to improve the adhesion of vulcanized NR and SBR soles. Chlorination with solutions of trichloroisocyanuric acid (TCI) in different organic solvents is by far the most common surface preparation for vulcanized NR and SBR.

Roughening of the SBR soles removes the over-vulcanized layer and surface contaminants (oils, molding release agents, antiadherend moieties, etc.) and creates roughness. After roughening, residues of the treatment must be removed by solvent wiping and/or the application of pressurized air. Although the removal of weak layers and the creation of surface heterogeneities may produce improved adhesion of the vulcanized NR and SBR soles, an additional chemical treatment is mandatory for achieving sufficient adhesive strength.

The soles can be chemically treated with concentrated sulfuric acid to improve their adhesion to polyurethane (Cepeda-Jiménez et al. 2000). This treatment is not restricted to the surface but also produces a bulk modification of the rubber because a decrease in the tensile strength and the elongation at break are caused. If the SBR contains paraffin wax, the treatment with sulfuric acid promotes its migration to the surface, and solvent wiping with petroleum ether is mandatory for obtaining good adhesion.

Several chlorinating agents have been used for SBR sole bonding. Acidified sodium hypochlorite aqueous solutions have been used successfully (Table 1), and the mechanism of chlorination has been established (Vukov 1984) that consists in the formation of  $\text{H}_2\text{ClO}^+$  species which produces the evolution of chlorine; then, the chlorine reacts with the double  $\text{C}=\text{C}$  bond of the rubber producing chlorinated hydrocarbon moieties on the surface and some cross-linking.

The most commonly used chlorinating agent in the chemical treatment of the SBR sole is ethyl acetate or MEK (butan-2-one) solution of trichloroisocyanuric acid (TCI). The organic solvent in the TCI solution determines the degree of rubber wetting, and the actual chlorinating species are  $\alpha$ -chloro ketones in TCI/MEK solutions, whereas acid chlorides are the reactive moieties in TCI/ethyl acetate solutions (Pastor-Blas et al. 2000). The reaction of these chlorinating species with the double  $\text{C}=\text{C}$  bonds of the rubber produces  $\text{C}-\text{Cl}$  species, and the reaction is not restricted to the surface, but it is penetrating about 100  $\mu\text{m}$  depth. On the other hand,

**Table 1** T-peel strength values (kN/m) of surface-chlorinated rubber/polyurethane adhesive/leather joints

Rubber	As-received	NaClO + HCl
SBR 1	1.8 (A)	5.6 (R)
SBR 2	0.2 (A)	14.0 (R)
SBR 3	0.9 (A)	7.8 (R)

A: Adhesion failure between the rubber and the adhesive  
R: Cohesive rupture of the rubber

the improved adhesion of the SBR soles treated with TCI solutions is due to the contribution of several mechanisms of adhesion: mechanical adhesion (cracks and pits are produced on the surface), chemical adhesion (chlorinated hydrocarbon, C=O moieties), removal of weak boundary layers (zinc stearate, paraffin wax), and thermodynamic adhesion (a decrease in contact angle is produced, i.e., improved wettability) (see ► Chap. 6, “Thermodynamics of Adhesion”). Furthermore, unreacted solid prismatic TCI crystals deposit during the application of the chlorination treatment on the SBR surface which can be dissolved in contact with the organic solvent in the polyurethane adhesive facilitating the creation of in situ reactive species.

The effectiveness of the chlorination treatment of the SBR soles with TCI solutions strongly depends on several experimental variables of the treatment (Martín-Martínez 2008). The most relevant ones are the application procedure of the TCI solution (brushing providing the best performance), the time between the application of the TCI solution and the polyurethane adhesive (a minimum of 10 min is necessary), the TCI concentration in the solution (less than 3 wt% TCI is recommended), and the roughening or solvent wiping before chlorination (more extensive treatment is produced).

The active chlorine content of the ethyl acetate solutions containing 3 wt% TCI determined the extent of the surface treatment of vulcanized SBR. The active chlorine concentration in the TCI solutions was not the only parameter determining the adhesion of vulcanized SBR, as the highest adhesive strength was not achieved by treating the rubber with the TCI solution with higher active chlorine content (García-Martín et al. 2010). Furthermore, the chlorine concentration in the TCI solutions was not stable in the course of time; the increase in time between TCI solutions preparation and SBR treatment allowed an increase in adhesive strength, the highest value corresponded to the joint produced with the vulcanized SBR treated with the TCI solution prepared for 60 days.

The influence of the temperature on the effectiveness of the chlorination treatment of vulcanized SBR with TCI solutions in organic solvents has been addressed. Vulcanized SBR was treated with 1 and 2 wt% TCI solutions in ethyl acetate and then thermally treated at 23 °C, 50 °C, or 65 °C for different time (Yin et al. 2012). Although this study was not intended for shoe industry, the results obtained revealed that the increase of the chlorination temperature up to 50 °C was very effective for SBR surface modification by TCI, leading to enhanced surface wettability, creation of chlorinated hydrocarbon moieties, and increased shear strength (from 2.0 to 9.7 MPa). However, later study (Yañez-Pacios et al. 2013) has shown that the application of temperature during chlorination of high antiozonant content vulcanized NR with TCI solutions in MEK did not increase the adhesion strength of the upper-to-sole joints. However, changes in wettability, surface chemistry, and roughness of the rubber were produced, all being irrelevant for improving adhesion likely due to the migration of antiozonants to the polyurethane adhesive-vulcanized NR interface with time after joint formation.

Due to organic solvent restrictions in the industry, aqueous chlorinating solutions have been tested as an alternative to TCI solutions in ethyl acetate or MEK. Aqueous

solutions of sodium dichloroisocyanurate (DCI) have been recently demonstrated to increase the adhesion of vulcanized SBR soles (Cepeda-Jiménez et al. 2002). The surface treatment with aqueous DCI solutions creates C–Cl moieties, removes antiadherend moieties from the SBR surface, and creates roughness. The use of a low DCI concentration in water is sufficient to obtain good peel strength values in SBR/waterborne polyurethane joints. Furthermore, vulcanized NR has been treated with aqueous sodium hypochlorite solution for various chlorination times up to 30 min (Radabutra et al. 2009). The degree of chlorination increased with the chlorination time up to 10 min then leveled off, but the roughness and stiffness increased gradually with chlorination time. The maximum peel strength was found at 1 min of chlorination time and decreased afterward because of the increase in the surface stiffness that acted as weak boundary layer.

As for TR, successful treatments of vulcanized NR and SBR soles with aqueous *N*-chloro-*p*-toluenesulfonamide solutions and electrochemical treatments have been reported at laboratory scale. Similarly, the treatment of SBR sole with oxidant inorganic salts (acidified potassium dichromate, potassium permanganate, Fenton's reactive) has been shown to be partially successful (Brewis and Dahm 2003).

*Primers* have also been used to improve the adhesion of SBR soles. Due to its high reactivity, isocyanate wipe has been proposed, but the most common treatment uses organic acid solutions. Solutions of lactic acid applied with stiff-bristled brush and with a scrubbing action are adequate to remove metal soap contamination (i.e., zinc stearate) on the surface of SBR sole and even replace roughening (Carter 1969). Solutions of different carboxylic acids (fumaric acid, maleic acid, acrylic acid, succinic acid, malonic acid) in ethanol have also been used as primers of SBR sole (Pastor-Sempere et al. 1995). The nature of the carboxylic acid determines the rate of diffusion into the polyurethane adhesive and the extent of rubber-adhesive interfacial interaction. Finally, mixtures of TCI and fumaric acid solutions have been tested in improving the adhesion of difficult-to-bond SBR sole, but it was demonstrated that the effectiveness of this treatment was mainly due to chlorination by TCI (Romero-Sánchez and Martín-Martínez 2003).

Treatment with supercritical fluids was also tested to remove zinc stearate and waxes from vulcanized SBR soles (Garelik-Rosen S, Torregrosa-Maciá R, Martín-Martínez JM (2003), unpublished results). The relative effectiveness of this treatment was ascribed to the dissolution of antiadherend moieties by penetration of the fluid into the rubber surface.

An alternative to water-based treatment is the use of low-pressure RF gas plasmas in the enhancement of the adhesion of vulcanized rubbers. The treatment in oxygen plasma for 1 min is enough to noticeably increase the adhesion of vulcanized SBR sole to polyurethane adhesive (Pastor-Blas et al. 1998). Later, three different configurations (direct, etching, and secondary downstream) of low-pressure RF oxygen plasmas for length of treatment between 1 and 10 min were used to modify the surface of vulcanized SBR (Torregrosa-Coque and Martín-Martínez 2011c). The direct oxygen plasma was the most aggressive treatment and the secondary downstream plasma the less one, and the oxygen plasma treatment caused surface oxidation and ablation on the SBR surface, as well as an increase of the temperature

that also determined the extent of paraffin wax migration which was produced for at least 24 h after oxygen plasma treatment; as a consequence, poor adhesion to polyurethane adhesive was obtained, due to the creation of a weak boundary layer of paraffin wax at the rubber–polyurethane interface.

Vulcanized ethylene propylene diene polymethylene (EPDM) rubber surface was treated with low-pressure RF argon–oxygen plasma to improve adhesion with compounded natural rubber (NR) during co-vulcanization (Basaka et al. 2011). The plasma treatment changed both surface composition (formation of C–O and C=O functional groups) and roughness of EPDM rubber, and consequently increased peel strength was obtained. In a different study, vulcanized NR containing intentionally noticeable excess of processing oils in its formulation was treated with argon–oxygen (Ar–O<sub>2</sub>) (2:1, vol/vol) low-pressure plasma for achieving a satisfactory level of adhesion to waterborne polyurethane adhesive (Cantos-Delegido and Martín-Martínez 2015). The effectiveness of the Ar–O<sub>2</sub> low-pressure plasma treatment depended on both the configuration of the plasma chamber shelves and the treatment time, the direct configuration provided the most effective surface modification of the vulcanized NR. However, even important surface modifications were produced by Ar–O<sub>2</sub> low-pressure plasma treatment, adhesion was not improved due to the creation of weak boundary layer at the polyurethane–rubber interface after joint formation. Heating at 80 °C for 12 h prior to Ar–O<sub>2</sub> low-pressure plasma treatment enhanced the extent of the surface modifications, and improved adhesion was obtained for treatment times higher than 600 s.

*Atmospheric plasma torch treatment* of vulcanized NR with different excess of paraffin wax and processing oils was carried out for improving adhesion to waterborne polyurethane adhesive (Kotrade et al. 2011). Similar chemical modifications (new C=O and C–N functional groups) and roughness were produced by plasma torch treatment in all rubbers, and the best results were obtained at a rubber surface nozzle of the plasma torch distance of 5 mm and a platform speed of 1 m/min. However, although the rubber surfaces were effectively modified by plasma torch, the adhesion to waterborne polyurethane adhesive was not improved. In a different study (Moreno-Couramjou et al. 2009), vulcanized NR was treated by atmospheric dielectric barrier discharges to improve its adhesion to silicone adhesive. The atmospheric plasma treatment with the use of allyl alcohol improved noticeably the adhesion by a factor of 10 due to the preferential formation of C–O bonds.

More recently the treatment with UV radiation combined with ozone (UV–ozone) in improving the adhesion of difficult-to-bond vulcanized NR (it contained an excess of processing oils) to waterborne polyurethane adhesive in footwear has been carried out (Moyano and Martín-Martínez 2014). Both the length of the treatment and the distance between the UV radiation source to the rubber surface were varied, and the effects of the treatment on the surface chemistry, wettability and surface energy, and topography of the rubber were analyzed. The treatment of the vulcanized rubber with UV–ozone removed hydrocarbon moieties and zinc stearate from the surface, surface oxidation (C–O, C=O, and COO- groups formation) occurred, and improved wettability and increased surface energy (mainly due to the polar component) were obtained. The UV–ozone surface treatment also caused heating of the surface and

increased the adhesion of the vulcanized rubber to waterborne polyurethane adhesive; the highest adhesion was obtained in the joints made with UV–ozone-treated rubber for 3 and 6 min at a UV radiation source–rubber surface distance of 5 cm.

### Polymeric Soles

Ethylene–vinyl acetate (EVA) block copolymer soles are common in sport and casual shoes due to their low density and easy coloring. EVA soles are difficult to bond with the polyurethane and polychloroprene adhesives commonly used in shoe industry, mainly due to their low surface energy. The higher the vinyl acetate content, the less difficult to bond the EVA sole is. The lightweight microcellular EVA soles can usually be adequately bonded after scouring using polyurethane and polychloroprene adhesives. The injection-molded EVA soles are more difficult to bond although roughening followed by application of two-component polychloroprene adhesive can give moderate bond strength (Martínez-García et al. 2003a). Corona discharge has been shown to be useful to improve the peel strength of injection-molded EVA soles containing 12 and 20 wt% vinyl acetate/polychloroprene adhesive joints. The improvement is ascribed to the creation of C=O and R-COO<sup>−</sup> moieties. Treatment with sulfuric acid also provided improved adhesion of injection-molded EVAs with vinyl acetate contents between 9 and 20 wt%, because this treatment produces sulfonation and creation of oxygen moieties on EVA surface (Martínez-García et al. 2003b). Oxygen and other gases low-pressure plasmas are very effective in improving the peel strength of joints produced with EVA soles with different vinyl acetate contents and two-component polyurethane adhesive (Cepeda-Jiménez et al. 2003b). The treatment is more effective with non-oxidizing plasmas, giving rise to a high roughness. Finally, the treatment with UV–ozone has been developed to enhance the bond strength between EVA sole and polyurethane adhesive (Landete-Ruiz and Martín-Martínez 2005). The surface modifications produced by UV–ozone treatment of two ethylene–vinyl acetate (EVA) copolymers containing 12 (EVA12) and 20 wt% (EVA20) vinyl acetate have been studied (Landete-Ruiz and Martín-Martínez 2015). The treatment with UV–ozone improved the wettability of both EVAs due to the creation of new carbon–oxygen moieties, and the extent of these modifications increased with increasing the time of treatment; the modifications produced in EVA20 were produced for shorter lengths of treatment. The UV–ozone treatment also created roughness and heterogeneities, and whereas roughness formation prevailed on the UV–ozone-treated EVA12, important ablation was dominant on the treated EVA20. T-peel strength values in joints made with polychloroprene adhesive increased. Short length of UV–ozone treatment (1 min) produced higher T-peel strength in joints made with EVA20, whereas higher T-peel strength values in joints made with EVA12 were obtained after treatment for 5–7.5 min in which a cohesive failure into a weak boundary layer on the treated EVA surface was found. Finally, the aging resistance of the treated EVA/polychloroprene adhesive joints was good, and the surface modifications on the UV–ozone-treated EVAs lasted for 24 h after treatment at least.

Ethylene–vinyl acetate (EVA) copolymers intended for sport sole manufacturing may contain noticeable amounts of low-density polyethylene (LDPE) – *Phylon*-type

soles – for improving abrasion resistance and decreasing cost; however, the EVA–PE blend had low polarity and showed poor adhesion. Good results have been obtained by applying extensive organic solvent wiping, followed by application of an UV-activated primer and by using two-component polyurethane adhesive. More recently, an effective environmental-friendly and fast surface treatment based on UV–ozone has been used to increase the wettability, polarity, roughness, and adhesion of EVA–PE material to leather with waterborne polyurethane adhesive (Jofre-Reche and Martín-Martínez 2013). The more extended length of treatment and the shorter UV source–substrate distance increased the wettability and created new carbonyl groups mainly, and the amounts of hydroxyl and carboxylic groups were increased. The UV–ozone treatment produced ablation and etching of the EVA–PE material surface, mainly in the vinyl acetate of the EVA; this topography was also caused by heating during UV–ozone treatment. For low length of UV treatment or high UV source–material distance, the modifications of the EVA–PE material were mainly produced in the ethylene causing the selective removal of vinyl acetate, whereas more aggressive conditions produced strong oxidation in the EVA–PE material. Finally, adhesive strength was noticeably increased in the UV–ozone-treated EVA–PE/polyurethane adhesive joints, and a cohesive failure in the leather was obtained.

Only polyurethane adhesives should be used to bond *PVC soles*. The adhesion problems of PVC derive from the presence of plasticizers and stabilizers (stearate type) able to migrate to the surface impeding the contact with the adhesive (creation of weak boundary layers). A solvent wiping on the PVC surface is usually effective in improving adhesion, and solvents such as MEK are adequate. On the other hand, treatment with 10 wt% aqueous solutions of sodium hydroxide has been successfully applied to increase the adhesion performance of plasticized PVC soles (Abbott et al. 2003).

*Polyurethane soles* usually contain silicone mold release agents which prevent adhesion. To remove them, mild roughening following by solvent wiping is necessary. The application of an isocyanate primer is very useful before polyurethane adhesive is applied. Solvent-free treatments have been proposed for polyurethane soles, mainly cryoblasting (Abbott et al. 2003). Cryoblasting consists in the bombardment of the PVC soles with particles of solid carbon dioxide at pressures about 0.4 MN/m<sup>2</sup>. The impact of the solid particles successfully removed mold release agents from the polyurethane surface improving their adhesion to polyurethane adhesive.

### 51.3.3 Adhesives in Upper-to-Sole Bonding

Contact adhesives based in one- and two-component polychloroprene (*neoprene*) and mainly polyurethane adhesives are the most commonly used in shoe industry to bond upper to sole (see ► Chaps. 14, “Adhesive Families,” and ► “Sealant Families”). These adhesives are bonded by autoadhesion which implies the application of the adhesive to both surfaces to be joined; diffusion of polymer chains must be achieved across the interface between the two adhesive films on the substrates to be

joined to produce intimate adhesion at molecular level. To achieve an optimum diffusion of the polymer chains, both high wettability and adequate viscosity and rheology of the adhesive should be achieved.

In the past, polychloroprene adhesives were more extensively used in upper-to-sole bonding, but nowadays polyurethane adhesives are preferred. Polychloroprene adhesives have better tack and improved wettability than polyurethane adhesives, but the polychloroprene adhesives are not compatible with the surface-treated rubber soles and cannot be used to joint PVC soles. Therefore, polyurethane adhesives show higher versatility on broader range of substrates and also have lower oxidative degradation in time. However, they require always the surface preparation of the materials to be bonded.

### 51.3.4 Polyurethane Adhesives

In 1960s, the solvent-borne polyurethane adhesives replaced the polychloroprene adhesives in the bonding of PVC soles for sport shoes. Today, the use of solvent-borne polyurethane adhesives is in decline due to environmental regulations and safety issues. Shoe industry was initially reluctant to the use of waterborne polyurethanes due to higher cost and reduced green strength. However, the use of waterborne polyurethanes is more common nowadays because their solid content is high and small amount of adhesive is needed to produce a similar joint than with solvent-borne adhesives. On the other hand, during the last decade, solvent-free polyurethane adhesives have been tested in shoe bonding. Although these adhesives have been widely used and effectively tested in the automotive industry, the advent in the shoe manufacturing is not as successful, likely because different machinery and bonding concepts need to be implanted. Shoe industry is, in general, quite reluctant to change bonding technologies, particularly when it implies a cost increase!

In this section, the solvent-borne, the waterborne, and the solvent-free polyurethane adhesives will be considered separately.

#### Solvent-borne Polyurethane Adhesives

Elastomeric thermoplastic polyurethanes are the main components in solvent solution adhesives for shoe industry. These polyurethanes are generally prepared in the form of pellets or chips by reacting an isocyanate (such as MDI – 4,4'-diphenylmethane diisocyanate), a long-chain diol (polyester or  $\epsilon$ -caprolactone type), and a chain extender (glycol) to produce a linear polymer with negligible chain branching and relatively low-molecular-weight ( $M_w = 200.000\text{--}350.000$  Da). The isocyanate to hydroxyl equivalent ratio (NCO/OH ratio) is usually kept near 1, thus producing a polymer with terminal hydroxyl groups which are able to form hydrogen bonds with the urethane moieties.

From a polymer physics point of view, the configuration of the elastomeric polyurethanes corresponds to a segmented structure (block copolymer of  $(AB)_n$  type) consisting of *soft* and *hard* segments (Fig. 8). Typically the *soft* segments are

**Fig. 8** Scheme of the segmented structure of thermoplastic polyurethane

composed of a rubbery polymer (mainly the polyol), the glass transition temperature ( $T_g$ ) which is located well below ambient temperature. The *hard* segments are generally produced by the reaction of the isocyanate and the short chain glycol (chain extender) and have a rigid and crystalline structure. The nonpolar low-melting *soft* segments are incompatible with the polar high-melting *hard* segments. As a result, phase separation (segregation) occurs in the polymer network.

Typical elastomeric polyurethanes used as adhesives in upper-to-sole bonding have a relatively low content of hard segments, and their properties are mainly determined by the soft segments. Therefore, these polyurethanes will be elastic in the range of temperature between the glass transition temperature (generally located between  $-30$  and  $-40$  °C) and the softening temperature of the elastomeric domains ( $50$ – $80$  °C). The low melting point permits the elastomeric polyurethane to be softened at relatively low temperature, with sufficient thermoplasticity (i.e., loss of cohesion at moderate temperature) and surface tack to ensure correct bond.

Solvent-borne polyurethane adhesives are generally prepared by dissolving the solid elastomeric polyurethane pellets or chips in a solvent mixture. Because polyurethanes have a linear molecular structure, the solid polymer does not need mastication prior to dissolving. The solubility of the elastomeric polyurethanes in ketone solvents is mainly governed by the degree of crystallinity in the polyester soft segments. The crystallinity can be varied by selecting the reactants and by controlling the molecular weight of the polyester. Generally, the elastomeric polyurethanes with low crystallization rates have long open times but poor peel strength and heat resistance. Those polyurethanes with high rates of crystallization have short open times but high peel strength and improved heat resistance. For this reason, mixtures of low and high crystallization rate polyurethanes are used to balance the open time and adhesion of the solvent-borne adhesives.

The solvents determine the viscosity and solubility of the elastomeric polyurethane, its storage stability, its wetting properties, and its evaporation rate when

applied on a substrate. The most common solvents are aromatic (toluene, xylene), tetrahydrofuran, dioxane, cyclohexanone, esters (ethyl acetate, butyl acetate), and ketones (acetone, methyl ethyl ketone). Commonly, two or more solvents are employed, a low-boiling and a high-boiling solvent. The low-boiling solvent assures rapid flash-off of the majority of the solvent after applying the adhesive solution on the substrate. The higher-boiling solvent helps to control the crystallization kinetics of the soft segments, thereby helping to extend the open time of the adhesive. In fact, once crystallization of the soft segments occurs, the open time expires. Other function of the high-boiling solvent is to keep the viscosity of the adhesive low (this is the reason for being called diluents), allowing the adhesive solution to wet the substrate by facilitating the polyurethane to penetrate the substrate surface, thus improving the mechanical interlocking. On the other hand, the addition of toluene avoids gel formation of the adhesive solutions during storage.

The formulation of the solvent-borne polyurethane adhesives may include several additives such as tack and heat resistance modifiers, plasticizers, fillers, tackifiers, antihydrolysis agents, and cross-linkers. Carboxylic acid as an adhesion promoter can also be added. A typical formulation of a solvent-borne polyurethane adhesive contains less than 20 wt% solid content only.

The spotting tack and/or the heat resistance of the elastomeric polyurethane adhesives may be extended by adding resins (alkyl phenolic, epoxide, terpene phenolic, coumarone) or polymers (low-crystallizing polyurethane, acrylic, nitrile rubber, chlorinated rubber, acetyl cellulose) (Penczek and Nachtkamp 1987) having low miscibility with the polyurethane. To improve adhesion together with heat resistance, reactive alkyl phenolic resins, chlorinated rubber, or other chlorine-containing polymers can be added.

The main additives used in the formulation of solvent-borne polyurethane adhesives are described in more detail below.

**Tackifiers.** One of the limitations of the elastomeric polyurethane adhesives is the lack of high immediate (green) adhesion to rubbers and polymers. One way to increase the green strength of the elastomeric polyurethanes is the addition of tackifiers mainly rosins or hydrocarbon resins (Arán-Aís et al. 2002). Addition of rosin as internal tackifier (i.e., incorporated during the synthesis of the polyurethane) favors the miscibility between the tackifier and the polyurethane. The hard segment content of the elastomeric polyurethanes containing rosin is higher than in regular polyurethanes because two kinds of hard segments are produced, urethane and urea–amide (this is produced by reaction of the isocyanate groups with the carboxylic acid of the rosin). Addition of rosin increases the molecular weight of the polyurethane and retards its kinetic of crystallization, and the immediate adhesion to vulcanized SBR sole is also increased.

A model system (phenyl isocyanate and acetic acid) has been studied to understand the reaction between the isocyanate group and the rosin (Irusta-Maritxalar ML, Fernández-Berridi MJ (2002), personal communication). The expected by-products of the reaction of the isocyanate and the carboxylic acid moieties are given in Eq. 1:

An unstable intermediate carbo-anhydride is formed (compound **I**), which under heating decomposes to produce urea (compound **II**) and anhydride (compound **III**) derivatives. These two compounds react by heating or by standing several days at room temperate to produce an amide compound (compound **IV**).

**Fillers.** Fillers should be highly dispersible in solution and should not settle down during the storage period of the adhesive. Whiting, talc, barite, calcium carbonate, attapulgit, and quartz flour have been suggested as fillers to lower the cost of the solvent-borne polyurethane adhesive, improve joint filling, and reduce the loss of adhesive during setting. In general, the fillers are incorporated during the preparation of the adhesive solutions by adding a small amount of solvent under high stirring speed for a short time, followed by addition of the other ingredients of the adhesive and all solvent under lower stirring rate and longer time (Maciá-Agulló et al. 1992).

*Pyrogenic (fumed) silicas* are the most common fillers of the polyurethane adhesives in shoe industry. When bonding highly porous materials (leather, textiles), fumed silicas are added to prevent undesirable penetration of the adhesive. The addition of the fumed silica adjusts the viscosity and rheology (thixotropy, pseudoplasticity) for application of the polyurethane adhesive solutions. The rheological properties of the polyurethanes containing fumed silica are due to the creation of hydrogen bonds between the silanol groups on the fumed silica particles and the urethane and carbonyl groups of the polymer, which increase the mechanical and rheological properties of the adhesives (Jauregui-Beloqui et al. 1999; Vega-Baudrit et al. 2009; Bahattab et al. 2011, 2012; Donate-Robles et al. 2014). Consequently, the cohesion properties of the polyurethane are increased, and improved initial peel strength is obtained, in a greater extent by increasing the amount of fumed silica (Bahattab et al. 2012). Several parameters of the fumed silica determine its performance as rheological additive of solvent-borne polyurethane adhesives. Low particle size and degree of agglomeration, specific surface areas between 200 and 300 m<sup>2</sup>/g, and the hydrophilic nature of fumed silicas increase the rheological, mechanical, and adhesion properties of the solvent-borne polyurethane adhesives (Pérez-Limiñana et al. 2003; Bahattab et al. 2011).

*Calcium carbonate* fillers have also been added to solvent-borne polyurethane adhesives for improving their mechanical properties and initial adhesion (Donate-Robles and Martín-Martínez 2011a, b). The addition of precipitated calcium carbonate (PCC) filler produced a moderate increase in the rheological and viscoelastic properties of the polyurethane due to the poor dispersion of filler and the weak interactions between the PCC nanoparticles and the polymer chains. Furthermore, the first glass transition temperature of the polyurethane decreased by adding PCC filler and the crystallinity of the soft segments as well, because of the disruption of the degree of phase separation in the polyurethane. The initial adhesive strength in

PVC/polyurethane adhesive/PVC joints increased noticeably by adding PCC filler; the greater the amount of filler, the greater the initial adhesive strength, and the highest final adhesive strength (72 h after joint formation) was obtained in the joint produced with the solvent-borne polyurethane adhesive containing 10 wt% PCC. The thermoplastic polyurethane–calcium carbonate interactions have been studied by using flow microcalorimetry and diffuse reflectance Fourier transform infrared spectroscopy (Donate-Robles et al. 2014). Three calcium carbonates (coated and uncoated precipitated calcium carbonate and natural ultramicrosized uncoated calcium carbonate) were added to solvent-borne polyurethane adhesives, and stronger polyurethane–filler interaction was shown in the uncoated precipitated calcium carbonate due to the fact that more of the surface was available for interaction. In fact, the polyurethane strongly adsorbed onto untreated calcium carbonate via the ester groups, and the stearate treatment of calcium carbonate greatly reduced the strength of interaction with the polyurethane due to blockage of the surface adsorption sites.

Nanometric *carbon black* (CB) filler has been added to solvent-borne polyurethane adhesives for improving adhesion. The CB and the polyurethane pellets were adequately dispersed in methyl ethyl ketone matrix, and an increase in the number and size of the carbon black aggregates in the polyurethane matrix was obtained by increasing the carbon black loading (Alvarez-García and Martín-Martínez 2015). The addition of the carbon black improved the rheological and viscoelastic properties of the adhesive, and the addition of higher amounts of CB changed the viscoelastic behavior of the polyurethane which became mainly elastic. On the other hand, the addition of CB loadings up to 12 wt% increased the thermal stability of the polyurethanes and increased their elongation at break without noticeable reduction in tensile strength. However, the polyurethane adsorbs less carbon black than fumed silica and calcium carbonate due to less accessible surface groups due to the presence of relatively important amount of micropores (Donate-Robles et al. 2014).

*Carboxylic acids.* It has been shown that improved adhesion can be obtained in joints produced with solvent-borne polyurethane adhesives containing small amount of different carboxylic acids. These carboxylic acids can be aliphatic or aromatic, can be unsaturated or saturated, may contain one or more carboxylic acid functionalities, and have hydroxyl, carbonyl, or halogen groups. Fumaric and maleic acids are the most common carboxylic acids added to the solvent-borne polyurethane adhesives for the joining of vulcanized SBR sole.

The effectiveness of the carboxylic acid as adhesion promoter is governed by its compatibility with the polyurethane and the solubility in the organic solvent selected to dissolve the polyurethane. It has been established (Pastor-Sempere et al. 1995) that the mechanism by which adhesion of SBR is increased is due to the carboxylic acid migration to the polyurethane adhesive surface once the adhesive joint is formed, removing zinc stearate and paraffin wax from the rubber surface. On the other hand, the carboxylic acid reacts with the polyurethane in the presence of a tiny amount of water which results in chain cleavage and disruption of polyurethane crystallinity (Eq. 2).

The addition of carboxylic acid decreases the molecular weight, tensile strength, and glass transition temperature of the polyurethane more markedly upon increasing the time after the adhesive is prepared and more noticeably for high amounts of carboxylic acid. As a consequence, lower viscosity of the polyurethane adhesive solutions and smaller peel strength values are obtained. The increased amount of the carboxylic acid in the solvent-borne polyurethane adhesive enhances its bond strength to SBR until a maximum value is reached. On the other hand, the nature of the polyurethane determines the degree of effectiveness of the carboxylic acid on adhesion of vulcanized rubber.

**Cross-linkers.** Polyisocyanates with functionality greater than two (such as p, p'', p''' – triisocyanate triphenylmethane, thiophosphoric acid tris(p-isocyanatophenyl) ester) can be added to improve specific adhesion and heat resistance of the polyurethane adhesives (especially those with slower crystallization rate). Most of them have 20–30 wt% solids and 5.4–7 wt% free NCO, and the most common solvent is ethyl acetate. About 5–10 wt% polyisocyanate is generally added in the adhesive solution just before application on the substrate, and it acts as cross-linking agent. Since all isocyanates react with the residual hydroxyl groups on the polyurethane, in solution they yield adhesive systems with a limited pot life (1–2 h to several days). The addition of the polyisocyanate improves the spotting tack and the heat activation of the freshly dried adhesive films, but after several days they lose their capacity to be reactivated.

In finished bonds, the elastomeric polyurethanes show a relatively low cross-link density and then are exposed to outstanding hydrolytic degradation under high humidity and temperature that can lead to a partial or complete loss of strength during shoe use. The hydrolytic degradation of the polyurethane can be inhibited by adding 2–4 wt% carbodiimide to the adhesive solution because the carbodiimide forms acyl ureas by reaction of the carboxyl groups arising from the hydrolytic degradation of the polyurethane (Dollhausen 1988).

### Waterborne Polyurethane Adhesives

Organic solvents are, in general, volatile, flammable, and toxic, in some degree. Further, organic solvent may react with other airborne contaminants contributing to smog formation and workplace exposure. Although solvent recovery systems and afterburners can be effectively attached to ventilation equipments, many shoe factories are switching to the use of waterborne adhesives.

Waterborne polyurethane adhesives are an environmental-friendly alternative to the solvent-borne polyurethane adhesives. Those are the more logical choice to replace the solvent-borne adhesives because they can be processed on the same

machines, their performance in many applications is just as good as that of solvent systems, and they can be used economically despite their higher raw material and processing costs. However, the use of the waterborne polyurethane adhesives needs some minor changes in the current existing technology, essentially the additional heat required to remove water before joint formation. Furthermore, the waterborne polyurethane adhesives show additional limitations: (i) lack of tackiness at room temperature (heat activation is needed), (ii) poor wettability of some substrates (particularly greased leather), and (iii) polyurethane dispersions are thermodynamically unstable, and therefore they show relatively poor storage stability (dispersion collapses in the presence of metallic contaminants, at low temperature (generally below 5 °C), or by applying high stresses).

The polyurethane dispersions are constituted by urethane polymer particles wholly dispersed in water. The dispersion of the polymeric particles is feasible because of the presence of ionic hydrophilic groups chemically bonded to the main polymer chains which are oriented to the surface of the particles (Fig. 9). These dispersions are based on crystalline, hydrophobic polyester polyols (such as hexamethylene polyadipate), and aliphatic isocyanates (such as  $H_{12}$ MDI – methylene bis(cyclohexyl isocyanate) – or IPDI, isophorone diisocyanate).

There are several routes to produce polyurethane dispersions, the two most common are the so-called acetone and prepolymer methods. In the *acetone method*, the polyol, the anionic internal emulsifiers (such as dimethylolpropionic acid or

**Fig. 9** Scheme of the structure of waterborne polyurethane adhesive

diethylamine sodium sulfonate), and the isocyanate are reacted to obtain a prepolymer with hydrophilic groups (García-Pacios et al. 2010). The prepolymer is dissolved in acetone for decreasing viscosity, and the ionic groups are neutralized by addition of an amine (trimethylamine is generally used to neutralize the carboxylic acid moieties). The chain extension of the prepolymer is carried out by addition of or diol; both hydrazine and ethylene diamine are commonly used as chain extenders because of their faster reaction with isocyanates than with water. Then, water is added for obtaining the polyurethane micelles by phase inversion, and the acetone is removed by distillation at reduced pressure. In the *prepolymer method*, two basic steps are needed in order to produce a waterborne polyurethane dispersion: a prepolymer step and a chain extension step. The prepolymer obtained by reacting the polyol and the aliphatic isocyanate is modified through an internal emulsifier containing hydrophilic groups, thereby eliminating the use of external emulsifiers. The prepolymer containing the internal emulsifier is reacted with a tertiary amine (such as triethylamine) to increase the length of the polymer chain and increase the molecular weight of the polyurethane. The amine reacts with the pendant carboxylic acid groups, forming a salt that under adequate stirring allows the dispersion of the prepolymer in water. The chain extension step takes place in the water phase. The waterborne polyurethane dispersions obtained by the acetone and the prepolymer methods contain high-molecular-weight polyurethane chains, and they have polyurethane and polyurea linkages.

The method for preparing the waterborne polyurethane dispersions determines their properties, and it has been scarcely studied. In general, the acetone method produces more homogeneous anionic dispersions and well-controlled polyurethane structure. It has been shown that the method of synthesis determined the mean particle size, the crystallinity, and the viscosity of the waterborne polyurethane dispersions (Barni and Levi 2003). In later study it has been shown that the acetone method produced dispersions with narrower particle size distributions and higher crystallinity than the prepolymer method, and the adhesive strength was similar in the joints made with waterborne polyurethane dispersions prepared with both methods (Pérez-Limiñana et al. 2006).

The waterborne polyurethane dispersions generally have a pH between 6 and 9 and higher solid content (35–50 wt%) and lower viscosities (about 100 mPa.s) than the solvent-borne polyurethane adhesives. They are high-molecular-weight linear polyester ureas or urethanes constituted by small rounded spherical particles of about 0.1–0.2  $\mu\text{m}$  diameter.

The adhesive characteristics of the waterborne polyurethanes are mainly defined by the melting point and the crystallization kinetics of the polymer backbone. It is highly desirable to activate the adhesive at room temperature, but most of the waterborne polyurethane adhesives have melting point above 55 °C and need reactivation. The crystallization kinetics defines the open time of the adhesive. On the other hand, unlike solvent-borne adhesives, the viscosity of waterborne polyurethane adhesives is not dependent on the molar mass of the polymer but on the solids content, average particle size of the dispersion, and the existence of additives in the formulation.

The adhesion properties of the waterborne polyurethane adhesives are greatly determined by the polymer, and the formulations are generally simple including only small amounts of a thickener and an emulsifier. When formulating the waterborne polyurethane adhesives, the application conditions (heat activation, contact bond time, pressure) and substrate type must be taken into account. Because the properties of the waterborne polyurethane adhesives are mainly determined by the structure of the polyurethane, several studies analyzing the influence of different raw materials and the experimental variables of the synthesis procedure have been published. It has been concluded that the content of ionic groups, the hard-to-soft segment ratio, the nature and molecular weight of the polyol, the nature of the chain extender, the degree of neutralization of the prepolymer, and the nature of the counterion determined the properties of the waterborne polyurethane dispersions (Kim and Lee 1996; Jang et al. 2002).

Several studies have considered the influence of the *hard-to-soft segments or NCO/OH ratio* on the properties of the waterborne polyurethane dispersions. Most studies have shown that the increase in the NCO/OH ratio increased the mean particle size and enhanced the viscoelastic properties of the polyurethane dispersions (Pérez-Limiñana et al. 2007; García-Pacios et al. 2010; Vicent and Natarajan 2014). The variation of the viscosity of the waterborne polyurethane dispersion with the NCO/OH ratio is controversial. García-Pacios et al. (2011a) found that the increase in the NCO/OH ratio in waterborne polyurethane dispersions prepared with polycarbonate diol decreased the mean particle size and increased the Brookfield viscosity of the dispersions; however, the opposite trend was described previously (Madbouly et al. 2005). On the other hand, the increase in the NCO/OH ratio increases the urea and urethane hard-segment content in the polyurethane, and, therefore, the mechanical properties (i.e., Young's modulus and tensile strength) and the glass transition temperature increased by increasing the NCO/OH ratio of the waterborne polyurethane dispersion. On the other hand, the NCO/OH ratio affected the T-peel strength and single-lap shear adhesive strength of the waterborne polyurethane adhesives, and a maximum value is obtained for an NCO/OH ratio of 1.5 (García-Pacios et al. 2011a).

The influence of the nature, the structure, and the amount of the *diisocyanate* on the properties of waterborne polyurethane adhesives has been extensively studied. The cycloaliphatic diisocyanates (methylene bis(cyclohexyl isocyanate) – H<sub>12</sub>MDI – isophorone diisocyanate, IPDI) are the most commonly used because of the controlled reactivity during prepolymer formation. It has been shown that the waterborne polyurethane dispersions prepared with IPDI had lower mean particle size but lower mechanical properties than the ones prepared with H<sub>12</sub>MDI (Kim et al. 1994). Aromatic diisocyanates such as MDI and TDI have been used for preparing waterborne polyurethane dispersions, and they showed higher thermal and mechanical properties than the ones prepared with cycloaliphatic diisocyanates (Yang et al. 1999). Mixtures of aliphatic and aromatic diisocyanates have been used for preparing waterborne polyurethane dispersions, and the mechanical properties and adhesive strength were higher in the polyurethane made with MDI and lower with the one prepared with H<sub>12</sub>MDI (Rahman et al. 2014). However, after accelerated aging in

1070 salt water, the mechanical strength and adhesive strength were better in the poly-  
1071 urethanes prepared with mixture of H<sub>12</sub>MDI and MDI diisocyanate.

1072 The nature (diol, diamine), chain length, and amount of the *chain extender*  
1073 determined the properties of the waterborne polyurethane dispersions. The diol  
1074 chain extender produced polyurethanes with high degree of phase separation, higher  
1075 crystallinity, and good adhesive strength; this later is higher by increasing the chain  
1076 length of the diol (Orgilés-Calpena et al. 2016a). On the other hand, the diamine  
1077 chain extenders produced polyurea-urethanes that show lower crystallinity, lower  
1078 degree of phase separation, and lower peel strength than the ones prepared with diol  
1079 chain extenders (Rahman 2013).

1080 With respect to other raw materials, the *polyol* determines in greater extent the  
1081 properties of the waterborne polyurethane adhesives. The increase in the molecular  
1082 weight of the polyol (i.e., soft segments) produces dispersions with lower mean particle  
1083 size and increased toughness and elongation at break (Mumtaz et al. 2013), but both the  
1084 hardness and tensile strength decrease (Wang et al. 2015). On the other hand, the peel  
1085 strength decreases by increasing the molecular weight of the polyol (García-Pacios  
1086 et al. 2013a). The nature of the polyol (polyester, polyether, polycarbonate diol,  
1087 polycaprolactone) determines the degree of phase separation in the polyurethane and  
1088 affects noticeably the properties of the waterborne polyurethane dispersions. Because  
1089 of the existence of carbonate groups, the use of polycarbonate diol produces lower  
1090 degree of phase separation and increased shear adhesion with respect to the use of  
1091 polyester and polyether (García-Pacios et al. 2013b). More recently the polyols derived  
1092 from natural oils have been used for the synthesis of waterborne polyurethane disper-  
1093 sions (Yang et al. 2014; Hu et al. 2015). The waterborne polyurethane dispersions  
1094 prepared with natural dimer fatty acid-based polyester polyols exhibited excellent  
1095 water resistance, outstanding hydrolytic resistance and superior thermal stability than  
1096 the ones prepared with nonnatural-derived polyester polyols (Liu et al. 2011).

1097 The properties of the waterborne dispersions are also affected by the nature and  
1098 amount of the *ionic groups*. The increase in the content of dimethyl propionic acid  
1099 (DMPA) decreases the mean particle size and increases the viscosity of the water-  
1100 borne polyurethane dispersions (Huang and Chen 2007). Increased DMPA amounts  
1101 result in the higher hard-segment contents and the increase in the mechanical  
1102 properties of the polyurethanes (Cakić et al. 2013). Furthermore, the increase of  
1103 the DMPA content decreased the adhesion of the polyurethane dispersions (Rahman  
1104 and Kim 2006).

1105 The influence of the *solids content* on the properties of the polyurethane disper-  
1106 sions has been studied, and contradictory findings with respect to their influence on  
1107 the mean particle size have been found. It has been stated that the increase of the solids  
1108 content caused an increase in the mean particle size that was related to the decrease in  
1109 the viscosity of the polyurethane dispersions (Lee and Kim 2009). Another study  
1110 concluded that the mean particle size of the polyurethane dispersion decreased by  
1111 increasing its solids content, and an increase in the viscosity was found, and this was  
1112 related to the decreased particle-particle interactions and the higher degree of phase  
1113 separation (García-Pacios et al. 2011b). On the other hand, the increase in the solids  
1114 content does not affect the peel strength and decreases the single-lap shear strength of

the waterborne polyurethane dispersions (García-Pacios et al. 2011b). A recent study analyzed the structure and properties of high solids content waterborne polyurethane dispersions synthesized by combining ionic and nonionic monomers (Lijie et al. 2015). The adequate combination of the molecular weight of the polyether and the amount of DMPA improved the stability of the dispersion and increased the solids content of the polyurethane dispersion up to 52 wt%. Additionally, the glass transition temperature of the soft segments and the crystallinity of the polyurethane decreased, although the mechanical properties were improved.

*Thickeners* (polyvinyl alcohol, polyurethanes, polyacrylates, cellulose derivatives) are added to increase the low viscosity of the waterborne polyurethane adhesives and to avoid excessive penetration in porous substrates (Orgilés-Calpena et al. 2009a). The mechanism of thickening of the waterborne polyurethane adhesives by adding urethane-based thickener has been analyzed by confocal laser microscopy (Fig. 10). The addition of the thickener produces an entanglement in the polyurethane adhesive (seen as denser and whiter images in Fig. 10) which can be ascribed to the existence of interactions between the urethane-based thickener and the polyurethane. Several interactions take part in the thickening mechanism of the polyurethane adhesive dispersions by adding urethane-based thickener: (i) interactions between the terminal hydrophobic groups of the thickener with the polyurethane micelles, (ii) interactions by ionic adsorption of the polyester chains of the thickener with the ionic groups on the surface of the polyurethane particles, and (iii) interactions by hydrogen bonds between the urethane groups of the polyurethane dispersion and the urethane-based thickener (Orgilés-Calpena et al. 2009a, b). Figure 11 shows a schematic diagram of the thickening mechanism of waterborne polyurethane adhesive containing urethane-based thickener in which the formation of 3D micelle network is seen. On the other hand, the hard-to-soft segment ratios and the

**Fig. 10** Micrographs of confocal laser microscopy corresponding to the waterborne polyurethane adhesives without (14D6) and with (14D6/5e) 5 wt% urethane-based thickener

**Fig. 11** Thickening mechanism of waterborne polyurethane adhesive containing urethane-based thickener through the formation of 3D micelle network (Orgilés-Calpena et al. 2009b)

content of ionic groups determine the properties of the waterborne polyurethane adhesives. Thus, the addition of 5 wt% urethane-based thickener markedly increases the viscosity of the waterborne polyurethane adhesive more noticeably by decreasing the hard-to-soft segments ratio and by increasing the ionic group contents (Orgilés-Calpena et al. 2009a). On the other hand, as the hard-segment content of the thickened polyurethane adhesive decreases, the kinetics of crystallization is favored as a result of stronger polyurethane-thickener interactions.

*Emulsifiers* (surface active agents) assist to stabilize the pH of the waterborne polyurethane dispersion and to decrease its surface tension to obtain improved wettability. The emulsifiers are always oriented on the interface between the polymer particles and the aqueous phase. Small amounts must be added to avoid loss in bonding characteristics.

On the other hand, to achieve particular performance, dispersions of several polymers (vinyl acetate, acrylic ester) and resins (hydrocarbon resin, rosin esters) can be added to waterborne polyurethane adhesives. Special attention must be paid to the compatibility with the polyurethane to avoid dispersion collapse. In general, fillers are not added to waterborne polyurethane adhesives although dispersions of silicas can be added for adjusting the viscosity and the rheology.

To produce adequate bond, the waterborne adhesive solution is applied to the two substrates to be joined, and the water is evaporated at room temperature for about 30 min or by heating with hot air or infrared lamps at 50–60 °C for a few minutes. When the water comes out, the polyurethane viscosity rises, and a continuous film is formed

on the substrates. Then, the dry films are heat activated, and the melting of the crystalline soft segment is produced imparting tackiness to the films. The heat activation process of the waterborne polyurethanes is affected very strongly by the substrates to be bonded and by the process parameters such as temperature, pressure, and contact bond time. Increasing the adhesive film temperature, raising the pressure, and extending the time of contact have all similar effect, i.e., an increase of the actual contact area is produced, and better bond is obtained. After heat activation, the decrystallized polyurethane film is an amorphous viscoelastic melt with good flow properties. The decrease in viscosity after heat reactivation allows the adhesive film to wet the substrate, and the joining to the adhesive film on a second substrate under pressure is produced. Once the adhesive joint is formed, the bulk viscosity and the modulus of the adhesive increase, initially by cooling and afterward by the recrystallization of the polyurethane.

If an isocyanate is added as *cross-linker* of the waterborne polyurethane adhesive, the bond formation occurs much slower than with only the polyurethane, but a further increase in viscosity with time is obtained. The cross-linking reaction does not initially bring any increase in the peel adhesive strength at room temperature but increases the heat resistance of the bond. The most common cross-linkers are polyisocyanates (adequately modified with surface active agents to become emulsifiable in water), although azyridines, polycarbodiimides, and epoxies can also be used. The cross-linker is normally added to the dispersion and stirred in before application on the substrates. Once the cross-linker is added, the drying off of the water is important because the reaction with water reduces its effectiveness. Depending on the formulation, the adhesives can be applied over a period of 4–10 h without affecting the adhesion properties. The isocyanate cross-linker generally takes several days before the cross-linking reaction is completed. Unlike solvent-borne adhesives, the pot life of the adhesive dispersions is not associated with an increase in viscosity.

In general, the durability of the polyurethane adhesives is acceptable although they are water sensitive, particularly the polyether-based polyurethane. Protection against water degradation can be reduced by adding carbodiimides and/or polyisocyanates during curing.

The bond strength of the waterborne polyurethane adhesives is particularly dependent on the substrate. Good results are obtained with surface-chlorinated vulcanized rubbers and PVC, but adhesion to TR may be poor or variable (Abbott 1992). Adhesion to leather is sometimes insufficient, and roughening must be always carried out; adhesion to greasy or waterproof leathers and unroughened polyurethane coatings may also be difficult.

### **Solvent-free Polyurethane Adhesives**

Currently, the waterborne adhesives are being introduced into the shoe industry. Their performance is quite similar to that of the solvent-borne adhesives, so it can be estimated that for several years, they will be used in shoe industry. However, the future seems to be directed through the use of moisture-curing hot-melt urethane and thermoplastic urethane adhesives as they are 100% solids systems and evaporation of solvents is not necessary. Although the hot-melt urethanes could replace

waterborne adhesives, this could take longer to occur because of the vastly different equipment requirements and the change in the bonding concept by the shoe manufacturers.

Some literature has been published dealing with *moisture-reactive hot-melt polyurethane adhesives* (Frisch 2002). Most moisture-curing hot-melt adhesives are obtained by reacting a crystallizable polyol such as poly(hexamethylene adipate) and monomeric MDI (NCO/OH ratios = 1.5–2.2). A catalyst such as dimorpholinediethyl ether is also necessary. The polyester polyol plays a key role because the open time, the viscosity, and the glass transition temperature can be adequately tailored. A mixture of hydroxyl-terminated polyesters having different characteristics allows control of the adhesion and hardening time of the adhesive. Recently, reactive polyurethane hot-melt adhesives containing polycarbonate polyols derived from CO<sub>2</sub> and 4,4'-diphenylmethane diisocyanate (MDI) have been developed from improving the T-peel strength of leather/polyurethane adhesive/vulcanized SBR joints, and they show good green and final strength before and after high temperature/humidity aging and hydrolysis tests (Orgilés-Calpena et al. 2016a, b).

The moisture-curing hot-melt adhesives must be stored in nitrogen-sealed containers, and moisture must be fully excluded. These adhesives are crystalline solids at room temperature, and for application, heating is necessary (about 125 °C) to become low-viscosity liquids, and they are only applied on one of the substrates to be joined; the second substrate is immediately joined with minimal pressure. Simultaneously to the application of the adhesive, water can be sprayed onto the adhesives/materials in the amount necessary for facilitating the curing process. Although after cooling down the crystallinity is reached, about 24 h is necessary to develop the strength of a structural adhesive. Initial strength can be improved by adding polyester, thermoplastics, or polymerized acrylates. Addition of ketone–formaldehyde and terpene phenolic resins also increases adhesive performance. Limitations of these adhesives derive from the special equipments necessary for application and from the substrate nature (not all substrates can be bonded). However, some pre-reacted hot-melt adhesive types are liquids and may be applied by hand, by spraying, or even better by nozzles.

When the polyurethane hot-melt adhesive comes into contact with moisture, the irreversible curing of the adhesive is initiated. First, the water adds to the isocyanate group producing unstable carbamic acid, which in turn is transformed into a primary amine group. These amine groups generate linear urea bridges by reaction with additional isocyanate; a three-dimensional network is produced by cross-linking with more isocyanate groups, providing the structural bonding in moisture-cured hot-melt polyurethane adhesives.

The *thermoplastic polyurethane adhesives* are another future alternative for bonding in shoe industry. These adhesives have good holding strength after crystallization, but their cost is higher than the majority of the adhesives used in shoe industry. Most thermoplastic polyurethane adhesives are based in fast crystallization polyesters. They are prepared using a NCO/OH ratio near 2, and they have linear structure. They consist in two components (polyol and isocyanate) which have to be mixed at about 60 °C in the presence of a catalyst such as dibutyltin dilaurate; after reaction, the

1251 resulting polymer is pelletized and packed in nitrogen- and moisture-free atmosphere  
1252 containers. Application temperatures are higher than 170 °C, and to produce bonding  
1253 the same procedure as for moisture-cured hot-melt urethane is used.

### 1254 51.3.5 Polychloroprene Adhesives

1255 Although polychloroprene adhesives (more often called *neoprene* adhesives because  
1256 of the trade name given by Du Pont to the first commercial product) were extensively  
1257 used in the past in the sole-to-upper bonding, nowadays they have been practically  
1258 substituted by polyurethane adhesives. Therefore, there is no sense in providing an  
1259 extensive description of the polychloroprene adhesives in this chapter which the  
1260 prime aim is to provide an actual overview. A detailed description of the poly-  
1261 chloroprene adhesives for shoe bonding can be found in Chap. 14 of the book  
1262 entitled “Adhesive Bonding. Science, Technology and Applications” (Adams  
1263 2005). Therefore, in this chapter, the main features of these adhesives will be only  
1264 considered, and the reader can refer to that chapter for more detailed information.

1265 Solvent-borne polychloroprene adhesives are less used in shoe industry because  
1266 of the presence of aromatic organic solvents in their formulation which are currently  
1267 unacceptable. However, the most recent developed waterborne polychloroprene  
1268 adhesives can compete with waterborne polyurethane adhesives because of their  
1269 good performance in the upper-to-sole bonding. Furthermore, they are extremely  
1270 useful as nonpermanent adhesives in several mounting operations (previously to the  
1271 sole-to-upper attachment) involving porous substrates in the shoe manufacturing.

### 1272 Solvent-Borne Polychloroprene Adhesives

1273 Polychloroprene adhesives are contact adhesives (see ► Chap. 14, “Adhesive Fam-  
1274 ilies”). The diffusion process in polychloroprene rubber adhesives is mainly affected  
1275 by the solvent mixture of the adhesive (which determines the degree of uncoiling of  
1276 rubber chains) and by the ingredients in the formulation (mainly the amount and  
1277 nature of tackifier). The chemical nature and molecular weight of the poly-  
1278 chloroprene greatly determine its adhesive properties. The polychloroprene  
1279 adhesives show high peel strength; high green strength and noticeable resistance to  
1280 moisture, chemicals, and oils; excellent aging properties; and excellent temperature  
1281 resistance. These characteristics are important in shoe industry.

1282 Polychloroprene elastomers are produced by free radical emulsion polymeriza-  
1283 tion of 2-chloro-1,3-butadiene monomer. The emulsion polymerization of chloro-  
1284 prene involves the dispersing of monomer droplets in an aqueous phase by means of  
1285 suitable surface active agents, generally at a pH of 10–12. Polymerization is initiated  
1286 by addition of free radical catalyst at 20–50 °C. To obtain a high conversion in the  
1287 polymerization reaction and processable polymer, the addition of sulfur, thiuram  
1288 disulfide, or mercaptans is necessary (Whitehouse 1986).

1289 The crystallinity in the polychloroprene is essential in sole-to-upper bonding in  
1290 shoe industry. Crystallinity is produced by noticeable *trans*-1,4 addition (more than  
1291 90%) during polymerization. As a result of crystallization, the cohesive strength of

the polychloroprene is much greater than that of the amorphous polymer. Crystallization is reversible under temperature or dynamic stresses. Thus, for a temperature higher than 50 °C, uncured polychloroprene adhesives lose their crystallinity, and upon cooling the film recrystallizes, and cohesive strength is regained. The increase in the crystallinity improves the modulus, hardness, and cohesive strength of the polychloroprene adhesives but decreases their flexibility.

A typical composition of solvent-borne polychloroprene adhesive for upper-to-sole attachment is given in Table 2.

The role of the different components in solvent-borne polychloroprene adhesive is described below in more detail.

The sulfur-modified *polychloroprenes* with little or no branching are the most commonly used in shoe adhesives as they are soluble in aromatic solvents, and for difficult-to-bond substrates, methacrylic graft polymers show better performance. The polymer type influences several properties of the solvent-borne polychloroprene adhesives, mainly the molecular weight and the rate of crystallization. The increase in the molecular weight of the polychloroprene imparts higher solution viscosity, adhesive strength, and heat resistance. On the other hand, the increase in the crystallization rate of the polychloroprene improves the rate of development of the bond strength and the ultimate strength at high temperature, but a reduction in open time (*tack*) is obtained. However, the tack can be varied by changing the pressure during joint formation and by an adequate selection of the solvent; the lower the volatility of the solvent, the longer is the open time of the solvent-borne polychloroprene adhesive.

*Metal oxides* provide several functions in solvent-borne polychloroprene adhesives. The main function of the metal oxides in the polychloroprene adhesive formulations is acting as acid acceptor. Upon aging, small amounts of hydrochloric acid are released which may cause discoloration and substrate degradation. Magnesium oxide (4 phr) and zinc oxide (5 phr) act synergically in the stabilization of the solvent-borne polychloroprene adhesives against dehydrochlorination. On the other hand, the magnesium oxide retards scorch during mill processing of the polychloroprene adhesives and also reacts in solution with the *t*-butyl phenolic resin to produce an infusible resinate (a small amount of water is also necessary) which provides improved heat resistance. Furthermore, the zinc oxide produces a room temperature cure of the solvent-borne polychloroprene adhesives, giving increased strength and improved aging resistance.

**Table 2** Typical composition of a solvent-borne polychloroprene adhesive. *phr* means parts per hundred parts of rubber

Polychloroprene	100 phr
Tackifying resin	30 phr
Magnesium oxide	4 phr
Zinc oxide	5 phr
Water	1 phr
Antioxidant	2 phr
Solvent mixture	500 phr

1327 Addition of *resins* to solvent-borne polychloroprene adhesives serves to improve  
 1328 its specific adhesion, increases tack retention, and increases hot cohesive strength.  
 1329 *Para-tertiary* butyl phenolic resins are the most common, and amounts between  
 1330 35 and 50 phr are generally added. In general, the tack decreases by increasing the  
 1331 phenolic resin content in the polychloroprene adhesive, and bond strength reaches a  
 1332 maximum at about 40 phr, decreasing for higher amounts of phenolic resin.

1333 Solutions of polychloroprene adhesives containing metal oxides and *t*-butyl  
 1334 phenolic resin may show phasing (e.g., clear upper layer and flocculated lower  
 1335 layer of metal oxides) on standing upon days or months. To recover the full utility  
 1336 of the metal oxides, agitation before use is sufficient. Phasing is ascribed to the wide  
 1337 molecular weight distribution of the *t*-butyl phenolic resins.

1338 Terpene phenolic resins can also be added to solvent-borne polychloroprene  
 1339 adhesives to increase open tack time and to provide a softer glue line than the  
 1340 *t*-butyl phenolic resins. To provide adequate hot-bond strength, these resins are  
 1341 used in combination with a polyisocyanate-curing agent.

1342 An *antioxidant* (about 2 phr) should be added to the polychloroprene adhesives to  
 1343 avoid oxidative degradation and acid tendering of the substrates. Derivatives of  
 1344 diphenylamine (octylated diphenylamine, styrenated diphenylamine) provide good  
 1345 performance, but staining is produced. To avoid staining, hindered phenols or  
 1346 bisphenols can be added.

1347 *Solvent* affects the adhesive viscosity, the bond strength development, the open  
 1348 time, and the ultimate strength of the polychloroprene adhesives. Blends of three  
 1349 solvents (aromatic, aliphatic, oxygenate – e.g., ketones, esters) are generally added.  
 1350 Typical solvent blends for polychloroprene adhesives are given in Table 3. The open  
 1351 tack time of the solvent-borne polychloroprene adhesives partially depends on the  
 1352 evaporation rate of the solvent blend. If a solvent evaporates slowly, the solvent-  
 1353 borne polychloroprene adhesive will retain tack longer, whereas if the solvent  
 1354 evaporates quickly, the cohesive strength will develop more rapidly.

t.1 **Table 3** Influence of the solvent on the viscosity and the tack of polychloroprene adhesives.  
 Formulation: 100 phr polychloroprene elastomer; 4 phr MgO; 5 phr ZnO; 2 phr hindered phenolic  
 antioxidant; 500 phr solvent mixture (Whitehouse 1986)

t.2	Solvent	Mixing ratio	Solution viscosity 20 °C (mPa.s)	Tack time (min)

t.11	Dichloromethane	–	4670	30
t.12	1,1,1-Trichloroethane	–	4600	38

*Isocyanates* can be added to solvent-borne polychloroprene adhesive solutions as two-part adhesive systems. The reaction of the isocyanate with polychloroprene that leads to improved heat resistance property has not been fully explained as there are no active hydrogen atoms in the polychloroprene to allow reaction with isocyanate group. The two-part adhesive system is less effective with rubber substrates containing high styrene content and with butadiene–styrene block (thermoplastic rubber) copolymers. To improve the specific adhesion to those materials, addition of poly- $\alpha$ -methylstyrene resin to solvent-borne polychloroprene adhesives is quite effective (Tanno and Shibuya 1967).

**Waterborne Polychloroprene Adhesives**

In recent years, the use of solvent-borne polychloroprene adhesives has been seriously restricted, and waterborne adhesives have been developed. Polychloroprene latex differs from its solid elastomer counterpart (used in solvent-borne polychloroprene adhesive) in that it is a gel polymer (e.g., insoluble in organic solvents). Latex systems derive their bond strength characteristics from the gel structure rather than crystallinity as in solvent solution systems. Higher gel content leads to the same properties than polymers with higher crystallinity (Lyons and Christell 1997). Polymers with higher gel content exhibit higher cohesive strength, modulus, and heat resistance, but tack, open time, and elongation at break are reduced.

The initial formulations of the polychloroprene latex adhesives contain essentially the same components than the solvent-borne adhesives, except that water-based ingredients have to be used, surfactant, thickener and antifoaming agent must be added, and the compounding is particularly exigent. A typical composition of initial waterborne polychloroprene adhesive is given in Table 4.

In the last years, more simple and efficient formulations of waterborne polychloroprene adhesives for shoe industry have been developed (Kueker et al. 2016). The typical formulation of the current waterborne polychloroprene adhesives is given in Table 5 and consists in polychloroprene, acrylic or silica sol dispersion, zinc oxide, surfactant, antifoaming agent, and antioxidant. The preparation of these waterborne polychloroprene adhesives starts with the addition of the antioxidant to the polychloroprene dispersion, followed by slow addition of zinc oxide and the final incorporation of the acrylic or silica sol dispersion.

The final adhesive strengths obtained with the current waterborne polychloroprene adhesives are due to the cross-linking between the polychloroprene

**Table 4** Typical composition of the initial waterborne polychloroprene adhesive formulation

1389 and the silica or acrylic micelles, and similar adhesive strengths to the ones obtained  
1390 with solvent-borne adhesives are obtained, although the open time is generally  
1391 longer. The use of silica sol dispersions with low mean particle size (i.e., about  
1392 5 nm) improves more the initial adhesive strength or wet bonding to leather than the  
1393 use of silica sol dispersions with higher mean particle size, and the increase in  
1394 the amount of silica causes softening and a decrease in the mechanical properties  
1395 of the polychloroprene. Finally, the heat resistance of the polychloroprene adhesives  
1396 can be noticeably increased by using hydroxylated polychloroprene dispersion due  
1397 to the hydrogen bond formation with the silica sol particles; in fact when this  
1398 hydroxylated polychloroprene dispersion is used, there is no need of adding poly-  
1399 isocyanate cross-linker for increasing the aging resistance, and this is even better  
1400 than by using solvent-borne polychloroprene adhesives (Kueker et al. 2016).

1401 Recently, the magnetic conditioning for 3 h of aqueous-based polychloroprene  
1402 contact adhesive has been proposed for increasing its adhesion (Souza et al. 2016).  
1403 To promote adhesion, a nanometric zinc oxide, carbon dioxide as catalyst, hydrox-  
1404 ylamine, and a magnetic conditioning process before the application of the adhesive  
1405 were carried out. The magnetic conditioning was performed in magnetic cell com-  
1406 prising of containers for circulation of the adhesive, two submerged centrifugal  
1407 hoses for transfer of the adhesive, a set of magnets iron–boron–neodymium with  
1408 magnetic field of 2120 gauss, gaussmeter, and agitators. Noticeable increase in shear  
1409 adhesion was obtained.

1410 The *polychloroprene latex* determines the initial tack and open time, the bond  
1411 strength and the hot-bond strength, the application properties, and the adhesives  
1412 viscosity. Because most of the latexes have low viscosities, most of the waterborne  
1413 polychloroprene rubber adhesives are sprayable. Thickeners such as fumed silicas  
1414 can be added to some formulations for increasing viscosity and thixotropy.

1415 Grafting of methyl methacrylate (MMA) onto polychloroprene rubber latex  
1416 (CRL) has been carried out by emulsion polymerization using a redox initiator,  
1417 and the surface diffusion-controlled process model was proposed to describe the  
1418 grafting mechanism (Zhang et al. 2012). The graft copolymer was blended with  
1419 tackifier and filler for waterborne contact adhesive applications, and the 180° peel  
1420 strength to canvas to other decoration materials showed similar performance than  
1421 solvent-based contact adhesive and superior to the one obtained with poly-  
1422 chloroprene and polymethyl methacrylate.

1423 Based on the synergistic effect of polychloroprene latex and styrene–acrylate  
1424 emulsion, waterborne contact adhesive containing 40 wt% styrene–acrylate emulsion

1425 and 1.25 wt% boric acid has been developed (Zhang et al. 2009). The blend had a good  
1426 shelf stability, its set time was 5 min, its tensile strength was reasonable, and it had very  
1427 high elongation at break. The performance of the waterborne contact adhesives was  
1428 found to be comparable to the solvent-based contact adhesives because they offered  
1429 good wetting ability to substrate, high initial tack was obtained, it possessed excellent  
1430 crystallization ability, and it enhanced the cohesive strength of the adhesive.

1431 Although noncompounded polychloroprene latex has good mechanical and stor-  
1432 age stability, *surfactants* are added commonly for stabilization. They function by  
1433 strengthening the interfacial film by maintaining or increasing the degree of solva-  
1434 tion or by increasing the charge density on the latex particle. More precisely,  
1435 surfactants are added to improve storage stability, substrate wetting, and attain  
1436 improved freeze resistance. However, incorporation of surfactants has an adverse  
1437 effect on cohesive properties and should be kept to a minimum. Water resistance and  
1438 tack may also be affected. Excessive stabilization of the adhesive mixture may  
1439 negatively affect coagulation (which is desirable in the wet bonding process).  
1440 Anionic emulsifiers (alkali salts of long-chain fatty acids and alkyl/aryl sulfonic  
1441 acids) or nonionic emulsifiers (condensation products of long-chain alcohols, phe-  
1442 nols, or fatty acids with ethylene oxide) can be used.

1443 Zinc oxide is the most effective *metal oxide* and plays three main functions:  
1444 (i) promote cure; (ii) improve aging, heat, and weathering resistance; and (iii) acid  
1445 acceptor. In general, 2–5 phr zinc oxide is added in latex formulations.

1446 *Resins* influence the adhesion, open time, tack, and heat resistance of the water-  
1447 borne polychloroprene adhesives. In some formulations, 30–60 phr is added, and  
1448 attention should be paid to the pH and compatibility with the surfactant. The glass  
1449 transition temperature, the softening point, the polarity, and the compatibility of the  
1450 resin with the polymer determine the adhesive properties. Thus, the hot-bond perfor-  
1451 mance is generally proportional to the softening point of the resin. *t*-Butyl phenolic  
1452 resins cannot be used in waterborne polychloroprene adhesives because of colloidal  
1453 incompatibility. Instead, terpene phenolic resins can be added to polychloroprene  
1454 latex without great reduction in hot strength as the resin content is increased; however,  
1455 the contact ability is reduced, and an adhesion failure is obtained, even at the 50 phr  
1456 level. Furthermore, the terpene phenolic resins have relatively poor tack but impart  
1457 good resistance to elevated temperatures to the polychloroprene latexes and require  
1458 either heat activation or pressure to achieve adequate bond strength. Rosin ester resin  
1459 emulsions are also effective in latex adhesives as they extend the tack life of the  
1460 polychloroprene latexes, but they do not have the reinforcing characteristics of the  
1461 terpene phenolic or alkyl phenolic resins. Hence, the cohesive strength and heat  
1462 resistance are sacrificed to obtain surface tack.

1463 New nitrogen-containing compounds have been proposed as highly efficient  
1464 *adhesion promoters* for adhesive compositions based on polychloroprene (Keibal  
1465 et al. 2011). On the other hand, similar *antioxidants* than for solvent-borne poly-  
1466 chloroprene adhesives can be used in the formulation of waterborne polychloroprene  
1467 adhesives.

1468 Addition of *thickeners* increases the viscosity of the polychloroprene latex adhe-  
1469 sives. Amounts up to 1 wt% of polyacrylates, methyl cellulose, alginates, and

polyurethane thickeners can be used. Particular attention should be paid to fluctuations in pH when thickener is added in the formulations. For low pH (7–10) formulations, fumed silica or some silicates can be used.

*Curing agents* have little effect on the performance of latexes with the highest gel content, but they are sometimes used with low-gel polymers to improve hot-bond strength while maintaining good contactability. Suitable curing agents are thiocarbonylides either alone or in combination with diphenylguanidine, zinc dibutyldithiocarbamate, and hexamethylenetetramine. Two-part systems have been developed using more active materials such as aqueous suspension isocyanates and hexamethoxy melamine. These agents produce a cross-linking reaction at room temperature and give fast bond development but exhibit a finite pot life. The most common use of the curing agents is with carboxylic latices. Isocyanates and melamines can be used, but zinc oxide is the most common curing agent. Zinc oxide cross-links carboxylated latices and improves bond strength by ionomer formation (Cuervo and Maldonado 1984). Carboxylated polychloroprene reacts slowly with zinc oxide in dispersed form, causing a gradual increase in adhesive gel content that can lead to restricted adhesive shelf life. Resin acid sites compete with the polymer acid sites for  $\text{Zn}^{II}$ ; the more resin acid sites, the more stable the adhesive is.

---

## 51.4 Testing of Adhesive Joints in Shoe Bonding

In order to produce an optimum adhesive bonding of upper to sole, apart from the adequate surface preparation of the sole and upper materials and the adequate choice of the adhesive, the procedure to produce the joint should be carefully controlled and optimized. To achieve adequate adhesion of upper to sole, the following issues should be considered.

1. Selection of the upper and sole materials. In general, formulators of upper and sole materials do not consider that they have to be bonded, but they pay more attention to match the hardness and mechanical properties and aesthetic of the materials. Furthermore, depending on fashion, different difficult-to-bond materials are used to produce shoes which make problematic to standardize bonding. In general, the formulation of the shoe materials must elude the presence of additives able to decrease the adhesion to polyurethane or polychloroprene adhesives (plasticizers, excessive amounts of processing oils, inadequate selection of antioxidants, and antioxidants), and especially the use of too greased leather upper must be avoided. On the other hand, the formulations must be repetitive, and first-class raw materials must be used. As a general rule, the use of adequately formulated uppers and soles avoid more than 90% of the bonding problems in shoe industry.
2. Selection of the adhesive. The adhesive must be selected considering the performance required for each joint. Adhesive must properly wet the upper and sole surfaces, and in this aspect, solvent-borne adhesives are excellent. One of the problems in the use of waterborne adhesives is their poor wettability, although an

adequate formulation may solve quite satisfactorily this limitation. In the selection of an adhesive, the following aspects should be particularly considered: nature and formulation of the materials to be bonded; stresses produced during shoe use; environment of use (solvents, acid, or alkali media), only for safety shoes; adhesive application restrictions (viscosity, rheological properties); specific requirements of the adhesive (pot life, working scheme in the shoe factory); and safety regulations.

3. Design of the joint. Fashion dictates the shape and geometry of the shoes. Sometimes, the shoes become difficult to bond because of high heels or heterogeneous shapes of soles. In general, the shoe designers do not pay attention to the bonding.

4. Adequate bonding operation. Several cases of poor adhesion in shoe bonding arise from a deficient operation. As a summary, the following aspects must be properly obeyed to assure an adequate upper-to-sole bonding:

- Surface treatments of upper and sole. The way to produce the surface preparation and the instruments used are critical. Furthermore, proper surface preparation for each upper and sole must be selected.
- Adhesive application. A thin film of adhesive (about 100  $\mu\text{m}$  thick) is applied to each of the two substrates to be bonded, and the solvent is removed by natural or forced evaporation. A heavier coat of adhesive is more likely to result in a cohesive failure in the substrate. The application procedure (brush, doctor knife, spray gum, roller, coater) and the amount of adhesive must be carefully controlled. The choice of the adhesive application devices depends mainly on the type and size of the materials to be bonded as well as on the rheological properties of the adhesive. Furthermore, the viscosity of the adhesive must be controlled, and the operation times (evaporation rate of organic solvents or water, open time, shelf life) must be strictly obeyed.
- Adhesive film drying. Controlled drying of the shoe bottom cements is preferable to natural drying. Removed excess water or organic solvent from an adhesive film is not entirely governed by the process of evaporation but also by the speed of absorption into the substrate. Porous substrates (such as leather) absorb water or organic solvents without detrimental effect on bond strength, whereas nonporous substrates need the complete solvent removal to produce adequate adhesion. Furthermore, a force drying may produce skin formation on the surface of the coating (especially if heavier adhesive coating is applied) leading to poor coalescence of the adhesive. A slight trace of organic solvent in the cement film on the upper at sole attaching is beneficial in giving complete coalescence. When necessary, although very fast drying can be achieved by radiant heat, the use of IR radiation and hot air is a more convenient method, and both provide more uniform heating.
- Bond formation. The components with the dry adhesive film are placed for 10–30 s in a “flash heater” – hot air or IR radiation can also be used – where a radiant heat source raises suddenly the temperature of the adhesive film above the crystalline melting of the polyurethane (heat activation or reactivation process). Recommended reactivation temperature for polyurethane adhesives

ranges between 45 and 85 °C, depending on the substrates and the adhesive characteristics. An insufficient reactivation temperature causes non-coalescence of the adhesive, and an excessive reactivation temperature decreases creep because the substrate is too hot and the adhesive is still soft when sole and upper are attached (SATRA 1963). In some particular cases, the reactivation temperatures of the adhesives higher than 100 °C are recommended to produce good performance. While still in their amorphous state, the adhesive films are brought together under pressure (typically 35–200 kPa) for 10–30 s (*stuck-on* process). The time interval after the heat activation process during which the films adhere is known as the “spotting tack.” Both the applied pressure and the pressing time of the upper to the sole must be adequately selected for each joint.

- Crystallization or curing of the adhesive. After bond formation, the adhesive joint needs time to gain sufficient cohesion. Time can vary, although in general a minimum of 24 h is required for crystallization, being 72 h the optimum. For waterborne adhesives, the curing time may be longer.

T-peel (see ► Chap. 20, “Fracture Tests”) and creep (see ► Chap. 34, “Creep Load Conditions”) tests are the most commonly used to establish the adhesion performance in shoe bonding. The peel test serves to determine the bonding properties of upper to sole in shoe industry. Peeling rate, material thickness, and size of test samples must be optimized. Standard T-peel tests require two rectangular test pieces of 150 mm long, 30 mm width, and 3 mm thick that are stuck together to cover it other to a length of at least 50 mm (Fig. 12). Standard peel rate is 100 mm/min. The joints are stored for 72 h in standard atmosphere (23 °C and 50% relative humidity) before carrying out the separation tests. Both the peel resistance and the way in which the separation occurs help to assess the bond. A minimum of five replicates, preferably ten, for each joint must be tested and averaged. Bond strength should be expressed as kN/m, although very often N/mm is used in the shoe industry. The loci of failure of the joints are generally expressed using the following capital letters:

- A: Adhesion failure (detachment of the adhesive film from one of the materials)
- C: Cohesive failure in the adhesive (separation within the adhesive film without detachment from the material)
- N: Non-coalescence failure (failure of the two adhesive films without detachment from the material)
- S: Surface cohesive failure of the material (breakdown of a substrate of low structural strength at its surface)
- M: Cohesive failure of one of the substrates

Under the influence of force and when heated, the adhesive layers of footwear material bonds suffer plastic flow. The creep test at constant temperature serves to assess the behavior of shoe material bonds when heated under the influence of a

**Fig. 12** T-peel test sample

constant peeling force over a fixed time. Weight between 0.5 and 2.5 kg can be fixed on the lower holders outside a heating oven where the test pieces can be heated at 50–70 °C. The unbounded ends of five test pieces are bent apart carefully and inserted in the holders. Temperature is generally raised to 60 °C after a warm-up period of 1 h. The test pieces are loaded with the chosen weight constantly for 10 min. Then, the heating oven is opened, and the separations of the bonds are marked.

Moisture and temperature are the main agents able to degrade the shoe joints. Therefore, adequate *aging tests* have been developed to assure adequate performance. In general, addition of polyisocyanate hardener increases the durability and retards aging in most of the upper-to-sole adhesive joints. Several tests have been proposed to establish the aging resistance of upper-to-sole bonds. The most common aging tests involve the immersion in hot water, the exposition of the joints to 50 °C and 95% relative humidity for 1 week, freeze-thaw cycles, and/or UV light. Generally, after aging T-peel tests are carried out to determine durability.

## 51.5 Conclusions

This review considered the current state of the art of the main issues involved in the bonding process of upper to sole in footwear manufacturing. The main innovations in the surface treatments of soles of different materials and the waterborne adhesives were addressed.

**Acknowledgment** The chapter was not possible without the help of several people who work in my laboratory. The financial support from the Spanish Research Agency (CICYT, MCYT, MICINN), the Generalitat Valencia (Conselleria de Educaci3n, Cultura y Deporte, Conselleria de

1619 Industria), and the University of Alicante is greatly appreciated. Last but not least, my deep  
1620 recognition and gratitude to Antonia Armentia-Agüero (Toñi) for her love and for her help in  
1621 several figure designs.

Abstract

There has been an increase in using adhesives in the oil industry in the last years. The main advantage of using adhesive bonding is to avoid the fire risk concerning the traditional weld process. Adhesives also feature protection against corrosion which is a main concern in offshore installations. Different from other industrial applications, where adhesive bonding is used to manufacture new structures or some parts of them, the oil industry mainly uses adhesives to repair pipelines, pipework, and offshore structures. This chapter shows that the use of composites has become a real alternative to structural repairs in situ as these materials become more and more reliable. The chapter also brings a summary of the most applied standards and the best practices recommended to perform bonded repair in offshore units. Finally, some examples of actual applications of adhesives are presented.

52.1 Introduction

There has been an increase in the use of structural adhesives in the oil and gas industry recently. These materials have some inherent performance advantages over other types of joining, mainly welding. They avoid hot work process, which is one of the main advantages in some areas of the oil and gas industry. They also feature protection against corrosion, and the assembly process is faster compared to other types of joining.

In oil installations, process plants, or ship platforms, some maintenance repairs are required during their operating life. Corroded pipes or sidewalls of ships and semisubmersible platforms are some examples. Usually the offshore production units must be sent to shipyards in order to perform repairs of metallic structures. Sometimes it is possible to stop the production for maintenance, but even in these cases an apparatus for inerting of tanks is needed for welding. It results in high direct and indirect costs. The use of composite repairs is an alternative to structural repairs in situ, avoiding the fire risk concerning the traditional weld process. Beyond the security issue, economical aspects should be considered. When welding is carried out in FPSO (floating, production, storage, and offloading) units, not only the tank to be repaired must be emptied but also the other surrounding tanks. It means that the storage capacity of the unit is compromised during the welding process. The reduction in storage capacity of the vessel leads to the reduction in the production of the unit causing financial losses. On the other hand, the use of composite patch repairs kept the reduction in storage capacity of the vessel to a minimum while the repair took place (Turton et al. 2005).

In what concerns corroded pipelines, adhesively bonded composite systems are also seen to be more economical than other repair alternatives. Duell et al. (2008) state that in this case, the use of composite repairs can be one fourth less expensive than welded steel sleeve repairs and three fourths less expensive than the complete replacement of the damaged segment.

Adhesively bonded composite repairs can be considered an effective repair for mechanical damage, such as dent on the longitudinal weld, by increasing the fatigue life of the defective pipe. In most applications, the use a primer adhesive is recommended. But sometimes the lamination resin is at the same time responsible for the adhesion between the repaired metallic substrate and the composite. Depending on the surface conditions, it can be necessary to use a resin as a filler to provide a smooth surface. Thickened resins are often used to fill corroded areas before applying the first layer of the composite material (Rohem et al. 2016).

Many commercial carbon fiber repair systems use epoxy resins (Alnaser and Keller 2015). An epoxy-based primer can also be applied to prevent galvanic corrosion and increase adhesion. The carbon fiber fabric is normally wetted with the epoxy resin, and the wetted fabric is wrapped by the hand around the pipe (Goertzen and Kessler 2007).

When using glass fiber fabric, some authors reported that a vinyl ester resin was found to provide an attractive combination of on-site processability, metal-composite bond toughness, and overall resistance to corrosion (Mablesen et al. 2000). Originally developed to be applied to onshore pipelines, glass fiber composite repairs were gradually proposed to be used in offshore pipelines such as risers. The complex combined loads acting on risers are one of main concerns, since it is completely different from onshore pipelines where the main load is internal pressure (Alexander and Ochoa 2010).

Some examples that show the viability of the use of bonded composite repairs to the two most widely encountered damage scenarios in floating offshore units, fatigue cracking and thickness loss due to corrosion, can be found in the literature. McGeorge et al. (2009) have demonstrated that these repairs can be applied for full-scale trials even under severe sea conditions.

In situ, submerged repairs of damaged piping using composites face several challenges. According to Dhanalakshmi et al. (1997), the primary challenge is the curing and material property development of composite systems that are based on liquid resins that wet out reinforcement and then are applied while submerged. The choice of the appropriate materials to be used is not the only issue. The entire repair operation must be carefully studied, and logistics issues, including the use of divers and the application of repairs to moving structures, must be considered (Mally et al. 2013).

Da Costa Mattos et al. (2014) report the use of a polyurethane pre-impregnated bidirectional glass fiber composite applied to repair corroded pipelines (Fig. 1). According to them, the water-activated polyurethane resin reduces composite preparation time by 50% and is fully cured after 2 h at 24 °C.

Different from other industrial applications, where adhesive bonding is used to manufacture new structures or some parts of them, the oil industry mainly uses adhesives to repair pipelines, pipework, and offshore structures. In most of those

**Fig. 1** Polyurethane pre-impregnated repair

**Fig. 2** Pipeline repair  
(courtesy of TEAM/  
FURMANITE) <https://twitter.com/furmanite/status/723008415182798848>

situations, field conditions are very difficult needing much skill to accomplish the repair operation (Fig. 2). The use of sophisticated surface preparation methods before applying the adhesive is so laborious that the repair becomes too expensive.

Mechanical surface preparation methods are more indicated rather than chemical modification of the surface. Abrasive methods are commonly applied to obtain a specific surface roughness (De Barros et al. 2015). Traditional abrasive wear and erosive wear, such as sandpapering and sandblasting, are still used, but they have been replaced by new methods. The bristle blasting system MBX (Monti Tools Inc., Houston, USA) has been widely used because it can be easily taken to field situations (De Barros et al. 2016). This system uses high-carbon steel wire bristles as shown in Fig. 3.

A new abrasive method is the use of different kinds of Sponge Media™ (Sponge-Jet Inc., Newton, USA). These composite abrasives incorporate micro-abrasive particles within high-performance synthetic sponge (Fig. 4). The main advantage, compared to sandblasting, for instance, is that the synthetic sponge can capture most of the contaminant particles resulting from the blasting operation.

**Fig. 3** MBX system**Fig. 4** Sponge-Jet system

This chapter is structured in three sections. After this introduction showing not only the advantages but also the challengers involving the use of adhesives in oil and gas industry, the next section brings a summary of the most applied standards and the best practices recommended to perform bonded repair in offshore units. The chapter ends with six examples to illustrate actual applications that have been proposed for adhesives in field situations.

---

## 52.2 Standards and Recommended Practices

In offshore structures, an important document, approved by classification societies, is “Design, Fabrication, Operation and Qualification of Bonded Repair of Steel Structures” – DNVGL-RP-C301 from DNV GL (Det Norske Veritas – Germanischer Lloyd). This Recommended Practice (RP) is based upon a project guideline developed within the Joint Industry Project (JIP) “Qualification of Adhesive Bonding in Structural Repair of FPSO’s” sponsored by ConocoPhillips, Norsk

Hydro, Petrobras, Petronas, Shell, and Statoil. The main focus of this document was placed on FPSOs and similar ship-like floating structures, but it can be also equally applicable to the repair of other types of offshore units.

The main objectives of this document are to:

- Provide an international RP of repairs practices for floating units using composite adhesive patches
- Serve as a technical reference document in contractual matters
- Reflect the state-of-the-art and consensus on accepted industry practice and server as a RP for composite adhesive patch repair design, analysis, application, and maintenance

Section 7 of this RP describes materials and bonding agents and points out special considerations for adhesive composite patches on steel substrates.

In what concerns composite repairs, a complementary document is the DNVGL-OS-C501 – Composite Components. It contains more information on the use of adhesives in composite laminated joints.

A list of important standards is summarized following.

#### **52.2.1 ISO 24817:2015: Petroleum, Petrochemical and Natural Gas Industries – Composite Repairs for Pipework – Qualification and Design, Installation, Testing and Inspection**

The objective of this standard is to ensure that pipework, pipelines, tanks, and vessels repaired using composite systems that are qualified, designed, installed, and inspected using this standard will meet the specified performance requirements. Repair systems are designed for use within the petroleum, petrochemical, and natural gas industries and also within utility service applications. The main users of this standard will be plant and equipment owners of the pipework and vessels, design contractors, suppliers contracted to provide the repair system, certifying authorities, installation, maintenance, and inspection contractors.

The qualification, design, installation, testing, and inspection procedures for composite repair systems in this standard cover situations involving the repair of damage commonly encountered in oil, gas, utility pipework systems, and vessels. The procedures are also applicable to the repair of pipelines, caissons, and storage tanks with appropriate consideration.

Procedures described in this standard cover the repair of metallic and GRP pipework, pipework components, and pipelines originally designed in accordance with a variety of standards, including ISO 15649, ISO 13623, ISO 14692, ASME B31.1, ASME B31.3, ASME B31.4, ASME B31.8, and BS 8010.

This standard is not a defect assessment standard. Within this standard, no statements are made regarding whether a specific defect is acceptable or unacceptable for repair. The standard assumes that a defect assessment has already been performed to, for example, ASME B31G or API RP 579. The starting point

for this standard is that a decision has been taken to repair a given defect with a composite repair system and the output from the defect assessment, e.g., MAWP (maximum allowed work pressure) or minimum remaining wall thickness is used as input for the repair design. The main concern of this standard is with the subsequent activities of repair qualification, design, installation, and inspection.

Repair systems are applied to restore structural integrity. The following repair situations are addressed:

- External corrosion, where the defect is or is not through wall. In this case, the application of a repair system will usually arrest further deterioration.
- External damage such as dents, gouges, and fretting (at supports).
- Internal corrosion, erosion, where the defect is or is not through wall. In this case, corrosion and/or erosion can continue after application of a repair system, and therefore the design of the repair system shall take this into account, i.e., the size of the defect at the end of the required design life of the repair should be taken as the size of the defect when designing the repair.
- Crack-like defects, where the defect is or is not through wall. It is a requirement that the length of the crack is known and will not increase during the lifetime of the repair. For through-wall cracks, the crack should be modeled as a type B defect (through-wall defect), either a circumferential or axial slot (depending on the crack orientation). For non-through-wall cracks, the crack should be modeled as type A defect (non-through-wall defect).
- Strengthening and/or stiffening in local areas.

Services that are covered within the scope of this standard include those normally found in an oil and gas production or processing installation. These include the following:

- Utility fluid, diesel, seawater, and air
- Chemicals (liquids)
- Production fluids, including liquid hydrocarbons, gaseous hydrocarbons, and gas condensates

The upper temperature limit is defined in this standard for different class of repairs in a detailed table. The lower temperature limit is dependent on the type of repair laminate being used. This limit is determined by the design requirements presented in detailed in a table of this standard.

The upper pressure limit is a function of defect type (internal, external, or through wall), defect dimensions (depth and extent), pipe diameter, design temperature, and repair design lifetime. Therefore, a unique number cannot be quoted, but rather the limit is derived for a given set of conditions by calculations in accordance with this standard using the qualification test data. The lower pressure limit, e.g., vacuum conditions, is determined by the design requirements based on external loads. All equations for thickness design are described on this standard.

The composite materials constituting the repair laminate considered within this standard are typically those with aramid (AFRP), carbon (CFRP), glass (GRP), or polyester (or similar material) fiber reinforcement in a polyester, vinyl ester, epoxy, or polyurethane polymer matrix. Other fiber and matrix types are also permissible once qualified.

The pipework and vessel substrates considered within the standard include carbon steel, 6 moly steel, stainless steel, duplex steel, super duplex steel, GRP, cupifer, aluminum, galvanized steel, and titanium. Careful consideration is required before repair of GRP lines because the damage in the pipe may be more extensive than is visible on the surface and may affect a longer length of the pipe than is immediately obvious; advice of the GRP pipe manufacture and repair system supplier shall be sought before a repair is installed.

### **52.2.2 API 653: Tank Inspection, Repair, Alteration, and Reconstruction**

This standard covers steel storage tanks built to API 650 and its predecessor API 12C. It provides minimum requirements for maintaining the integrity of such tanks after they have been placed in service and addresses inspection, repair, alteration, relocation, and reconstruction.

The scope is limited to the tank foundation, bottom, shell, structure, roof, attached appurtenances, and nozzles to the face of the first flange, first threaded joint, or first welding-end connection. Many of the design, welding, examination, and material requirements of API 650 can be applied in the maintenance inspection, rating, repair, and alteration of in-service tanks. In the case of apparent conflicts between the requirements of this standard and API 650 or its predecessor API 12C, this standard shall govern for tanks that have been placed in service.

This standard employs the principles of API 650; however, storage tank owner/operators, based on consideration of specific construction and operating details, may apply this standard to any steel tank constructed in accordance with a tank specification.

This standard is intended for use by organizations that maintain or have access to engineering and inspection personnel technically trained and experienced in tank design, fabrication, repair, construction, and inspection.

This standard does not contain rules or guidelines to cover all the varied conditions which may occur in an existing tank. When design and construction details are not given, and are not available in the as-built standard, details that will provide a level of integrity equal to the level provided by the current edition of API 650 must be used.

This standard recognizes Fitness-for-Service assessment concepts for evaluating in-service degradation of pressure-containing components. API 579-1/ASME FFS-1, Fitness-for-Service, provides detailed assessment procedures or acceptance criteria for specific types of degradation referenced in this standard. When this standard does not provide specific evaluation procedures or acceptance criteria for

a specific type of degradation or when this standard explicitly allows the use of Fitness-for-Service criteria, API 579-1/ASME FFS-1 may be used to evaluate the various types of degradation or test requirements addressed in this standard.

### **52.2.3 ASME PCC-2–2015: Repair of Pressure Equipment and Piping**

This standard provides methods for repair of equipment and piping within the scope of ASME Pressure Technology Codes and Standards after they have been placed in service. These repair methods include relevant design, fabrication, examination, and testing practices and may be temporary or permanent, depending on the circumstances. The methods provided in this standard address the repair of components when repair is deemed necessary based on appropriate inspection and flaw assessment. These inspection and flaw evaluation methods are not covered in this standard, but are covered in other post-construction codes and standards.

This document is divided into five parts:

Part 1 covers the scope, organization, and intent and is applicable to all articles in this standard and also provides guidance for the applicability of repair methods listed in this standard.

Part 2 covers repair methods and techniques that include the use of welding, brazing, soldering, or other methods involving metal deposit.

Part 3 covers mechanical repairs, with or without sealant, such as bolted clamps or fixtures, and includes all repair methods not covered in Part 2 or Part 4.

Part 4 covers repairs using nonmetallic means, such as nonmetallic liners and wraps, and bonding (e.g., joining by epoxy), including bonding of metallic components.

Part 5 covers examination and testing methods and techniques.

This standard provides technical information, procedures, and recommendations for repair methods that were determined by consensus to be recognized and generally accepted good engineering practice. Where equipment repair is subject to jurisdictional regulation, jurisdictional approvals may be required.

---

## **52.3 Actual Applications**

Steel and fiber-reinforced plastic (FRP) are commonly used materials in the oil industry. Sometimes there is a need to join them using adhesive bonding. There are three kinds of situations where adhesives have been used, and their application depends on the substrates to be joined – FRP/FRP joint, FRP/steel joint, or steel/steel joint:

### **FRP/FRP joints**

- FRP pipe connections
- Nonmetallic pipe saddle supports

### FRP/steel joint

- Repair of steel pipes
- Repair of naval structures
- Repair of storage tanks

### Steel/steel joint

- Metallic pipe saddle support

In what follows, some examples of actual applications of adhesives are presented considering these three types of substrate material combination.

## 52.3.1 FRP Pipe Connections

Two joining systems are normally adopted for the assembly of offshore production plant pipework, namely, socket/spigot and laminated joints, as displayed in Fig. 5. The first one is easier to apply in the field and has a self-aligning design but depends on good workmanship to provide a safe and sound connection. If the adhesive joint surfaces are badly cleaned or the adhesive itself is not properly prepared, the joint will have a high probability of failure in service.

The laminated type, on the other hand, is considered to be more reliable as it can be made as thick and long as required, to provide the necessary reinforcement. As several layers of reinforcing cloth and resin are applied from inside out, its final resistance is less variable. In the end, the choice between one type and another is much dependent on the contractor design philosophy.

## 52.3.2 Repair of Steel Pipes

Composite sleeve repair systems, now of widespread use in the market, were originally developed for the reinforcement of corroded pipelines and continue to gain wider acceptance in the pipeline industry for repairing a range of pipeline anomalies (Meniconi et al. 2002). Figure 6 presents the visual aspect of steel pipes before and after the application of the composite repair.

ISO/TS 24817 (2015) and ASME PCC-2 are the codes that cover all aspects of the technology, encompassing material qualification, repair design, installation, testing, and inspection. The documents allow reinforcement of a defected metallic pipe due to presence of general wall thinning, local wall thinning, pitting, gouges, blisters, laminations, cracks, and through-wall penetration. The defects can be located at the external or internal side of the pipe wall. Concerning the last case, the effectiveness of the repair is time-dependent, according to the evolution of the defect. The kinds of services covered are those normally found on hydrocarbon processing plants, like utility fluids, seawater, air, chemicals, production fluids, and

**Fig. 5** Two basic types of FRP pipe connections. (a) Socket and spigot. (b) Laminated

liquid and gaseous hydrocarbons. The composite materials most commonly used for the repair laminates are glass or carbon fibers for reinforcement and vinyl ester or epoxy resins for matrix. The upper limits for pressures and temperatures are obtained from qualification tests. The ISO document establishes three classes of repairs. The higher the class, the more demanding is the application and the information required, concerning material data, design capability, surface preparation, and degradation with time. In relation to lifetime, repairs are classified as short term (2 years), medium term (10 years), or long term (20 years).

### 52.3.3 Ship Hull and Naval Structures

Offshore production structures like floating, production, storage, and offloading (FPSO) vessels are designed to remain in station for 25 years or more. This is a major deviation from the traditional ship maintenance scheme, which involves dry docking every 5 years or so, for overhaul maintenance. Due to this scenario, in place

**Fig. 6** Steel pipes before (a) and after (b) the application of the composite repair

repair techniques are an excellent option to restore structural integrity without the need of interrupting production.

Composite patch repairs are one of those techniques, because no hot work is involved, turning the operation intrinsically safe. Many successful application cases of this technique are reported (Grabovac and Whittaker 2009). Figure 7 shows the first composite repair applied to the metallic hull of a ship platform operating in offshore Brazil.

The repair procedure based on reliability design method, as proposed by DNVGL-RP-C301, provides repair solutions that assure a minimum safety level in relation to a given limit state. For a specific repair, there is a need to identify all the possible failure modes that can cause bad performance in relation to its functional requirements. Examples of composite repair failure modes are debonding, matrix cracking, delamination, fiber rupture, fluid permeation, etc. Examples of functional requirements are load-bearing capacity, level of stiffness, fluid tightness, chemical inertness, erosion resistance, fire survival, etc. The concept of risk adopted is the

**Fig. 7** Composite repair applied to a ship hull

usual combination of probability and consequence of failure. Statistical methods are applied to guarantee a minimum reliability, corresponding to a probability of failure of  $10^{-3}$  once the repair is completed.

Composite bonded repairs are separated in four reliability repair classes with different levels of effort and optimization:

- Class 0 – Emergency repairs, done empirically without integrity and efficiency qualification by any code or standard.
- Class I – Noncritical repairs qualified by reliable estimates based on short-term and small-scale tests. Repair efficiency is evaluated by standard statistical methods.
- Class II – Noncritical repairs qualified by accelerated time degradation tests together with long-term behavior simulation models. The reliability level is higher than that of class I repairs. Classes I and II are the ones considered by the design document.
- Class III – Repairs qualified by long-term degradation tests, designed to assure the desired reliability level along the whole life of the structure. Given the little experience accumulated so far with composite bonded repairs, class III is not covered by DNVGL-RP-C301, yet.

The design equations criteria are formulated in terms of load and resistance characteristic values, affected both by partial safety factors, which take into account the random nature of design input data. Basically, the design process aims to satisfy the following inequality:

$$\gamma_F \cdot \gamma_{Sd} \cdot S_k \leq \frac{R_K}{\gamma_M \cdot \gamma_{Rd}} \quad (1)$$

where  $S_k$  is the characteristic effect of the load applied to the repaired structure that can lead to the failure mode under analysis. It is multiplied by partial load factors  $\gamma_F$ , associated to the variability of loading, and  $\gamma_{Sd}$  related to the uncertainties of the adopted model of structural behavior. Similarly,  $R_k$  is the characteristic structural resistance, divided by the partial resistance factors  $\gamma_M$ , referred to time and sampling variations of material strength and  $\gamma_{Rd}$ , concerning geometric aspects and fabrication processes. When dealing with the static capacity of the adhesive layer between the metallic substrate and the composite patch, the equation criterion above is written as:

$$J \leq \frac{R_{II}}{\gamma_M} \quad (2)$$

The load  $J$ , expressed as the energy per unit area of resulting adhesive debonding introduced by mechanical factored load combination, needs to be smaller than or at most equal to the mode II toughness of the interface,  $R_{II}$ , divided by the partial material factor  $\gamma_M$ , obtained from the Recommended Practice.

For the first applications of DNVGL-RP-C301, only class I repairs were considered. This class of repair is qualified by small-scale, short-term tests which results are statistically treated to make sure that the necessary repair capacity is achieved within design lifetime. This generally implies that larger partial safety factors are adopted, to account for aging effects. A minimum reliability level of  $10^{-3}$  is achieved when all the requirements are fulfilled.

The first scenario chosen for the application of composite repairs was the reposition of metallic thickness loss due to corrosion, given its simpler nature. Nevertheless, this kind of repair is classified as structural, because it attracts mechanical loading once deployed. The repair is also two-dimensional in nature, making it easier to design and qualify. It can be applied whenever there is sufficient lateral area to transfer the load from the metallic substrate to the composite patch repair, via shear stresses in the adhesive layer. Furthermore, it is a type of remedial action with great demand from an aging production platform fleet.

The two-dimensional repair qualified is rated “simple” according to the design document because it can be calculated by means of a basic theoretical model, since it fulfilled four requisites:

- The lamination directions coincide with those of the main loading.
- The overlap length  $L$  is long enough to provide regions in the bondline at the borders of the repair where the shear stresses at the adhesive were equal to zero, according to Fig. 8.

**Fig. 8** Modified double-strap specimen where notches are used to obtain the desired overlap length

This is achieved when the following expression holds:

$$L > 2 \frac{F}{w \cdot \tau_p} \text{ or } L > 2 \cdot e_m \tag{3}$$

where  $F$  is the repair failure load, estimated from simple models, and  $w$  is the composite patch width. The parameter  $\tau_p$  is the adhesive critical plastic shear stress and  $e_m$  is the maximum adhesive layer overlap effective length, obtained from double-lap shear tests (Meniconi et al. 2010).

Shorter overlap lengths can be accepted if:

- It is demonstrated that the minimum shear stress in the adhesive is smaller than 10% of the interface critical plastic shear stress.
- Bending stresses are limited, resulting in reduced adhesive peel stresses. Adhesives normally display limited strength against this kind of loading.
- Adhesive critical plastic shear stress is smaller than the out-of-plane shear strength of the repair laminate, estimated in a conservative way. This implies a failure mode by debonding of the adhesive layer rather than by delamination of the composite repair laminate.

For the bondline, there are two distinct failure modes that need to be considered. The most fundamental one is debonding propagating from the center at the discontinuity in steel. This corresponds to the case where a cracked steel plate is repaired. The other one is debonding propagating from the edges of a patch repair, but in general this only occurs after failure in steel by yielding had already developed thus showing that bondline fracture toughness is not the governing factor for the capacity of the repaired plate.

Common practice is to provide repair border edge thickness tapering widths of 10–20 times the total laminate thickness, which are generally enough to efficiently reduce the out-of-plane stresses that would trigger debonding from there. The thickness reduction at the boundaries of composite patch repairs also helps to protect them from lateral impacts and other contact damage. Table 1 lists the functional requirements proposed for a patch repair designed for metallic plating thickness loss reposition.

Some demonstration repairs already performed in the field showed that the design methodology proposed by DNVGL-RP-C301 proved feasible, at least for the

**Table 1** Functional requirements to be achieved by a thickness reposition patch repair

Functional requirements	Comments
Strength	Restore steel plating strength
Stiffness	Restore steel plating stiffness
Corrosion resistance	Not to be degraded by exposition to ambient
Temperature resistance	Material properties still acceptable at 60°C
Electric insulation	To prevent the formation of a galvanic pair

simpler case of restoration of steel thickness loss greater than the maximum allowable by the classification society of the offshore platform. Even though ambient conditions are generally far from ideal, it was possible to provide enough cleanliness, illumination, temperature, and humidity to make manual lamination work feasible. The importance of adequate surface preparation should never be underestimated.

It is strongly advised to pay special attention in planning surface preparation and execution of the first sealing layer of the repair. The previous cleaning and drying of the repair area are also important. Grit blasting is essential to get the necessary surface profile. Polymer-coated grit helped in performing a clean operation, but conventional grit will also suffice, if one considers that normally the areas to be repaired are not too extensive. The volume of dust to be aspirated afterward will not be excessive. It must be assured that the initial tasks – surface preparation, cleaning, and sealing – are performed sequentially without any delay, given the need of a dry, rust-free surface to obtain good adhesion between the patch repair and the metallic substrate. This is the optimal situation, but it demands good logistics to move and replace quickly the equipment and personnel involved in those tasks. It should be remembered that the repair location can be situated in a remote and difficult-to-access part of the platform.

Inspections executed afterward confirmed that the repairs already performed remain intact. More inspections will occur along the years, to make sure this situation continues. As this is a new development, only repair performance during the entire platform operational lifetime in real operational conditions will assure that the proposed solution works (Meniconi et al. 2014).

#### 52.3.4 Metallic Storage Tanks

Metallic storage tanks are cylindrical structures which hold oil and their derivatives and are very important to the supply chain in the oil industry. These tanks are made of thin steel plates welded together, and the large-capacity ones often are of the floating roof type. During operation, corrosion wall thickness loss frequently occurs at the inner metallic surface of the tank shell in contact with the roof seal, where rainwater tends to accumulate. The thickness loss can happen in wide areas, as the roof position changes during operation. Figure 9 shows defects found inside steel tank plating, characterized by general wall loss due to corrosion.

This corrosion mechanism may lead to a value less than acceptable minimum corroded wall thickness according to API 579 and can affect the structural integrity of the tank. In this case, welding repair is the most commonly used to restore integrity. This repair technique is quite complex and expensive, and hot working is necessary. Special care is needed to prevent severe deformation of the slender tank wall as it is heated during the welding process. In this context, composite repair seems to be an excellent alternative as this technology is very simple, fast, and cost-effective. The repair is accomplished by applying layers of carbon or glass fiber, at the outer surface of the tank wall, opposite to the corroded area. This is to avoid

**Fig. 9** Defects found in steel tank: inside view (*left*) and corroded surface detail (*right*)

**Fig. 10** Repairing a storage tank: repair overview (*left*) and repair application (*right*)

interference with the correct operation of the floating roof. An example of a repair in a storage tank can be seen in Fig. 10.

Differently from pipelines, there is no specific code to cover the repair of storage tanks by composite materials. Due to this factor, a design methodology for composite repairs of corroded storage tanks was proposed that considers the requirements of API 653, ISO/TS 24817 and DNVGL-RP-C301.

Two main factors turn composite repairs very suitable for this application. Firstly, the wide tank surface provides an extensive area to transfer loading from the steel plates to the composite laminates by means of shear stress in the adhesive layer between the two materials. Secondly, the steel tank wall plating is in a state of plane stress, mainly unidirectional, adequately resisted by composite laminates, which shows high stiffness and strength in lamination plane and fiber direction. Moreover, the materials, equipment, and workmanship involved are quite similar to those needed for painting operations, very common in this industrial environment.

The properties of the adhesive interface already mentioned, the critical plastic shear stress  $\tau_p$  and the maximum effective overlap length  $e_m$ , define a limit in steel thickness loss that can be reinstated by a patch repair. Figure 11 illustrates this

**Fig. 11** Schematic description of a patch repair, with relevant parameters

principle, by means of a segment of tank shell with unitary height. There is a corrosion thickness loss at the inside surface of the shell, remediated by a composite laminate reinforcement at the corresponding outside surface.

The local circumferential stress at the non-corroded plating away from the defected area is  $\sigma$ . The composite laminate thickness  $T_{lam}$  is readily obtained as the main design drive is to reinstate the stiffness loss caused by corrosion:

$$E_{lam} \cdot T_{lam} = E_{steel} \cdot T_{lost} \Rightarrow T_{lam} = \frac{E_{steel} \cdot T_{lost}}{E_{lam}} \quad (4)$$

The laminate elastic modulus  $E_{lam}$  (as well as all other composite properties) are referred to the circumferential direction of the tank wall. Once the circumferential stress is transferred from the metallic wall to the composite laminate through shear stresses at the adhesive interface, the highest unitary load  $f_p$  that can be transmitted is given by:

$$f_p = \tau_p \cdot e_m = \sigma_{lam} \cdot T_{lam} \quad (5)$$

The equilibrium of resultant forces implies that:

$$\begin{aligned} \sigma \cdot T_{nom} &= \sigma_{remain} \cdot T_{remain} + \sigma_{lam} \cdot T_{lam} \\ \sigma \cdot T_{nom} &= \sigma_{remain} \cdot (T_{nom} - T_{lost}) + \tau_p \cdot e_m \end{aligned}$$

so

$$\sigma_{remain} \cdot T_{lost} = T_{nom} \cdot (\sigma_{remain} - \sigma) + \tau_p \cdot e_m \quad (6)$$

The formulation above considers linear elastic behavior. Since the elastic modulus of the laminate is usually smaller than that of steel, the laminate thickness turns considerably greater than the steel thickness loss. Knowing composite laminates typical elastic moduli, high-strength carbon fiber is applied instead of fiberglass, to keep laminate thickness feasible to be applied in practice. As high-strength carbon is the chosen repair material, once the stiffness replacement criterion is fulfilled, the composite laminate circumferential stress  $\sigma_{lam}$  results low when compared with the corresponding strength. For this reason, it is possible to allow the stress acting on the

remaining steel wall,  $\sigma_{\text{remain}}$ , to reach steel yield strength  $S_y$ . The design code for atmospheric storage tanks limits the average circumferential stress at the shell,  $\sigma$ , to a typical value of  $0.75 S_y$ , during hydrostatic test. Considering this limit, the expression for the maximum steel thickness loss prone to be replaced by a patch repair then reads:

$$T_{\text{lost}} = 0.25 T_{\text{nom}} + \tau_p \cdot e_m / S_y \quad (7)$$

Typical figures are nominal steel plating thicknesses of 19 mm (at the level corrosion normally occurs), critical adhesive plastic shear stresses ( $\tau_p$ ) of 10 MPa, maximum effective overlap lengths  $e_m$  of 90 mm, and steel yield stresses of 250 MPa. In conclusion, up to 8.3 mm of steel thickness loss can be replaced by a composite patch repair laminate. This limit covers most corrosion cases that happen in practice. The major elastic modulus of the laminate is of the order of 100 GPa, compared with a modulus of 210 GPa for steel, so its thickness would be around 17 mm, roughly double the steel thickness lost. The average longitudinal stress at the composite laminate turns to be about 50 MPa, one sixth of its ultimate tensile limit of 300 MPa. The low stresses (and strains) at the laminate are important contributions for a long operational life of the repair and, moreover, of the adhesive interface.

### 52.3.5 Pipe Saddles

A pipe saddle is a structure used to support the pipe by transmitting the load or forces to the adjacent structure. It avoids direct contact between the pipe and the support, reducing stress concentration. Some of them are designed to allow longitudinal movement due to thermal expansion and contraction of pipe and are also designed to prevent damage to pipe thermal insulation. Figure 12 shows examples of adhesively bonding saddles with different substrates.

Carbon steel is the main material used for manufacturing the saddles. Stainless steel is another material that can be found. Saddles are installed just below the pipe mainly by welding, and this process can lead to some problems related to corrosion and metallurgical defects. These areas are susceptible to higher corrosion rates because of crevice and galvanic effects, and historically inspecting them has involved costly and time-consuming operations to lift the pipe or to cut the supports.

Corrosion under support is a well-known issue within all oil and gas assets around the world. The external corrosion forms itself between the pipe support and flow line and tends to be nonuniform and unpredictable. The corrosion is often caused by movement of the pipe on the support which damages the protective coating on the pipe. This leaves the exposed metal free to corrosion attack from the environment in an area where it cannot be detected and in most cases not even protected. The general problem with corrosion under pipe supports is that it is very hard to inspect the remaining wall thickness. In many cases the pipe would have to be lifted to understand the real impact of the corrosion attack. This is of course very labor intensive, risky, and expensive as the plant operations would have to be shut down.

**Fig. 12** Pipe saddles: (a) steel pipe and steel saddle (b) steel pipe and FRP saddle (c) FRP pipe and FRP saddle

Alternatively, pipe saddle can be glued onto the pipe surface instead of welding. In addition, it is possible to use pipe saddles made of nonmetallic materials as FRP. They provide many advantages to the system: to prevent from further corrosion on support area, to avoid galvanic effect, to not require hot work to install, and to be faster and easier to install compared to welding. It is important to mention that the adhesive must be thoroughly applied to avoid crevice corrosion caused by trapped water (Fig. 13).

### 52.3.6 Coamings

Coaming is a raised metal border around a ship's deck or an equipment, designed to avoid oil leaking or chemical fluids into the sea. Welding is the main process used to place coamings over the metallic surface (Fig. 14).

The installation of these structures demands lots of time, workmanship, and logistic to perform welding. Furthermore, hot work can damage surround and internal paintings, which makes necessary to repaint these affected areas. This activity can be very complex, especially for internal surfaces where it might be required to install scaffolding inside the oil tank, for instance.

When installed at the beginning of the assembly process, these coamings create a physical barrier making it difficult for technicians, equipment, and assembly devices to move over the platform, which is still in the test and integration phase.

**Fig. 13** Adhesive application: over pipe surface (*left*) and the saddle (*right*)

**Fig. 14** Coaming: around an equipment (*left*) and detail of welded coaming (*right*)

In this context, the possibility of using alternative technologies, such as adhesive bonding, to the traditional method (welding), arises, allowing to increase productivity and to prevent rework in the painting process.

## 52.4 Conclusion

In this chapter, it was shown that the application of adhesives in many different situations in the oil industry has increased in the last years. The use of composites has become a real alternative to structural repairs as these materials become more and more reliable. In this sense, the development of adhesive bonding methods has become inexorable. On the other hand, it was shown that field conditions do not allow the use of sophisticated process to perform the adhesive bonding. It makes necessary to adjust the surface preparations methods to these unfavorable situations, for instance.

The chapter also brings a summary of the most applied standards and the best practices recommended to perform bonded repair in offshore units. Besides, some examples of actual applications of adhesives are presented. In what concerns the materials to be bonded, the three main situations where the adhesives have been used

in oil industry are presented, namely, FRP/FRP joint, FRP/steel joint, and steel/steel joint.

Despite of all the challengers involving the use of adhesives in field situations, the advantages of applying this technique are pushing engineers and researchers to propose the necessary solutions. There is no doubt that adhesive bonding is becoming essential as a safe joint technique in oil industry.

simulation methods pertaining to adhesion technology are introduced, such as the molecular dynamics simulations, the quantum mechanics calculations, the molecular orbital method, the density functional theory, and the molecular mechanics simulations. Besides, some combined methods such as the hybrid quantum mechanics/molecular mechanics simulations, ab initio molecular dynamics, and the density-functional-based tight-binding method are reviewed. General features and routines of these methods as well as the basic theory are described. The advantages and disadvantages of these methods are compared and discussed. Each method has the distinctive advantage and is suitable for specific condition. Some examples are proposed to give the direct perception when investigating adhesion issues using various simulation methods. All these instances are expected to be helpful to readers when performing the corresponding simulations and analyzing of the results.

### 53.1 Introduction

As hierarchical, multiscale, and complex properties in nature, as shown in Fig. 1, adhesion is an interdisciplinary subject, which undergoes vast experimental, numerical, and theoretical investigations from microscopic to macroscopic levels. As an example, adhesion in micro- and nano-electromechanical systems (MEMS/NEMS) is one of the outstanding issues in this field including the micromechanical process

**Fig. 1** Hierarchical and multiscale nature of adhesion

of making and breaking of adhesion contact; the coupling of physical interactions; the trans-scale (nano–micro–macro) mechanisms of adhesion contact, adhesion hysteresis; and the new effective ways of adhesion control (Zhao et al. 2003).

Computer simulations including quantum mechanics (QM) calculations and molecular dynamics (MD) simulations have provided a powerful technique in understanding the fundamental physics of micro- and nanoscale adhesion (Shi et al. 2005; Yin et al. 2005; Chi and Zhao 2009; Yuan et al. 2009). QM method has been proven accurate and provided fundamental understanding for a wide variety of phenomena, including the energy levels of atoms, the band structure of lattice, and the chemical reaction of the materials. The key rule of the QM is to establish the Hamiltonians of the system and to solve the many-body Schrödinger equation (Leach 2001). QM method has the advantage over MD simulations that it includes the effects of charge transfer, polarization, and bond breaking and forming from the beginning. However, the QM computation is always expensive. So QM simulation is employed for the investigation of the chemical reaction in which a few number of atoms are needed, while MD simulation is well suited for the investigation of the dynamics process and time-dependent properties for relatively large systems (Allen and Tildesley 1989). Besides, the molecular mechanics (MM) simulation method is used to study the conformational transformation of the system. Due to some drawbacks of classical MD, *ab initio* MD (AIMD) is proposed to describe the molecular system dynamic behavior directly from the electronic structure. The development of the hybrid quantum mechanics/molecular mechanics (QM/MM) algorithm (Field et al. 1990) is guided by the general idea that an electronically important region of the system is treated with QM and the remainder admits a classical description, which combines both merits of QM and MM. The QM/MM method is a powerful and effective tool to investigate the adhesion issues such as the polymer interaction with metals. The density-functional-based tight-binding (DFTB) method is also one of the combined simulation methods which integrates the density functional theory (DFT) and the tight binding (TB) method. It should be noted that any one of the aforementioned methods has both advantages and disadvantages. One should pay extra attention when choosing a method before performing simulations.

---

## 53.2 Molecular Dynamics Simulation

Molecular dynamics (MD) is a computer simulation technique with which one can obtain the time evolution of a system of interacting particles (atoms, molecules, coarse-grained particles, granular materials, etc.). It was first introduced to study the interactions of hard spheres by Alder and Wainwright in the late 1950s (Alder and Wainwright 1959). With the rapid developments of the computer technology, MD simulations have become a powerful technique and are widely used in the study of proteins and biomolecules, as well as in materials science. This method is now routinely used to investigate the structure, dynamics, and thermodynamics of

biological molecules and their complexes addressing a variety of issues including tribology and adhesion (Bharat 2004).

### 53.2.1 Basic Theory

The basic idea of the MD simulations is to generate the atomic trajectories of a system of  $N$  particles by numerical integration, of a set of Newton's equations of motion for all particles in the system

$$m_i \frac{\partial^2 \vec{r}_i}{\partial t^2} = \vec{F}_i \quad (1)$$

where  $F_i$  is the force exerted on particle  $i$ ,  $m_i$  is the mass of particle  $i$ , and  $r_i$  is its current position. The force can be derived from the gradient of the potential energy

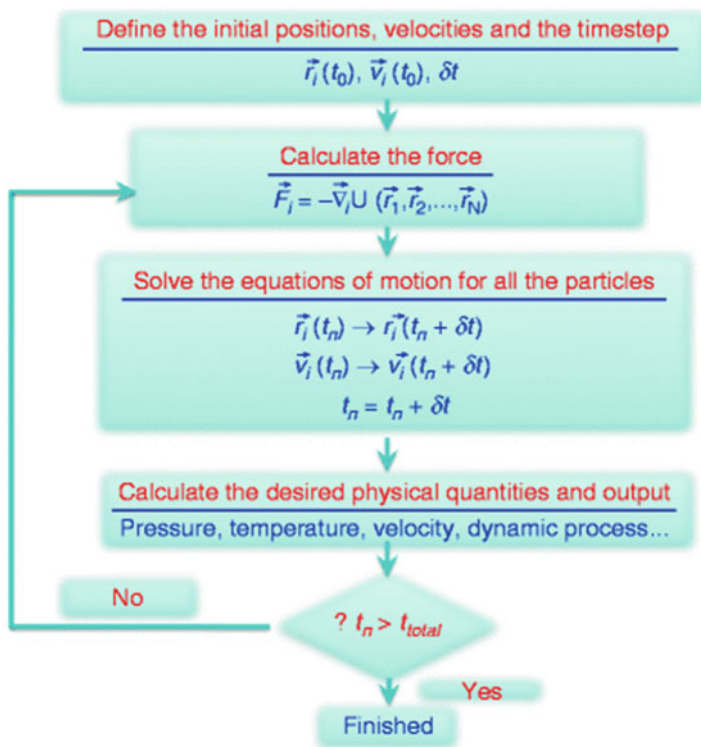

$$\vec{F}_i = - \frac{\partial U(\vec{r}_1, \vec{r}_2, \dots, \vec{r}_N)}{\partial \vec{r}_i} \quad (2)$$

in which  $U(\vec{r}_1, \vec{r}_2, \dots, \vec{r}_N)$  is the empirical interaction potential, depending on the position of the  $N$  particles. Given certain boundary conditions, as well as an initial set of positions and velocities, which are referenced as the initial condition, the equations of motions for a specific interatomic potential can be solved and then the information including atomic positions and velocities generated. One may have an interest in the conversion of this microscopic information to macroscopic observables such as pressure, energy, temperature, etc., which requires statistical mechanics. In contrast with the Monte Carlo method, MD is a deterministic technique: The subsequent time evolution is in principle completely determined. Two basic assumptions of the MD simulations are: (i) The motions of all the particles obey the classical Newton's laws of motion, and (ii) the interactions between any pair of the particles satisfy the superposition theorem.

To summarize, the highly simplified description of the MD simulation algorithm is illustrated in Fig. 2.

### 53.2.2 Force Fields

In a MD simulation, a force field which includes the functional form and parameter sets needs to be specified in order to describe the interaction between atoms and molecules, which is also called the potential energy of a system of particles. Force field functions and parameter sets are derived from both experimental work and high-level quantum mechanical calculations. Most force fields are empirical and consist of a summation of bonded forces associated with chemical bonds, bond angles, bond dihedrals, out-of-plane bending, and nonbonded forces associated with

**Fig. 2** Simplified flowchart of a standard MD simulation

119 van der Waals forces and the Coulomb forces. The most commonly used functional  
120 forms are

$$U = U_{\text{nobond}} + U_{\text{bond}} + U_{\text{angle}} + U_{\text{dihedral}} + U_{\text{improper}} + U_{\text{elec}} \quad (3)$$

121 Van der Waals interaction can be expressed as the best well-known  
122 Lennard–Jones (LJ) 12–6 function (Jones 1924),

$$U_{\text{nobond}} = 4\varepsilon \left[ \left( \frac{\sigma}{r} \right)^{12} - \left( \frac{\sigma}{r} \right)^6 \right] \quad (4)$$

123 where  $\varepsilon$  is the depth of the potential well,  $\sigma$  is the distance at which the interatom  
124 potential is zero, and  $r$  is the distance between atoms. In a MD simulation, the  
125 truncation schemes are always adopted. Here, we introduce the simplest one in  
126 which the potential is discontinuous at  $r = r_c$

$$U_{\text{nobond}}(r) = \begin{cases} U_{\text{nobond}}(r) - U_{\text{nobond}}(r_c), & r < r_c \\ 0 & r \geq r_c \end{cases} \quad (5)$$

127 The interaction between pairs of bonded atoms has the form of

$$U_{\text{bond}} = k_b(r - r_0)^2 \quad (6)$$

128 where  $k_b$  is the stiffness of the bond with the usual 1/2 factor included and  $r_0$  is the  
129 equilibrium bond distance. The interaction of valence angles in the molecule can be  
130 written as

$$U_{\text{angle}} = k_a(\theta - \theta_0)^2 \quad (7)$$

131 where  $k_a$  is the stiffness of the bond angle with the usual 1/2 factor included and  $\theta$   
132 and  $\theta_0$  are the bond angle and its reference value, respectively.

133 The dihedral interaction, also referred to as torsional terms, can be written as

$$U_{\text{dihedral}} = k_d[1 + \cos(n\phi - \gamma)] \quad (8)$$

134 in which  $\phi$  is the dihedral angle,  $\gamma$  acts as an equilibrium angle,  $k_d$  is the force  
135 constant, and  $n$  is the multiplicity which gives the number of minimum points in the  
136 function as the bond is rotated through 360°. The improper torsion is used to  
137 describe the out-of-plane bending term. It can be modeled using the form of

$$U_{\text{improper}} = k_i(\psi - \psi_0)^2 \quad (9)$$

138 in which  $k_i$  is the improper torsion force constant and  $\psi$  and  $\psi_0$  are the improper  
139 torsion angle and its reference value, respectively.

140 The coulombic pairwise interaction is given by

$$U_{\text{elec}} = \frac{Cq_iq_j}{r} \quad (10)$$

141 where  $C$  is an energy conversion constant and  $q_i$  and  $q_j$  are the charges on the two  
142 atoms.

143 The abovementioned potentials can be classified into the empirical ones, which may  
144 not be sufficiently accurate to reproduce the dynamics of molecular systems in some  
145 cases. There are also a wide variety of semiempirical potentials, known as TB poten-  
146 tials, which use QM matrix representation whose elements are obtained through  
147 empirical formulae. For more accurate cases, ab initio QM methods are used to calculate  
148 the potential energy of the system on the fly, which is the combination of first principles  
149 electronic structure methods with MD based on Newton's equations of motion.

### 150 53.2.3 Boundary Conditions

151 There are two major types of boundary conditions: isolated boundary condition and  
152 periodic boundary condition (PBC). PBC enables a simulation to be performed using

a relatively small number of particles in such a way that the particles behave as if it was infinite in size and there were no edge effects. All the particles are expected to experience forces as though they were in a bulk solution. When using PBC, particles are enclosed in a box, and one can imagine that this box is replicated to infinity by rigid translation in all the Cartesian directions, completely filling the space. In a two-dimensional (2D) example, each simulation box is surrounded by 8 mirror images, while in 3D the mirror image number would be 26. The concept of 2D PBC is illustrated in Fig. 3. The shaded box (marked as “E”) represents the system being simulated, while the surrounding boxes are the copies in every detail. Even the velocities (indicated by the arrows) and the forces are exactly the same. When a particle leaves the simulation cell, it is replaced by another with exactly the same velocity, entering from the opposite cell face. So the number of particles in the cell is conserved. Furthermore, no particle feels any surface force, as these are now completely removed.

Forces on the primary particles are calculated from particles within the same box as well as in the image box. In Fig. 3,  $R_{\text{cut}}$  is the cutoff radius that is normally applied when calculating the force between two particles. As one can see, a particle may

**Fig. 3** Illustration of 2D periodic boundary conditions. The shaded box E represents the system being simulated and the other ones are the images of E

interact with one in the neighboring cell (which is an image of one of the particles in the simulation cell) because it is within the cutoff radius. It ignores the equivalent particle in the simulation cell because it is too far away. In other cases the interaction comes from a particle in the simulation cell itself. Thus the interaction that is calculated is always with the closest image. This is known as the minimum image convention. These operating conditions greatly simplify the set up of a MD program and are commonly used. Of course, the size of the simulation box must also be large enough. If the simulation box is too small, a particle may interact with its own image in a neighboring box, which produces highly unphysical dynamics. The cutoff should be chosen such that a particle in the primary box does not see its image in the surrounding boxes. A practical suggestion is that one must always make sure that the box size is at least two times  $R_{\text{cut}}$  along all the directions where PBCs are effective.

There are boundaries existing inherently in some cases, where PBC cannot be used in computer simulations. Simulations which require no periodic boundaries are best suited to in vacuo simulations, such as the conformational study of an isolated polymer molecule. When simulating surfaces, it is particularly useful to apply the slab boundary conditions in which boundaries are periodic only in X and Y. The periodic cell in the XY plane can be any parallelogram. The origin of the X and Y atomic coordinates lies on an axis perpendicular to the center of the parallelogram. The origin of the Z coordinate is where the user specifies it, but it is recommended at or near the surface. The correct treatment of boundary conditions and boundary effects is crucial in MD simulations since it enables macroscopic properties to be calculated from MD simulations, which use relatively small numbers of particles (Leach 2001).

#### 53.2.4 Energy Minimization

In MM simulations, energy minimization (also called energy optimization or geometry optimization) methods are used to compute the equilibrium configuration of biomolecules, liquids, and solids. Moreover, MD simulations focusing on adhesion always deal with complex molecules or systems, in which the added hydrogens and broken hydrogen bond network in water would lead to quite large forces and structure distortion if the MD simulations were started immediately. To remove these forces, it is often preferable to carry out a short energy minimization on the conformation before MD simulations. Energy minimization is usually performed by gradient optimization; atoms are moved so as to reduce the net forces on them. The minimized structure has small forces on each atom and therefore serves as an excellent starting point for MD simulations. At that point, the configuration will hopefully be in local potential energy minimum. This can be done with two representative methods which involve the steepest descent algorithm and the conjugate gradient algorithm. In a steepest descent algorithm, at each iteration, the search direction is set to the downhill direction corresponding to the force vector (negative gradient of energy), while in a conjugate gradient algorithm, the force gradient is

combined at each iteration with the previous iteration information to compute a new search direction perpendicular (conjugate) to the previous search direction. Typically, steepest descent method will not converge as quickly as the conjugate gradient method, but may be more robust in some situations.

### 53.2.5 Integrators

MD simulation implement involves solving a system of three N second-order differential equations. Due to the complicated nature of this function, there is no analytical solution to the equations of motion, and they must be solved numerically. A standard method for solution of ordinary differential equations such as Eq. 1 is the finite difference approach. Given the initial conditions and the boundary conditions, one can solve the equations step by step. The time interval  $\delta t$  is always chosen to be one or several femtoseconds, which should be significantly smaller than the typical time taken for a molecule to travel its own length. Many different algorithms fall into the general finite difference pattern, such as Verlet, leapfrog, velocity Verlet, Beeman, and predictor–corrector algorithms. When choosing an algorithm to use, the following criteria should be considered: The algorithm should conserve energy and momentum. It should be computationally efficient and it should permit a long time step for integration. To illustrate the principles of the method, the velocity Verlet algorithm is selected, and its technical details which affect the choice in practice are discussed.

The velocity Verlet algorithm starts with the position  $r(t)$  and the velocity  $v(t)$  at time  $t$  and is carried out by repeating these instructions:

1. Calculate  $a(t)$ ,

$$a(t) = \frac{\partial^2 r(t)}{\partial t^2} \quad (11)$$

2. Calculate the position of the particle for the following time step,

$$r(t + \delta t) = r(t) + \delta t \cdot v(t) + \frac{1}{2} \delta t^2 \cdot a(t) \quad (12)$$

3. Calculate velocities at mid-step using

$$v\left(t + \frac{1}{2} \delta t\right) = v(t) + \frac{1}{2} \delta t \cdot a(t) \quad (13)$$

4. Calculate  $a(t + \delta t)$

$$a(t + \delta t) = \frac{\partial^2 r(t + \delta t)}{\partial t^2} \quad (14)$$

## 238 5. Complete the velocity move using

$$v(t + \delta t) = v\left(t + \frac{1}{2}\delta t\right) + \frac{1}{2}\delta t \cdot a(t + \delta t) \quad (15)$$

239 The velocity Verlet algorithm provides both the atomic positions and velocities at  
 240 the same instant of time and for this reason may be regarded as the most complete  
 241 form of Verlet algorithm. The advantage of this algorithm is that it requires less  
 242 computer memory, because only one set of positions, forces, and velocities need to  
 243 be carried at any one time. This convenience is not apparent in the original equations.  
 244 Besides, this algorithm conserves energy well even with relatively long time steps  
 245 and is numerically stable as well as simple to program.

## 246 53.2.6 Analysis of the MD Results

247 MD simulations provide the means to solve the equations of motion of the particles  
 248 and output the desired physical quantities in the term of some microscopic informa-  
 249 tion. In a MD simulation, one often wishes to explore the macroscopic properties of a  
 250 system through the microscopic information. These conversions are performed on  
 251 the basis of the statistical mechanics, which provide the rigorous mathematical  
 252 expressions that relate macroscopic properties to the distribution and motion of the  
 253 atoms and molecules of the N-body system. With MD simulations, one can study  
 254 both thermodynamic properties and the time-dependent properties. Some quantities  
 255 that are routinely calculated from a MD simulation include temperature, pressure,  
 256 energy, the radial distribution function, the mean square displacement, the time  
 257 correlation function, and so on (Allen and Tildesley 1989; Rapaport 2004).

258 The temperature of the system in MD simulations is calculated by

$$T = E_k / \left(\frac{d}{2} N k_B\right) \quad (16)$$

259 where  $E_k$  is the total kinetic energy of all the  $N$  particles,  $k_B$  is the Boltzmann  
 260 constant, and  $d = 2$  or  $3$  is the dimensionality of the simulation. The kinetic energy  
 261 of the system is obtained simply by the summation over all the particles,

$$E_k = \sum_{i=1}^N \frac{1}{2} m_i v_i^2, \quad (17)$$

262 where  $m_i$  and  $v_i$  are the mass and velocity of the  $i$ th particle, respectively. The radial  
 263 distribution function describes how the atomic density varies as a function of the  
 264 distance from one particular atom. It provides a particularly effective way of  
 265 describing the average structure of disordered molecular systems such as liquids.  
 266 The mathematical formula of the radial distribution function,  $g(r)$ , is

$$g(r) = \frac{n(r)}{4\pi\rho r^2\Delta r}, \quad (18)$$

in which  $n(r)$  is the mean number of atoms in a shell of width  $\Delta r$  at distance  $r$  and  $\rho$  is the mean atom density. The method needs not be restricted to one atom. All the atoms in the system can be treated in this way, leading to an improved determination of the radial distribution function as an average over many atoms.

The mean square displacement is a measure of the average distance a molecule travels. It is defined as

$$msd(t) = \left\langle [r_i(t) - r_i(0)]^2 \right\rangle, \quad (19)$$

where  $\langle \dots \rangle$  denotes here averaging over all the atoms and  $r_i(t) - r_i(0)$  is the distance traveled by atom  $i$  over some time interval of length  $t$ . The slope of the mean squared displacement versus time is proportional to the diffusion coefficient  $D$  of the diffusing atoms, which is given by the following Einstein relation,

$$D = \lim_{t \rightarrow \infty} \frac{1}{2dt} \left\langle [r_i(t) - r_i(0)]^2 \right\rangle, \quad (20)$$

where  $d$  has the same meaning as in Eq. 16. From a MD simulation, time-dependent properties such as correlation functions can also be calculated. A time correlation function is defined as

$$C(t) = \langle A(0)A(t) \rangle, \quad (21)$$

where  $\langle \dots \rangle$  represents an ensemble average and  $A$  is the dynamic variable of interest. Many other properties can be calculated based on the integral of this correlation function, such as diffusion coefficient  $D$ , the shear viscosity  $\eta$ , and the thermal conductivity  $\lambda$ . The corresponding computing formulas are listed as follows (Rapaport 2004):

$$D = \frac{1}{dN} \int_0^\infty \left\langle \sum_{i=1}^N v_i(0)v_i(t) \right\rangle dt, \quad (22)$$

in which  $d$  has the same meaning as in Eq. 16.

$$\eta = \frac{V}{3k_B T} \int_0^\infty \left\langle \sum_{x < y} p_{xy}(0)p_{xy}(t) \right\rangle dt, \quad (23)$$

where  $p_{xy}$  is the component of the pressure tensor (the negative of which is known as the stress tensor),  $V$  is the volume of the simulation box, and  $T$  is the temperature of the system.

$$\lambda = \frac{V}{3T^2} \int_0^\infty \langle S(0)S(t) \rangle dt, \quad (24)$$

where

$$S = \frac{1}{V} \left[ \sum_i e_i v_i + \frac{1}{2} \sum_{i \neq j} r_{ij} (f_{ij} \cdot v_i) \right], \quad (25)$$

and the instantaneous excess energy of the  $i$ th atom is

$$e_i = \frac{1}{2} m_i v_i^2 + \frac{1}{2} \sum_{i \neq j} u(r_{ij}) - \langle e \rangle. \quad (26)$$

In order to get the surface energy, for example, the surface energy of nanofilm, one should calculate the energy of nanofilm with PBC and the slab boundary conditions, respectively.

Then the surface energy can be expressed as

$$\gamma = \frac{E_{\text{pbc}} - E_{\text{slab}}}{2A}, \quad (27)$$

in which  $E_{\text{pbc}}$  is the total energy of the nanofilm with PBC, while  $E_{\text{slab}}$  is that with slab boundary conditions.

When carrying out a MD simulation, coordinates of the system can be obtained, which is called the trajectory of the system. It can be displayed graphically and also used for the analysis. To visualize (and analyze) the snapshots from MD simulations, one can use a variety of visualization programs including VMD (Humphrey et al. 1996) and AtomEye (Li 2003). At present there are several high-quality MD codes, which have been widely used by researchers. Some of them are open-source codes, such as LAMMPS (Plimpton 1995), GROMACS (Berendsen et al. 1995; Lindahl et al. 2001), and NAMD (Nelson et al. 1996; Kale et al. 1999). The last two show extra attention on the simulations of biomolecules. Besides, CHARMM (Brooks et al. 1983) and AMBER (Pearlman et al. 1995) are not free but are standard and extremely powerful codes in biology.

For more details of the MD simulations, there are numerous excellent books available on this subject (Allen and Tildesley 1989; Leach 2001; Rapaport 2004).

### 53.2.7 Water Models Used in MD Simulations

When dealing with adhesion issues of biomolecules surrounded by water, the solvent environment always has a significant influence on the properties of the biomolecules. Different types of the water models are illustrated in Fig. 4.

**Fig. 4** Illustration of three types of water model. The red, blue, and green balls represent O and H atoms and the massless charge, respectively

**Table 1** Parameters for water molecular models

Model	Type	$\sigma$ (Å)	$\epsilon$ kJ mol <sup>-1</sup>	$l_1$ (Å)	$l_2$ (Å)	$q_1$ (e)	$q_2$ (e)	$\theta^\circ$	$\phi^\circ$
SPC	A	3.166	0.650	1.0000	—	+0.410	-0.8200	109.47	—
SPC/E	A	3.166	0.650	1.0000	—	+0.4238	-0.8476	109.47	—
TIP3P	A	3.15061	0.6364	0.9572	—	+0.4170	-0.8340	104.52	—
TIP4P	B	3.15365	0.6480	0.9572	0.15	+0.5200	-1.0400	104.52	52.26
TIP5P	C	3.12000	0.6694	0.9572	0.70	+0.2410	-0.2410	104.52	109.47

The parameters of five representative and commonly used water models in MD simulations are listed in Table 1. SPC is the short term for “simple point charge,” and SPC/E denotes the extended simple point charge model with charges on the oxygen and hydrogen modified to improve the classical SPC water model; the SPC/E model results in a better density and diffusion constant than the SPC model. “TIP” in “TIPnP” stands for transferable intermolecular potential, while “nP” means there are n points used in the corresponding water model.

### 53.2.8 Examples of MD Implements

Barnacle cement is an underwater adhesive that is used for permanent settlement. Its main components are insoluble protein complexes. In the following simulations, 36-KD protein which has 38 amino acids and Mrcp-100K protein with 28 amino acids were chosen to study the adhesion properties of the barnacle cement (Yin et al. 2005). Energy minimization was performed first at the temperature of absolute zero in order to avoid improper structure of proteins. Then, the temperature of the system was increased to 300 K by giving every atom a prime velocity according to Boltzmann distribution, and the system was then thermally equilibrated for a short period of time. All the MD simulations were performed using GROMACS version

333 3.1. For the proteins, the standard GROMACS amino acid residue topology and  
334 parameters based on the GROMOS-96 force field (Lindahl et al. 2001) were used.  
335 The SHAKE algorithm (Ryckaert et al. 1977) was used to fix hydrogen bonds during  
336 the simulation. Leapfrog algorithm was employed to integrate the Newton's equa-  
337 tions of motion for all the atoms, with a time step of 1 fs. The temperatures of the  
338 system were always controlled at 300 K, where the weak coupling Berendsen  
339 scheme was used to control the temperature.

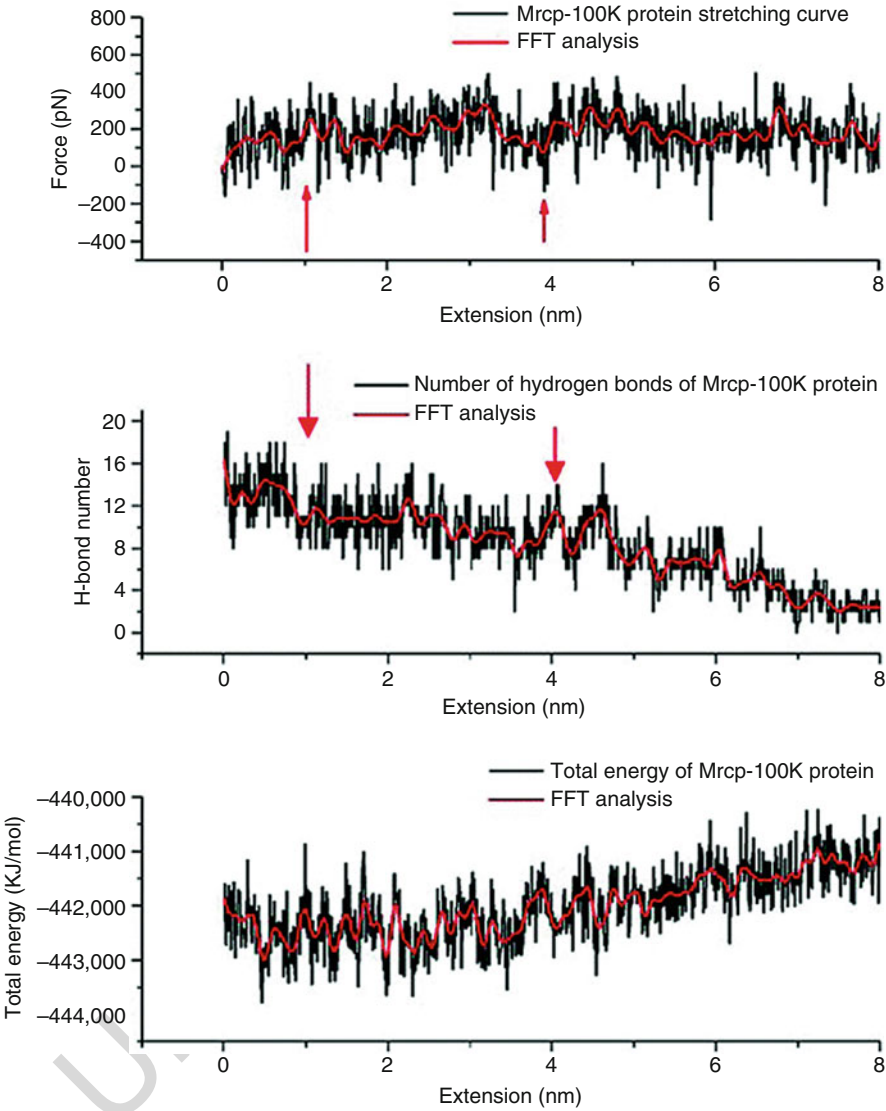

340 In this simulation, the proteins were stretched in a water solvent modeled by  
341 TIP3P water molecules (Jorgensen et al. 1983). The dimension of the simulation box  
342 was  $40 \times 40 \times 200$  Å with the PBC applied in all the three directions. The proteins  
343 were stretched at a velocity of 0.01 Å/ps.

344 It was found that there are mainly two regimes of protein deformation: fluctuation  
345 regime and extension regime. In the fluctuation regime, resistance to stretching is  
346 mostly due to the hydrogen bonds, while in the extension regime, the main resistance  
347 force is due to bonded interaction. Moreover, the hydrogen bonds in proteins play an  
348 important role in the adhesive ability of the protein. In Fig. 5, the stretching force  
349 becomes bigger when more hydrogen bonds are breaking and almost every peak of  
350 the force curve corresponds to a trough of the hydrogen bond number curve  
351 (indicated by the arrows). For proteins, the average energy needed to break or  
352 form a hydrogen bond is about 15–30 kJ/mol. It can also be found that the total  
353 energy of the Mrp-100K protein decreases with the increasing hydrogen bond  
354 number. All of this information shows that in fluctuation regime, hydrogen bonds  
355 are more significant than many other interactions, such as entropic force, van der  
356 Waals force, and so on. With this background knowledge, the efforts directed toward  
357 more detailed understanding of the properties of this adhesive and molecular biology  
358 studies would significantly contribute to progress in the basic field and potential  
359 applications such as biofouling prevention (Khandeparker and Anil 2007).

360 Since the barnacle is a saltwater organism, 36-KD protein stretching in seawater  
361 was also simulated.  $\text{Na}^+$  and  $\text{Cl}^-$  ions were also added to the water box with a  
362 concentration of about 17% to simulate the neutral seawater system. Figure 6 shows  
363 that the stretching force of 36-KD protein in seawater is larger than that in water. The  
364 more structural stability of 36-KD protein in seawater is due to two reasons. First, the  
365 electrostatic interaction between proteins and ions in seawater makes the structure  
366 more stable. Second, 36-KD protein forms more hydrogen bonds in seawater in  
367 fluctuation regime (there are 27 hydrogen bonds in seawater while only 19 hydrogen  
368 bonds in water).

369 Another example of MD simulations was performed to study adhesion and  
370 peeling of a short fragment of single-stranded DNA (ssDNA) molecule from a  
371 graphene surface (Shi et al. 2005). A short homogeneous ssDNA oligonucleotide  
372 containing 8 adenine bases in the B-helix form was placed on top of 3 graphene  
373 layers each containing 928 carbon atoms, with an average separation of about 7 Å.  
374 After energy minimization, the system was equilibrated at 300 K for 400 ps. In order  
375 to simulate the process of peeling ssDNA from graphene, a dummy atom was linked  
376 to one end of the ssDNA with a constraint force constant of 8 kcal/mol/Å<sup>2</sup>. Then the  
377 dummy atom was pulled at different peeling angles under a constant pulling velocity,

**Fig. 5** The variation of hydrogen bonds, strain (stretching), and total energy (stretching) (Reprinted from Materials Science and Engineering A, 409, Yin J and Zhao YP, Molecular Dynamics Simulation of Barnacle Cement, 160–166, Copyright (2005), with permission from Elsevier)

with the graphene fixed. All these simulations were performed using the code CHARMM (Brooks et al. 1983). Figure 7 depicts several snapshots of ssDNA peeled away from graphene under a constant velocity of 0.1 Å/ps and at a peeling angle of 90°.

**Fig. 6** 36-KD protein stretching in different solutions (Reprinted from Materials Science and Engineering A, 409, Yin J and Zhao YP, Molecular Dynamics Simulation of Barnacle Cement, 160–166, Copyright (2005), with permission from Elsevier)

**Fig. 7** Steered MD simulation snapshots of peeling ssDNA from graphene at a peeling angle of 90° (With kind permission from Springer Science+Business Media: Shi et al. (2005), Fig. 3)

During the simulation, the pulling force was calculated and was represented in Fig. 8, which indicated that the pulling force reaches a local maximum value when a tightly attached DNA base is pulled off the surface and is relaxed before the next tightly attached base is to be pulled off. The peel-off force can be calculated from the global maximum of the force profile. Simulations of the peeling process under various pulling rates (from 0.01 to 0.4 Å/ps) and peeling angles (75°, 90°, 120°, and 135°) were also performed, with the calculated peel-off forces summarized in Fig. 9.

The black line in Fig. 9 shows the prediction of the critical peel-off forces using the homogeneous peeling model (Kendall 1975),

$$F(1 - \cos \theta) + F\varepsilon - \int_0^\varepsilon g(\varepsilon)d\varepsilon = \Delta\gamma \quad (28)$$

**Fig. 8** The pulling force exerted on one end of an adsorbed ssDNA as a function of simulating time. To eliminate excessive thermal noise, the pulling force is smoothed with a Gaussian filter of half width 4 ps (white line) (With kind permission from Springer Science +Business Media: Shi et al. (2005), Fig. 4)

**Fig. 9** The critical peel-off forces of ssDNA oligonucleotide on graphene as a function of the peeling angle. The blue closed triangles are the results of direct MD simulations at peeling angles of 75°, 90°, 120°, and 135°, respectively (With kind permission from Springer Science+Business Media: Shi et al. (2005), Fig. 8)

where  $F$  is the peeling force at a peeling angle  $\theta$  from a substrate,  $g(\varepsilon)$  is used to describe the elasticity of the polymer,  $\varepsilon$  is the elastic strain along the length of the chain, and  $\Delta\gamma$  denotes the work of adhesion between the chain and the substrate. Considering the work of adhesion between ssDNA and substrate is not constant, the homogeneous peeling model can be modified as

$$F(1 - \cos \theta) + F\varepsilon - \int_0^\varepsilon g(\varepsilon) d\varepsilon = \Delta\gamma' \left( 1 - \left| \sin \frac{\pi}{l} x \right| \right) \quad (29)$$

where the constant work of adhesion is replaced by a sinusoidal function with  $l$  being the period of modulation of adhesion energy and  $x$  denoting the position along the chain. Equation 29 is the generalized elastic band model, and the corresponding results are illustrated as the red line in Fig. 9, which are in good agreement with the MD results. The simulations and models demonstrated that, for the same adhesion energy, the critical peel-off forces also depend on the peeling angle.

## 53.3 Molecular Orbital Method

### 53.3.1 Introduction

Molecular orbital (MO) theory is a method for determining molecular structure in which electrons are not assigned to individual bonds between atoms, but are treated as moving under the influence of the nuclei in the whole molecule (Daintith 2004). In this theory, each molecule has a set of MOs, in which it is assumed that each MO wave function  $\psi_i$  can be written as a summation of the following form (Pople and Beveridge 1970):

$$\psi_i = \sum_{\mu=1}^K c_{\mu i} \phi_{\mu}, \quad (30)$$

where  $\psi_i$  is a (spatial) MO,  $\phi_{\mu}$  is one of  $K$  atomic orbitals, and  $c_{\mu i}$  is the coefficient. This method is called the linear combination of atomic orbitals (LCAO) approximation and is widely used in computational chemistry.

MOs are often divided into bonding, antibonding, and nonbonding orbitals. In a bonding orbital, the electrons have a higher probability of being between nuclei than elsewhere. Electrons in the antibonding orbital tend to spend more time elsewhere than between the nuclei, while electrons in nonbonding orbital prefer to be in deep orbitals (nearly atomic orbitals) associated almost entirely with one nucleus.

In the MO theory, three necessary conditions must be satisfied when atomic orbitals combine together to form MOs:

1. The combining atomic orbitals must have the same symmetry about the molecular axis.
2. The combining atomic orbitals must be able to overlap to the maximum extent to form MOs, since the greater is the extent of overlap between the combining atomic orbitals, the greater will be the electron density in the region between the nuclei of the combining atoms and hence the stronger the bond between them.
3. The combining atomic orbitals must have the same or almost the same energy.

The first one is the most important, which decides whether these atomic orbitals can form MOs or not. The other two just affect the combination efficiency.

For diamagnetic species, MO method starts by assigning electrons in pairs to spatial functions  $\psi_1, \psi_2, \dots, \psi_n$ , which are then used in the construction of a many-electron wave function as a single determinant (Roothaan 1951; Pople and Beveridge 1970; Hehre 1976)

$$\Psi(1, 2, \dots, 2n) = \frac{1}{2^n} \times \begin{vmatrix} \psi_1(1)\alpha(1) & \psi_1(1)\beta(1) \cdots & \psi_n(1)\beta(1) \\ \psi_1(2)\alpha(2) & \cdots & \\ \vdots & & \\ \psi_1(2n)\alpha(2n) & \psi_1(2n)\beta(2n) \cdots & \psi_n(2n)\beta(2n) \end{vmatrix}, \quad (31)$$

where  $\alpha$  and  $\beta$  are spin functions. The MOs  $\psi_i$  are chosen so as to minimize the total energy of the system, that is, the expectation value of the many-electron Hamiltonian  $H$ ,

$$E = \int \dots \int \Psi(1, 2, \dots, 2n) H \Psi(1, 2, \dots, 2n) d\tau_1 d\tau_2 \dots d\tau_{2n}, \quad (32)$$

is in practice written in terms of a linear combination of nuclear centered atomic functions, as shown in Eq. 30. The coefficients,  $c_{\mu i}$ , in Eq. 30 are obtained at by solution of the Roothaan equations

$$\sum_{\nu} (F_{\mu\nu} - \varepsilon_i S_{\mu\nu}) c_{\mu i} = 0, \quad (33)$$

where  $S_{\mu\nu}$  is an overlap integral

$$S_{\mu\nu} = \int \varphi_{\mu}(1) \varphi_{\nu}(1) d\tau_1, \quad (34)$$

$\varepsilon_i$  is the one-electron energy associated with  $\psi_i$ , and  $F_{\mu\nu}$  is an element of the Fock matrix

$$F_{\mu\nu} = H_{\mu\nu} + \sum_{\lambda} \sum_{\sigma} P_{\lambda\sigma} [(\mu\nu|\lambda\sigma)(\mu\lambda|\nu\sigma)]. \quad (35)$$

Here  $H_{\mu\nu}$  is the element

$$H_{\mu\nu} = \int \varphi_{\mu}(1) \left[ -\frac{1}{2} \nabla^2 \right] \varphi_{\nu}(1) d\tau_1 + \sum_A^{\text{nuclei}} \int \varphi_{\mu}(1) \left[ \frac{1}{r_{1A}} \right] \varphi_{\nu}(1) d\tau_1. \quad (36)$$

which describes the motion of a single electron in a field of bare nuclei, and  $(\mu\nu|\lambda\sigma)$  is a two-electron integral

$$(\mu\nu|\lambda\sigma) = \iint \varphi_\mu(1)\varphi_\nu(1) \left[ \frac{1}{r_{12}} \right] \varphi_\lambda(2)\varphi_\sigma(2) d\tau_1 d\tau_2. \quad (37)$$

445 The one-electron density matrix,  $P$ , is given by

$$P_{\lambda\sigma} = 2 \sum_i c_{\lambda i} c_{\sigma i}, \quad (38)$$

446 where the summation is over the manifold of occupied MOs. Note that the  
 447 Roothaan equations are not readily amenable to solution in closed form. This is  
 448 simply because the quantity sought (the  $c_{\mu i}$ ) appears, disguised as  $P_{\lambda\sigma}$ , in their  
 449 formulation.

### 450 53.3.2 Density Functional Theory

451 The two basic methods in QM calculations are MO theory and density functional  
 452 theory (DFT). These two methods, often contrasting, but mostly cooperating, are  
 453 different approaches to tackling the electronic problems. MO method is always  
 454 adopted by the chemists who think that the MO is expressed as LCAO. The DFT  
 455 method is always used to treat infinite periodic systems by the physicists.

456 DFT is founded on the Hohenberg–Kohn (H–K) theorems (Hohenberg and Kohn  
 457 1964), which comes in two parts. The first one states that the ground state properties  
 458 of a many-electron system are uniquely functional of the ground state electron  
 459 density which depends on only three spatial coordinates. This implies that all  
 460 properties of the system are completely determined given only the ground state  
 461 density.

#### 462 The Hohenberg–Kohn Theorem

463 The second part of the H–K theorem states that the total energy of the ground state of  
 464 a many-electron system in an external potential  $V_{\text{ext}}(\vec{r})$  is a unique functional of the  
 465 electron density

$$E[n] = F[n] + \int n(\vec{r}) V_{\text{ext}}(\vec{r}) d\vec{r}. \quad (39)$$

466 This functional has its minimum (i.e., the ground state energy  $E_0$ ) for the ground  
 467 state electron density  $n_0(\vec{r})$

$$E_0 = E[n_0(\vec{r})] = \min_{n(\vec{r})} E[n]. \quad (40)$$

468 The functional  $F[n]$  is a universal function, independent of the external potential  
 469  $V_{\text{ext}}(\vec{r})$  and the same for all systems.

470 Levy gave a particularly simple proof of the Hohenberg–Kohn theorem (Levy  
471 1979): A functional  $O$  is defined as

$$O[n(\vec{r})] = \min_{|\Psi\rangle \rightarrow n(\vec{r})} \langle \Psi | \hat{O} | \Psi \rangle, \quad (41)$$

472 where the expectation value is found by searching over all wavefunctions,  $\Psi$ , giving  
473 the density  $n(\vec{r})$  and selecting the wave function which minimizes the expectation  
474 value of  $\hat{O}$ .

475  $F[n(\vec{r})]$  is defined by

$$F[n(\vec{r})] = \min_{|\Psi\rangle \rightarrow n(\vec{r})} \langle \Psi | \hat{F} | \Psi \rangle, \quad (42)$$

476 so

$$\hat{F} = \sum_i -\frac{1}{2} \nabla_i^2 + \frac{1}{2} \sum_{i \neq j} \frac{1}{|\vec{r}_i - \vec{r}_j|}. \quad (43)$$

477 Considering an  $N$ -electron ground state wavefunction  $\Psi_0$  which yields a density  
478  $n(\vec{r})$  and minimizes  $\langle \Psi | \hat{F} | \Psi \rangle$ , then from the definition of the functional  $E$

$$E[n(\vec{r})] = F[n(\vec{r})] + \int n(\vec{r}) V_{\text{ext}}(\vec{r}) d\vec{r} = \langle \Psi | \hat{F} + V_{\text{ext}} | \Psi \rangle. \quad (44)$$

479 The Hamiltonian is given by  $\hat{F} + V_{\text{ext}}$ , and so  $E[n(\vec{r})]$  must obey the variational  
480 principle,

$$E[n(\vec{r})] \geq E_o. \quad (45)$$

481 This completes the first part of the proof, which places a lower bound on  $E[n(\vec{r})]$ .

482 From the definition of  $F[n(\vec{r})]$  in Eq. 42, the following is obtained

$$F[n_0(\vec{r})] \leq \langle \Psi_0 | \hat{F} | \Psi_0 \rangle, \quad (46)$$

483 since  $\Psi_0$  is a trial wave function yielding  $n_0(\vec{r})$ . Combining  $\int n(\vec{r}) V_{\text{ext}}(\vec{r}) d\vec{r}$   
484 with the above equation gives

$$E[n_0(\vec{r})] \leq E_o, \quad (47)$$

485 which in combination with Eq. 46 yields the key result

$$E\left[n_0\left(\vec{r}\right)\right]=E_o. \quad (48)$$

### 486 The Kohn–Sham (KS) Equations

487 Kohn and Sham derived a coupled set of differential equations enabling the ground  
488 state density  $n_0\left(\vec{r}\right)$  to be found. The variational problems of minimizing the energy  
489 functional  $E\left[n\left(\vec{r}\right)\right]$  can be solved by applying the Lagrangian method of  
490 undetermined multipliers (Hohenberg and Kohn 1964). First, one considers an  
491 energy functional that does not explicitly have an electron–electron interaction  
492 energy term,

$$E_s\left[n\left(\vec{r}\right)\right]=\left\langle\Psi_s\left[n\left(\vec{r}\right)\right]\left|\hat{T}_s+\hat{V}_s\right|\Psi_s\left[n\left(\vec{r}\right)\right]\right\rangle, \quad (49)$$

493 where  $\hat{T}_s$  is defined as the kinetic energy of a non-interacting electron gas and  $\hat{V}_s$  is  
494 an external effective potential in which the non-interacting electrons are moving.  
495 Obviously,  $n_s\left(\vec{r}\right)\stackrel{\text{def}}{=}n\left(\vec{r}\right)$  if  $\hat{V}_s$  is chosen to be

$$\hat{V}_s=\hat{V}+\hat{U}+\left(\hat{T}-\hat{T}_s\right). \quad (50)$$

496 Thus, to find the ground state energy,  $E_0$ , and the ground state density,  $n_0$ , the  
497 one-electron Schrödinger equation,

$$\left[-\frac{\hbar^2}{2m}\nabla^2+V_s\left(\vec{r}\right)\right]\phi_i\left(\vec{r}\right)=\varepsilon_i\phi_i\left(\vec{r}\right), \quad (51)$$

498 should be solved self-consistently with

$$n(r)\stackrel{\text{def}}{=}n_s\left(\vec{r}\right)=\sum_i^N\left|\phi_i\left(\vec{r}\right)\right|^2. \quad (52)$$

499 The effective single-particle potential can be written in more detail as

$$V_s\left(\vec{r}\right)=V\left(\vec{r}\right)+\int\frac{e^2n_s\left(\vec{r}'\right)}{\left|\vec{r}-\vec{r}'\right|}d^3r'+V_{xc}\left[n_s\left(\vec{r}\right)\right], \quad (53)$$

500 where the second term is the so-called Hartree term describing the electron–electron  
501 Coulomb repulsion, while the final term  $V_{xc}$  is an implicit definition of the  
502 exchange–correlation potential. Here,  $V_{xc}$  includes all the many-particle interactions,  
503 which is given formally by the functional derivative  $V_{xc}\left(\vec{r}\right)=\frac{\delta E_{xc}\left[n\left(\vec{r}\right)\right]}{\delta n\left(\vec{r}\right)}$ .

Since the Hartree term and  $V_{xc}$  depend upon the density  $n(\vec{r})$ , which depends on the  $\phi_i$ , which in turn depends on  $V_s$ , the problem of solving the KS equation has to be done in a self-consistent (i.e., iterative) way. Usually, one starts with an initial guess for  $n(\vec{r})$ , then calculates the corresponding  $V_s$ , and solves the KS equations for  $\phi_i$ . Then, one calculates a new density and starts again. This procedure is then repeated until the input and output densities satisfy the accuracy.

### Exchange–Correlation Functionals

To solve Kohn–Sham equations, the exchange–correlation energy  $E_{xc}[n]$  must be known. However, because of the many-body effects,  $E_{xc}[n]$  cannot be derived exactly. Therefore, certain approximations are required for  $E_{xc}[n]$ . In physics, the most widely used approximation has been the local-density approximation (LDA), where the functional depends only on the density at the coordinate where the functional is evaluated,

$$E_{xc}[n] = \int \varepsilon_{xc}(n) n(\vec{r}) d^3r, \quad (54)$$

where  $\varepsilon_{xc}(n)$  is the exchange–correlation energy per particle of a uniform electron gas of density  $n$ . LDA has yielded valuable quantitative or at least semiquantitative results, especially for equilibrium structures of molecules and solids. The local spin-density approximation (LSDA) is a straightforward generalization of the LDA to include electron spin

$$E_{xc}[n_{\uparrow}, n_{\downarrow}] = \int \varepsilon_{xc}(n_{\uparrow}, n_{\downarrow}) n(\vec{r}) d^3r. \quad (55)$$

Highly accurate formulae for the exchange–correlation energy density  $\varepsilon_{xc}(n_{\uparrow}, n_{\downarrow})$  have been constructed from quantum Monte Carlo simulations of a free electron model (Perdew et al. 2005). Generalized gradient approximations (GGA) have yielded substantial improvements over the LDA for binding energies of molecules and solids as well as for barrier heights of chemical reactions. GGA are still local but also take into account the gradient of the density at the same coordinate

$$E_{xc}[n_{\uparrow}, n_{\downarrow}] = \int \varepsilon_{xc}(n_{\uparrow}, n_{\downarrow}, \vec{\nabla} n_{\uparrow}, \vec{\nabla} n_{\downarrow}) n(\vec{r}) d^3r. \quad (56)$$

Potentially more accurate than the GGA functionals are the so-called hybrid functionals, which have the generic form

$$E_{xc}[n_{\uparrow}, n_{\downarrow}] = \gamma E_x^{\text{exact}}[n(\vec{r})] + \int \varepsilon'_{xc}(n_{\uparrow}, n_{\downarrow}, \vec{\nabla} n_{\uparrow}, \vec{\nabla} n_{\downarrow}) n(\vec{r}) d^3r, \quad (57)$$

where  $E_x^{\text{exact}}$  is the exact exchange energy evaluated with KS orbitals and  $\gamma$  is a constant between 0 and 1.

### 53.3.3 Examples of DFT Calculations

Gas sensors based on metal oxide–semiconductor materials as well as metal-doped graphene have attracted considerable attention during the past decade. Zinc oxide (ZnO), tin dioxide ( $\text{SnO}_2$ ), and Al-doped graphene have been chosen as sensing materials because of their excellent characteristics such as low cost, high sensitivity, rapid response, and fast recovery. Here two examples are given to show the general routine of DFT calculations and the analysis of the results.

DFT calculations were employed to explore the gas-sensing mechanisms of zinc oxide (ZnO) with surface reconstruction taken into consideration (Yuan et al. 2009). Mix-terminated  $(10\bar{1}0)$  ZnO surfaces were examined. Simulations of the adsorption process of various gases, that is,  $\text{H}_2$ ,  $\text{NH}_3$ , CO, and ethanol ( $\text{C}_2\text{H}_5\text{OH}$ ) gases, on the ZnO  $(10\bar{1}0)$  surface, were carried out. All the ab initio calculations were performed using DFT implemented in the DMol<sup>3</sup> program (Delley 2000, 2002). The widely used GGA with the exchange–correlation functional parameterized by Perdew and Wang (PW91) was adopted, calculating with restricted spin. Compared with LDA, GGA will not lead to a strong bonding of molecules. So if the calculated molecules are adsorbed on the ZnO surface, they will definitely bind in a real system. However, GGA overestimates binding distance and underestimates binding energy consequently.

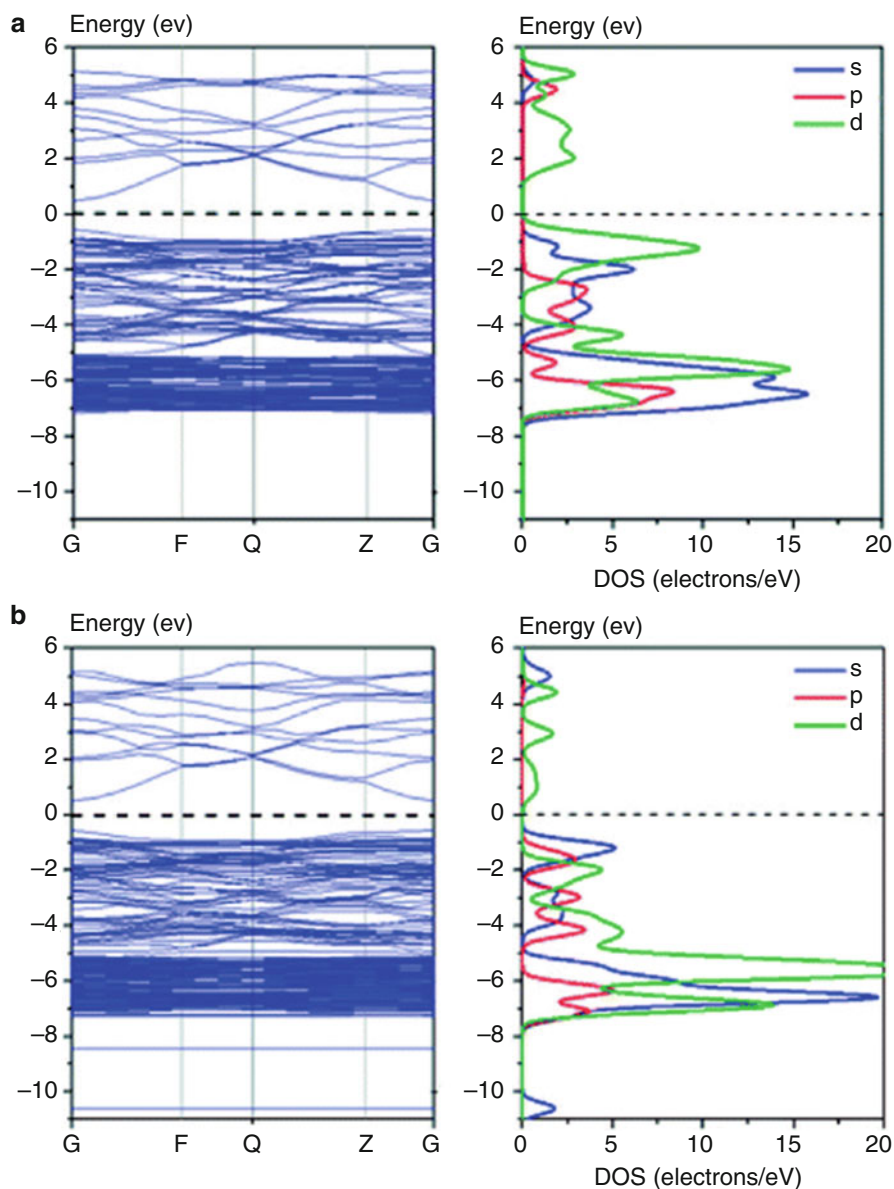

A plane-wave basis set with an orbital cutoff distance of 3.9 Å was used. All-electron calculations and a double numerical basis set with polarization functions (DNP) were employed. Wave function integration in reciprocal space was performed via fine grid sampling of k points with a separation of  $0.02 \text{ Å}^{-1}$ . For the calculation of the density of states (DOS), a  $5 \times 8 \times 3$  Monkhorst–Pack grid was used. Charge transfer was calculated based on the Mulliken population analysis (MPA) (Mulliken 1955).

The ethanol ( $\text{C}_2\text{H}_5\text{OH}$ ) molecule adsorption on the ZnO surface is shown in Fig. 10. When an ethanol molecule approaches the ZnO surface, electronic

**Fig. 10** Optimized configuration of the ethanol molecule on the ZnO surface. Blue line represents hydrogen bond between H and O atoms (Reprinted with permission from Yuan et al. (2009). Copyright 2009 American Chemical Society)

560 interactions among nuclei and electrons disturb the initial configuration, inducing  
561 adsorption of the gas molecule on the ZnO surface. After the surface reconstruction  
562 induced by adsorption, energy-level splitting is found (Fig. 11a). Band structure is  
563 deflexed because of charge transfer (Fig. 11b).

**Fig. 11** Band structure and PDOS of the (a) reconstructed and (b) ethanol-molecule-adsorbed ZnO surface (Reprinted with permission from Yuan et al. (2009). Copyright 2009 American Chemical Society)

Based on these calculations, two gas-sensing mechanisms were proposed and revealed that both surface reconstruction and charge transfer result in a change of electronic conductance of ZnO. When the gas molecule is adsorbed upon the surface, the electronic conductance of the gas sensor changes because of the joint effect of these two mechanisms. These results show good accordance with existing experiments and could help in understanding the sensing mechanism of ZnO-based gas sensors.

To search for a high sensitivity sensor for formaldehyde ( $\text{H}_2\text{CO}$ ), the adsorptions of  $\text{H}_2\text{CO}$  on the intrinsic and Al-doped graphene were investigated using DFT calculations (Chi and Zhao 2009). Structure optimizations as well as the corresponding total energy calculations were performed based on the GGA function with the Perdew–Burke–Ernzerhof (PBE) correction (Perdew et al. 1996). The DFT semicore pseudopotential (DSPP) core treatment (Delley 2002) was implemented for relativistic effects, which replaces core electrons by a single effective potential. To ensure that the results of the calculations are comparable, identical conditions were employed for the isolated  $\text{H}_2\text{CO}$  molecule, the graphene substrate, and also the adsorbed graphene system. The k-point was set to  $6 \times 6 \times 1$  for all slabs, which brought out the convergence criterion of  $10^{-5}$  a.u. on energy and electron density and that of maximum force of  $0.002 \text{ Ha}/\text{\AA}$ . Self-consistent field procedure was carried out with a convergence criterion of  $10^{-6}$  a.u. on energy and electron density. All DFT calculations were performed using DMol<sup>3</sup> code (Delley 1990, 2000).

In these calculations, the PBCs were applied to the supercells. A vacuum width of  $16 \text{ \AA}$  above was constructed, which ensured that the Z-axis of the periodic supercell (perpendicular to the graphene layer) was large enough so that there was no interaction between graphene sheets of adjacent supercells. Optimized configurations of intrinsic graphene and Al-doped graphene are illustrated in Fig. 12. The binding energy of the adsorbed systems is defined as

$$E_b = E_{\text{total}} - (E_{\text{sheet}} + E_{\text{H}_2\text{CO}}), \quad (58)$$

where the  $E_{\text{total}}$ ,  $E_{\text{sheet}}$ , and  $E_{\text{H}_2\text{CO}}$  denote the total energy of intrinsic or Al-doped graphene adsorbed system, isolated graphene or Al-doped graphene, and a  $\text{H}_2\text{CO}$  molecule, respectively. A negative  $E_b$  corresponds to a stable adsorption structure.

To investigate the changes of electronic structures in graphene caused by the adsorption of  $\text{H}_2\text{CO}$  molecule, electron density difference  $\Delta\rho$  is calculated, which illustrates how the charge density changes during this adsorption process.  $\Delta\rho$  is defined as

$$\Delta\rho = \rho_{\text{total}} - (\rho_{\text{sheet}} + \rho_{\text{H}_2\text{CO}}), \quad (59)$$

in which  $\rho_{\text{total}}$ ,  $\rho_{\text{sheet}}$ , and  $\rho_{\text{H}_2\text{CO}}$  denote electron density of the intrinsic or Al-doped graphene adsorbed system, graphene or Al-doped graphene, and a  $\text{H}_2\text{CO}$  molecule for the adsorbed system, respectively. The electronic density differences of energy

**Fig. 12** Optimized most stable configurations of (a) intrinsic graphene and (b) Al-doped graphene (Reprinted from Chi and Zhao (2009), Copyright (2009), with permission from Elsevier)

favorable intrinsic and Al-doped graphene with H<sub>2</sub>CO adsorptions are shown in Fig. 13. The net electron transfer from the Al-doped graphene to H<sub>2</sub>CO is four times more than that in the intrinsic grapheme, which indicates that the Al-doped graphene can be used as a novel sensor for the detection of H<sub>2</sub>CO molecules.

### 53.4 Hybrid Quantum Mechanics/Molecular Mechanics (QM/MM) Methods

As stated above, MD simulations and QM calculations show enormous capacity in handling problems in adhesion. However, in many cases, current force fields used in MD as well as MM simulations are not sufficiently accurate to reproduce the dynamics of molecular systems. At the same time, QM methods cannot deal with large systems because the simulations will be time-consuming or even become impossible. The simulation techniques have been expanded to combine the strength

**Fig. 13** The electronic density difference isosurfaces for (a) H<sub>2</sub>CO–graphene system and (b) H<sub>2</sub>CO–Al-doped adsorbed systems with energy preferred configuration (graphene systems). The blue region shows the electron accumulation, while the yellow region shows the electron loss (Reprinted from Chi and Zhao (2009), Copyright (2009), with permission from Elsevier)

of both MM simulations and QM calculations, which is called the hybrid quantum mechanics/molecular mechanics (QM/MM) approach.

### 53.4.1 Basic Theory

The basic strategy for the QM/MM method lies in the hybrid potential in which a classical MM potential is combined with a QM one (Field et al. 1990). The energy of the system,  $E$ , is calculated by solving the Schrödinger equation with an effective Hamiltonian,  $H_{\text{eff}}$ , for the mixed quantum mechanical and classical mechanical system

$$H_{\text{eff}}\psi(r, R_{\text{QM}}, R_{\text{MM}}) = E(R_{\text{QM}}, R_{\text{MM}})\psi(r, R_{\text{QM}}, R_{\text{MM}}), \quad (60)$$

where  $\psi$  is the electronic wave function of the quantum system,  $r$  is for the coordinates of the electrons,  $R_{\text{QM}}$  is the position of the quantum mechanical nuclei, and  $R_{\text{MM}}$  is for the molecular mechanical nuclei. The wave function,  $\psi$ , depends directly on  $r$ ,  $R_{\text{QM}}$ , and  $R_{\text{MM}}$ . The effective Hamiltonian for the mixed quantum and classical system is divided into three terms (Lyne et al. 1999)

$$H_{\text{eff}} = H_{\text{QM}} + H_{\text{MM}} + H_{\text{QM/MM}}, \quad (61)$$

where  $H_{\text{QM}}$  is the contribution from complete QM section (see QM in Fig. 14),  $H_{\text{MM}}$  is from the pure MM section (see MM in Fig. 14), and  $H_{\text{QM/MM}}$  is the interaction between the QM and MM portions of the system. Similarly, the total energy of the system calculated by solving the Schrödinger equation can likewise be divided into three component parts

**Fig. 14** An example of how to partition a molecule into QM and MM regions. The figure shows a histidine molecule, in which all the atoms in the imidazole ring are taken as QM atoms, while the remaining atoms are treated as MM atoms (Reprinted from Yang and Zhao (2006), Copyright (2006), with permission from Elsevier)

$$E_{\text{eff}} = E_{\text{QM}} + E_{\text{MM}} + E_{\text{QM/MM}}. \quad (62)$$

However, the pure MM term can be removed from the integral because it is independent of the electronic positions. So another way to express the total energy of the system is as the expectation value of  $H_{\text{eff}}$

$$E_{\text{eff}} = \langle \psi | H_{\text{QM}} + H_{\text{QM/MM}} | \psi \rangle + E_{\text{MM}}, \quad (63)$$

where  $H_{\text{QM}}$  is the Hamiltonian that can be obtained by either semiempirical, Hartree–Fock, or DFT.  $E_{\text{MM}}$  is an energy calculated based on a classical force field.  $H_{\text{QM/MM}}$  is the key term which involves combinations of the interaction of the MM atom “cores” with the electron cloud of the QM atoms, the repulsion between the MM and QM atomic cores, as well as the LJ term. The form of  $H_{\text{QM/MM}}$  is

$$H_{\text{QM/MM}} = - \sum_{iM} \frac{q_M}{|r_{iM}|} + \sum_A \frac{q_M Z_A}{|R_{AM}|} + \sum_{AM} 4\epsilon_{AM} \left( \frac{R_{\text{min},AM}^{12}}{R_{AM}^{12}} - 2 \frac{R_{\text{min},AM}^6}{R_{AM}^6} \right) \quad (64)$$

where  $q_M$  is the atomic point charge on the MM atom,  $r_{iM}$  is the QM electron to MM atom distance,  $Z_A$  is the core charge of QM atom  $A$ ,  $R_{AM}$  is the QM atom  $A$  to MM atom  $M$  distance, and  $\epsilon_{AM}$  and  $R_{\text{min},AM}$  are the LJ parameters for QM atoms  $A$  interacting with MM atom  $M$ . The critical term that allows the QM region to “see” the MM environment is the first term in the right side of Eq. 64 where the summation is over all interactions between MM atoms and QM electrons. The second term in Eq. 64 represents the core electron interaction between MM and QM atoms and is incorporated into the QM Hamiltonian explicitly. The van der Waals interaction between QM part and MM part is described by the third term in Eq. 64. As the integrated molecular orbital/molecular mechanics (IMOMM) method (Maseras and Morokuma 1995) is taken, the introduction of new parameters is avoided and the number of geometry variables is reduced as much as possible.

### 53.4.2 QM/MM Boundary Treatments

An important aspect of the formation of a hybrid potential is how to handle the covalent bonds between atoms that are described with different potentials, that is, the bonds existing at the interface of the QM and MM regions. Several methods have been proposed to deal with this problem, including the simple link-atom method (Field et al. 1990), the sophisticated hybrid-orbital technique (Ferre et al. 2002), and the pseudo-bond approach (Zhang et al. 1999).

In many situations, it is necessary to split a molecule between QM and MM regions, which means that there are covalent bonds between QM and MM atoms. These cleavage bonds must be treated in some way because the presence of broken bonds and unpaired electrons at the boundary of the QM region dramatically changes the electronic structure of the QM subsystem. As long as the QM and MM atoms are in different molecules, no such problem arises.

Here, the classical link-atom method was introduced as a typical example. The link atoms as shown in Fig. 14 are treated exactly like QM hydrogen atoms in the QM/MM scheme, and they are invisible to the MM atoms because no interactions between the link atoms and the MM atoms are calculated. Each bond that crosses the boundary between the two regions must be defined. The link atom should be placed along the bond between the QM and MM atoms. The exact distance does not matter since the position of the link atoms is optimized in subsequent calculations. For the IMOMM scheme, the introduction of link atom is modified to study organometallic reactions by subtracting the classical MM interactions with the real QM system.

### 53.4.3 Examples of QM/MM Simulations

The hybrid QM/MM method is employed to simulate the His-tagged peptide adsorption to ionized region of nickel surface. "His-tags" are used in nanomechanical systems and biosensors due to their functional side chains. Noji et al. exploited the high affinity of polyhistidine-tagged  $\beta$ -subunits for Ni-nitrilotriacetate (NTA) to immobilize an F1-ATPase  $\alpha 3 \beta 3 \gamma$  subcomplex on a solid surface as shown in Fig. 15 (Noji et al. 1997). His-tags were used by Montemagno et al. (Montemagno and Bachand 1999) to attach a biomolecular motor, F1-ATPase, to metal substrates, and they have tested the binding strength of a 6 $\times$ His-tagged synthetic peptide attached to Au-, Cu-, and Ni-coated coverslips.

The 6 $\times$ His-tagged synthetic peptide attachment to the ionized region in Ni substrate was studied with the peptide chelating with Ni ion considered (Yang and Zhao 2006). GAMESS (Schmidt et al. 1993) and TINKER (Ponder and Richards 1987) were employed for the QM/MM calculation of the His-tagged peptide chelating with Ni ion. GAMESS/TINKER can perform the IMOMM scheme (Maseras and Morokuma 1995), which spearheads the entry of hybrid QM/MM approaches in computational transition metal chemistry. In the QM/MM calculation, the imidazoles on the side chain of the peptide and the metal ion with several neighboring water molecules are treated as a QM part calculated by "GAMESS," and the remaining

**Fig. 15** Immobilization of F1-ATPase  $\alpha_3\beta_3\gamma$  subcomplex on solid surface by polyhistidine interaction with Ni-NTA (Noji et al. 1997) (Reprinted from Yang and Zhao (2006), Copyright (2006), with permission from Elsevier)

**Table 2** Binding energy and structural data for the optimized chelate structures

	$\Delta E$	$D_{(N-Ni)}$	$D_{(C1-L)}$	$D_{(C1-C2)}$	$D_{(Ni-O)}$	$\angle(N-Ni-N)$

HF(6-31+G**)/MM	-382.331	2.092	1.071	1.345	-	91.60
B3LYP(6-31+G**)/MM	-399.462	2.095	1.076	1.348	-	92.02
Experiment	-	2.112	-	1.355	2.065	93.50

atoms are treated as a MM part calculated by “TINKER.” The IMOMM method is used to deal with the QM part with the transitional metal.

All the geometry parameters and the binding energy are listed in Table 2. The QM/MM simulation results show that the 6×His-tagged peptide can form the most stable structure with high binding energy which is also confirmed experimentally. And the optimized structure data are obtained satisfactorily. The results obtained for the peptide-Ni chelate complexes also show that the present QM/MM approach is reasonable and effective. Such delicate properties as conformational changes and binding energy are modeled in the QM/MM calculations. It is shown that the QM/MM method can be used to probe aspects of metal chelate complexes from both fundamental and practical aspects.

**Fig. 16** The partition of DPPC and hydrated water molecules into QM and MM regions (Reprinted from Yin and Zhao (2009), Copyright (2009), with permission from Elsevier)

D is the distance,  $\angle$  is the angle (donor atom- $\text{Ni}^{2+}$ -donor atom), and L represents the link atom. All distances are in Angstrom, and energy in kJ/mol. Experimental data comes from references (Arici et al. 2002; Petrenko et al. 2004). “Reprinted from Materials Science and Engineering A, 423, Yang ZY and Zhao YP, QM/MM and classical molecular dynamics simulation of His-tagged peptide immobilization on nickel surface, 84–91, Copyright (2006), with permission from Elsevier”

In another example, the hybrid QM/MM method is applied to study the hydration phenomena of dipalmitoylphosphatidylcholine (DPPC) headgroup (Yin and Zhao 2009). In geometry optimization, the headgroup and its bound water molecules are treated at QM level of theory and the hydrocarbon chain with MM method (Fig. 16). All the geometry optimizations were carried out using the hybrid QM/MM method without any constraints, and hydrogen atoms were used as link atoms. First the hybrid QM/MM method was demonstrated to be both accurate and efficient enough to describe the conformations of DPPC headgroup. Then, both monohydration and polyhydration phenomena were investigated. In monohydration, different water association sites were studied. Both the hydration energy and the quantum properties of DPPC and water molecules were calculated at the DFT level of theory after geometry optimization. The binding force of monohydration was estimated by using the scan method. In polyhydration, more extended conformations were found and hydration energies in different polyhydration styles were estimated.

## 53.5 Ab Initio Molecular Dynamics (AIMD)

Classical MD is based on the established force fields or predefined interatomic potential. It is a powerful tool to serve problems of adhesion. The heart of any molecular dynamics scheme is the question of how to describe the interatomic interactions which always adopt some suitable functional forms to approximate the two-body, short-range or long-range interactions. The parameters used in the functions are always fitted by the experimental data or the ab initio simulation in some given condition.

Payne et al. listed some drawbacks of traditional MD in a review paper (Payne et al. 1992). Due to these reasons, AIMD has been established to describe the molecular system behavior directly from the electronic structure. In this way, the electronic system always keeps in the ground state and the dynamical behaviors of the system are all in the Born–Oppenheimer (BO) surface which is always called BOMD. Car and Parrinello introduced a new scheme (Car and Parrinello 1985) for AIMD that can perform finite temperature simulations and also did not involve electronic self-consistency at every MD step. Car–Parrinello molecular dynamics (CPMD) was the first to show that AIMD was possible. Some work has been performed using CPMD (Zang et al. 2009). The codes have been also utilized a lot in adsorption research. Mischler et al. used the CPMD to simulate the water adsorption on amorphous silica surfaces and the reaction of the water and the silicon (Mischler et al. 2005). The simulation procedures reveal that CPMD can perform a reaction dynamically.

CPMD has combined first principles electronic structure methods with MD based on Newton’s equations of motion. Ground state electronic structures were described according to DFT in plane-wave pseudopotential framework.

In CPMD, considering the parameters  $\{\psi_i\}$ ,  $\{R_I\}$ ,  $\{\alpha_\nu\}$  in energy function,

$$E[\{\psi_i\}, \{R_I\}, \{\alpha_\nu\}] = \sum_i \int_{\Omega} d^3r \psi_i^*(r) [-(\hbar^2/2m)\nabla^2] \psi_i(r) + U[n(r), \{R_I\}, \{\alpha_\nu\}], \quad (65)$$

are supposed to be time dependent, the dynamical Lagrangian,

$$L = \sum_i \frac{1}{2} \mu \int_{\Omega} d^3r |\dot{\psi}_i|^2 + \sum_I \frac{1}{2} M_I \dot{R}_I^2 + \sum_\nu \frac{1}{2} \mu_\nu \dot{\alpha}_\nu^2 - E[\{\psi_i\}, \{R_I\}, \{\alpha_\nu\}], \quad (66)$$

was introduced, where the  $\{\psi_i\}$  are subject to the holonomic constraints:

$$\sum_i \int_{\Omega} d^3r \psi_i^*(r, t) \psi_j(r, t) = \delta_{ij}. \quad (67)$$

In Eqs. 65 and 66,  $\{\psi_i\}$  are orbitals for electrons,  $\{R_I\}$  indicate the nuclear coordinates,  $\{\alpha_\nu\}$  are all the possible external constraints imposed on the system,  $\psi_i^*(r)$  is the complex conjugate of wave function  $\psi_i(r)$ ,  $\hbar$  is the reduced Planck constant,  $m$  is the mass of electron, and  $n(r) = \sum_i |\psi_i(r)|^2$  is the electron density; the dot indicates time derivative,  $M_I$  are the physical ionic masses, and  $\mu, \mu_\nu$  are arbitrary parameters of appropriate units. Then, the equations of motion can be written as:

$$\mu \ddot{\psi}_i(r, t) = - \frac{\delta E}{\delta \psi_i^*(r, t)} + \sum_k \Lambda_{ik} \psi_k(r, t), \quad (68)$$

$$M_I \ddot{R}_I = -\nabla_{R_I} E, \quad (69)$$

$$\mu_v \ddot{\alpha}_v = -\left(\frac{\partial E}{\partial \alpha_v}\right), \quad (70)$$

where  $\Lambda_{ik}$  are Lagrangian multipliers introduced in order to satisfy the constraints in Eq. 67. Then the equation of kinetic energy

$$K = \sum_i \frac{1}{2} \mu \int_{\Omega} d^3 r |\dot{\psi}_i|^2 + \sum_I \frac{1}{2} M_I \dot{R}_I^2 + \sum_v \frac{1}{2} \mu_v \dot{\alpha}_v^2, \quad (71)$$

is obtained (Car and Parrinello 1985). In fact,  $\mu, \mu_v$  have the dimensions of the mass which are called “fictitious mass.” In this scheme, the wave functions are treated as “particles” in which “mass” are  $\mu$ . When a suitable  $\mu$  is selected, the thickness of the BO surface can be controlled and the simulations are still close to the exact BO surface. So, the ground state wave function obtained by the initial configuration of the nuclei will stay close to its ground state during time evolution. Based on the technique mentioned, CPMD extends MD beyond the usual pair-potential approximation. In addition, it also extends the application of DFT to much larger systems.

Apart from the aforementioned combined simulation methods, the density-functional-based tight-binding (DFTB) method has been developed. DFTB is an accurate semiempirical method explicitly derived from Kohn–Sham DFT by making an expansion of the total energy functional around a reference charge density, which has been shown to be capable of producing reliable molecular structures and energy at a significantly reduced computational cost.

## 53.6 Conclusion

In this chapter, various simulation methods involving the adhesion technology have been reviewed, such as the MD simulations, the QM calculations, the MO method, the DFT calculations, the hybrid QM/MM simulations, the AIMD simulations, and the DFTB method. For each method, the basic theory and the general routine were described. Several representative examples of applications in the investigations of adhesion properties are given. Any one of the aforementioned methods has both advantages and disadvantages. Brief comparisons are listed in Table 3. To make a choice of the simulation method depends on the desired properties that one intends to obtain, while the computational capabilities should also be taken into account (as shown in Fig. 17).

Computer simulation forms a bridge between the molecules and the continuum mechanics of adhesion due to its multiscale, hierarchical, and complex nature (Kendall 2001). It is possible to speculate that the combined simulation methods with more efficiency and flexibility are still required and will lead the future directions of the simulation methodology in this fascinating field.

t.1 **Table 3** Brief comparisons of some simulation methods

t.2		Merits	Drawbacks
t.3	DFT	High accuracy; more details (electronic states, charge distribution, molecule orbits)	Limited to static states of small systems; slow and expensive
t.4	MD/MM	Available for large systems; fast and cheap	Disable in chemical reaction (bond breaking/forming); empirical potentials are used which lead to low accuracy
t.5	Hybrid QM/MM	Combined DFT with MM, extended the simulation system	Interactions between the QM region and MM region are difficult to describe
t.6	AIMD/CPMD	Combined MD with DFT; a balance between the time and precision	Limited to dynamic process of small systems
t.7	DFTB	Combined DFT with TB; works well for homonuclear system	Low accuracy for some heterogeneous system

Fig. 17 Choices for the simulation methods

## Abstract

Bioadhesion is a versatile tool used by many organisms for a variety of purposes. It has roles to play in construction, predation, defense, and attachment and covers different concepts based on biochemical and mechanical principles. The specific request on the bond combined with millions of years of evolution results in diverse inspirations for medical and technical applications. This requires knowledge of the adhesives themselves in terms of composition, structural design, and interaction with surfaces. This chapter gives an overview about natural adhesives and biological adhesives leading to bioinspired applications. The terminology used in this chapter is based on the adhesive's origin and usage and the underlying concept: while natural adhesives are composed of bio-based raw materials for artificial applications, biological adhesives are expressed by natural organisms for versatile purposes. The latter in particular can lead to bioinspired applications that are not restricted to adhesion, including concepts to avoid adhesion as in terms of antifouling. Both kinds of adhesive, i.e., natural and biological, are relevant for biocompatible adhesives. This characteristic is mandatory for applications as in cosmetics, food, or medicine. In view of their interaction with vital tissues and their medical eligibility, a brief digression into biomimetic adhesives is given.

## 54.1 Introduction

Bioadhesives are defined as natural polymers that act as adhesives. The compositions of bioadhesives are mostly complex and can contain proteins, carbohydrates, or lipids alone or complex mixtures with varying proportions. The first documented use of natural adhesives was 200,000 years ago by Neanderthals. They used tar from birch bark to join blades of rock with a shaft. Adhesives like wet lime, resins from trees, collagen, or semiliquid balsams were also used by the Egyptians, the Greeks, and the Romans for applications in marquetry, ceramics, and wood materials thousands of years ago. These adhesives had a natural origin in common. During the industrial revolution, the bioadhesives were replaced by synthetic ones. Nowadays the bioadhesive saga has reached a turning point, and new generations such as bioinspired and biomimetic adhesives are becoming more and more advanced (Mathias et al. 2016).

On the one hand, the increased focus on resource efficiency which is borne out from, among others, ecological needs is a major concern. Therefore natural adhesives are of particular interest. On the other hand, there is the challenging request of adhesion under harsh conditions like wet surfaces, which is excellently solved by marine organisms, many bacteria, and fungi. According to Aristotle, "If there is a better solution, nature has probably found it," and bioadhesives do indeed often provide inspiration and address needs like sustainability.

Adhesive materials and structures are used by many plants, animals, and microbes to attach themselves to inert substrates or to living tissue (Smith and Callow 2006; von Byern and Grunwald 2010; Smith 2016). Therefore, as for many technical applications, nature stands at parity for high-performance adhesion.

Among diverse purposes and complex raw materials, bioadhesives also serve solution approaches. The underlying principal mechanisms of adhesion are various. The octopus suction pad and the feet of geckos and flies, cases in which adhesion is achieved by physical means, are examples which show that biological adhesives do not necessarily have to involve complex biopolymers. Often the functional principles are worth investigating, and it is better to imitate these mechanisms than to attempt complete composition. Usually limited resources and high performance meet the technical requirements perfectly. There are three outstanding characteristics in connection with biological adhesion that are hardly reached by synthetic solutions: (i) bonding and debonding on demand, (ii) adhesion under wet conditions, and (iii) adherence to multiple substrates. The principle mechanisms of biological adhesion were classified into basically physical (interlocking, snap connection, staples, spreading device, suction, friction, capillary effects) and chemical (dry and wet adhesion). Sometimes different adhesion concepts are combined like interlocking, chemical interactions, as well as viscosity and capillarity forces (Schwotzer et al. 2012). Exemplary cases in particular for the chemical ones are reviewed in Sect. 3.

## 54.2 Natural Adhesives

Synthetic adhesives are required by industries in huge quantities for bonding nearly all kinds of substrates ranging from metal to human tissue. For many of these formulations, the environmental, health, and economic aspects are a matter of concern. There is an urgent need to substitute the majority of critical components deemed environmentally unsafe (Meyer-Rochow et al. 2015) such as phenol-formaldehyde or poly(vinyl acetate) (PVA) by biopolymers that are defined as high molecular mass compounds produced by living organism (Patachia and Croitoru 2016). Another objective is to avoid residual toxic chemicals such as volatile organic compounds (VOCs), epichlorohydrin, or methylene diphenyl diisocyanate (MDI). Beyond their composition, it is their end-of-life fate that has moved into focus (Erren et al. 2013). A global analysis of all mass-produced plastics ever manufactured revealed an estimated 8,300 million metric tons (Mt) of virgin plastics have been produced until 2017 of that less than 10% has been or can be recycled (Geyer et al. 2017). This scrutiny of the end-of-life management has also helped moving the focus to demands for recycling and degradation. The United States Environmental Protection Agency (US EPA) has already addressed these concerns, aiming to diminish the use of non-bioplastics in their pollution prevention program during the Obama administration (Gross and Kalra 2002). Despite the varying quality from batch to batch, adhesives originating from bioresources are commercially attractive, because of their numerous advantages like biodegradability, less toxicity, and natural biocompatibility. Today 15% of the adhesives are made out of renewable resources. The green content will increase in the next years by intensifying the use of second-generation biomass, which goes beyond the biofuel production used to synthesize biochemicals. There is a strong research and development focus to develop and commercialize the bioadhesive market. For adhesives

and sealants, the market is being driven by a rising trend in various end user segments to use eco-friendly or green adhesives. The projected goal is to reach about 1.24 billion US dollars in 2017 (<http://www.smithersapex.com/market-reports/green-adhesives-sealants-industrial-applications>). The bio-based adhesive market size accounts for roughly 1–2% of the overall demand. Using novel feedstock such as vegetable oil polyamides, polyisoprenes, soybean polyols, or epoxies could lead to a paradigm shift and change the product matrix of natural adhesives significantly (<http://www.adhesivesmag.com/articles/94808-auto-packaging-construction-lead-adhesives-and-sealants-market-growth>).

Placed into eight “families,” natural adhesives can be distinguished on the basis of their structure: nucleic acids, polyesters, polyisoprenoids, polyoxoesters, polyphenols, polysaccharides, polythioesters, and proteins (Kumar Patel et al. 2013). In the following sections, the most important species of natural adhesives are organized by source: starting with natural vegetable resins (rosin, terpene resins); followed by polyisoprenoids (natural rubber), natural polyesters (vegetable oil, shellac), carbohydrates (starch and dextrans, cellulose “derivatives,” gums, and exopolysaccharides), and proteins (collagen, blood, and vegetable proteins); and closing with polyphenols (lignin, bitumen). For an excursus to natural cross-linkers (e.g., genipin from *Gardenia spec.*) or bio-based epoxy curing agents, the reader is directed to Sung et al. (1998) and Shibata (2013).

## 54.2.1 Natural Resins

Numerous plants use exudates for repair or healing issues in case of injuries. These natural resins are from the chemical point of view related to terpenes and etheric oils. They are amorphous and consist of complex mixtures (phenols, resin acids, resin alcohols, unsaturated resins, resin esters). Natural resins are considered as green raw material, but due to their structure, they are hardly biodegradable. Of particular importance are resin sources of pine trees. Their isoprenoid terpene rosin and terpene resins are valuable additives to provide tack and peel to the adhesive mixture. Their multiple properties offer versatile applications that range from the usage in the preparation of thermoplastics like polyesters (Karak 2016) to uses within the formulation, e.g., of pressure-sensitive adhesives. Their individual chemical structures make significant differences in terms of their compatibility with the formulation. For instance, terpene resin derivatives from pines are tolerated by styrene-butadiene rubber but not d-limonene. In sum, natural resins offer a high potential for adjusting adhesives within the bio-based toolbox.

### Rosin

One of the oldest raw materials in the adhesion industry is rosin. It is used directly or converted to resin esters. Rosin is obtained from conifers and naturally synthesized as a defense compound. By distillation nonvolatile terpene components get separated from the fresh liquid resin. The semitransparent and colored solid has a piney odor and is brittle at ambient conditions. It consists out of abietic acid, an unsaturated

monobasic acid, and additional organic acids. Three classes of rosins can be distinguished: (i) gum rosin (pine gum), the secreted oleoresin from wounds in the living pine tree; (ii) wood rosin, resinous extract from the pine wood stump that was left after harvesting of the tree in the ground for about 10 years to enrich the heartwood in resin; and (iii) tall oil rosin (TOR), a distillate of tall oil (liquid rosin) named after the Swedish word for pine oil “tallolja.” Tall oil is a by-product from Kraft pulping (sulfate process) when pulping coniferous trees. The yellow blackish liquid composed of fatty acids (palmitic, oleic, and linoleic) and rosin acids (mainly abietic) results in TOR with reduced rosin content by fractional distillation. If the rosin content is too high, the material is brittle. In this case additives like beeswax or powdered biochar improve the adhesive strength. In formulations with traditional linseed oil and sand, it is used as gap filler in constructions. Due to its improvement of gloss, hardening, or antifouling properties, rosin-modified alkyd resins or rosin derivatives are used in paints and surface coatings (Karak 2016).

### Terpene Resins

Terpene resins are derivatives from turpentine ( $\alpha$ -pinene,  $\beta$ -pinene, 3-carene) or can be obtained from citrus plants (d-limonene). Three major structural classes can be distinguished: styrenated terpene resins, terpene-phenol resins, and polyterpene resins. Terpene resins can be obtained from terpenes by cationic polymerization. The oldest reference for terpene resins goes back to 1789, when turpentine was treated with sulfuric acid. Terpene resins are used in a wide variety of formulations, e.g., coating compositions or adhesive tapes (Adhesives & Sealants, Industry News 2017: Materials and Chemicals Overview, <http://www.adhesivesmag.com/articles/95737-materials-and-chemicals-overview>). To impart the tack in solvent-based or hot melt adhesives, terpene resins from monoterpenes are used in additive manufacturing (NPCS Board of Consultants and Engineers 2017). Terpene resins are supplied in solution or in solid forms, the latter available in a wide range of molecular weights and softening points (Adhesives & Sealants, Industry News 2017: Materials and Chemicals Overview, <http://www.adhesivesmag.com/articles/95737-materials-and-chemicals-overview>).

## 54.2.2 Natural Rubber

Natural rubber adhesive is based on cis-1,4-isoprenoid units. It belongs to the earliest substances used to bind materials. Because of its capacity to become elastic when heated, it is one of the most popular adhesives on the market and is typically used in bonding organic and porous materials like leather, paper, fabrics, as well as other rubber products. The adhesive is based on natural rubber, an extract from latex, which is the milk of the rubber tree, *Hevea brasiliensis*. The milk is composed out of 60–75% water, 25–35% rubber, 1.5–2.5% resins, 1.5–2% proteins, and 0.5–1% minerals. Eight types of basic natural rubber are recognized: ribbed smoked sheets, pale crepes, estate brown crepes, compo crepes, thin brown crepes (remills), thick brown crepes (ambers),

flat bark crepes, and pure smoked blanket crepes. The definition of these grades is described in the so-called Green Book (Cohen et al. 2008).

Natural rubber mixed with resin gives a sticky material, the adhesive. The unique chemical structure is responsible for its outstanding properties: high initial tack, excellent flexibility and tack retention. The cohesion is caused by the long entangled polymer chains of rubber and gives a highly elastic but brittle adhesive at low temperatures. By vulcanization, the addition of sulfur which acts as a cross-linker, the stability in terms of temperatures can be improved. The low strength due to the limited cohesion and adhesion at temperatures above 70 °C and the softening make it unsuitable for structural applications. Another disadvantage is the poor resistance to ultra violet radiation, ozone, organic solvents and oxidizing agents.

A well-known application is that for self-sealing envelopes. Also used in masking and cloth tapes, the compound found applications beyond those in packaging.

### 54.2.3 Natural Polyesters

Beeswax and vegetable oils belong to natural esters. While beeswax serves as appropriate softener within adhesive formulations but has no initial tack, the vegetable oils expose more suitable structures prerequisite to act as components in adhesives (Türünc et al. 2015). Vegetable oils are fatty acids or triglyceride esters from the seeds of plants (Karak 2016). The fatty acids, which are components of the triglycerides, can be saturated or unsaturated. Double bonds of unsaturated fatty acids are accessible for oxidation reactions, e.g., by cleavage or epoxidation. The modified oil gives access to dicarboxylic acids or epoxidized oils, respectively, which present appropriate reactive groups for formulations like pressure-sensitive adhesives (PSA) (Köckritz and Martin 2008; Li and Li 2014; Wu et al. 2015). Other than oxidation of double bonds, oleochemistry also uses hydrolysis to gain free fatty acids and glycerol or transesterification reaction to get fatty acid methyl esters (Türünc et al. 2015). Vegetable oil derivatives are preferably used for the polyester syntheses that have long-term durability and good adhesion. Advantages of triglycerides are their abilities to create three-dimensional networks and in case of ricinoleic acids from ricinolein (castor-oil-plant) an additional hydroxyl group, which serves as a natural polyol for polyurethanes.

### Shellac

Lacca in tabulis, lac, or shellac, also wrongly referred to as gummi lacca, is the general term for the refined form of lac, a natural polyester resin secreted by tiny scale insects. These phytophagous insects (*Kerria lacca*, *Laccifer lacca*, *Laccifer chinensis*) insert their mouthpart into the barks of specific trees. The insects secrete a sticky lac after transforming the ingested sap into a polyester resin. Therefore it is the only natural resin of economic interest with an animal origin. Shellac is neither a biopolymer nor a monomer; it's on a low level pre-polymerized. For refining issues to get shellac from the seed lac, three processes (bleaching, melting, and solvent extraction) are used. The resulting products vary in terms of characteristics like color

and properties. Depending on the refining method, four types of shellac are distinguished: bleached shellac (regular bleached shellac), bleached dewaxed shellac (refined bleached shellac), wax-containing shellac (orange shellac), and dewaxed shellac (dewaxed orange shellac) (Sankaranarayanan 1989).

Orange shellac and bleached shellac have molecular weights of 1006 g/mol and 949 g/mol, respectively, and the empirical formula for the average shellac molecule is  $C_{60}H_{90}O_{15}$ . Even with this relatively low molecular weight, shellac has excellent film-forming properties, good adhesion to a variety of surfaces, high gloss and surface hardness, good insulation qualities (sealing out moisture), abrasion resistance, and excellent UV stability that prevents darkening, and moreover it is nontoxic. An alcoholic (ethanol or methanol) solution results in good durability. Its solubility in water in the presence of alkalis makes it attractive for cosmetic purposes like hair spray and drug delivery. It consists of a complex mixture of aliphatic and alicyclic acids (jalaric acid, schellolic acid, and aleuritic acid, also butolic and kerrolic acids). Beyond its usage as a colorant, brush-on, wood finish, and food glaze, shellac has historically been used as an adhesive for wooden layers on the hulls of boats (Penning 1996; Specht et al. 1998; Buch et al. 2009). Shellac is one of just a few known bio-based duroplastics (Türk 2014).

#### 54.2.4 Carbohydrates

For many decades carbohydrates (monomeric, oligomeric, polymeric, and gum sugars) have been used as adhesives. Sugar and flour glue as well as corn starch glue are often used as homemade glues. The formulation is simple and the adhesive is versatile. These carbohydrates are chemically saccharides and appear in all organisms, namely, bacteria (xanthan gum and dextran), fungi (schizophyllan and scleroglucan), plants, and animals. Typically plants and animals often use the polymeric form (polysaccharides) as storage compounds (e.g., starch and glycogen), which can have adhesive properties. But polysaccharides are also used for cellular communication (glycosaminoglycans) or as structural biopolymers like chitin, alginate, chondroitin sulfate, or cellulose. Polysaccharides are eligible for adhesion because of the high density of polar functional groups and the high molecular weight leading to specific secondary structures (helical, sheet, or spiral conformation) due to noncovalent interactions. The degree of a carbohydrate's polymerization is highly dependent on origin, pretreatment, and measurement technology. The adhesion to substrates with high surface energy like wood or metals is favored by the polarity, while the cohesion benefits from conformational features. Both, adhesion and cohesion, benefit from the structural variability and can be enhanced by modifications of the functional groups (e.g., carboxylates or hydroxyl). Beyond the well-documented vegetable polysaccharide derivatives, chitosan with its origin in the exoskeleton (the most abundant polysaccharide after cellulose) of marine invertebrates and microbial exopolysaccharides show high potential for adhesives, especially for wood applications. In order to reduce the content of unwanted synthetically toxic components in commercial adhesive applications, one approach is to partly

substitute them with polysaccharides. Hence, numerous adhesives made of polysaccharides as a co-component have been developed. They are known as intermediate (bio)adhesives (Kumar Patel et al. 2013; Karak 2016).

Carbohydrate-based epoxy resins also moved into a tighter focus as a potential alternative with improved physical properties and more efficient curing than petroleum-based epoxy resins. Based on recent studies, covetable epoxy resins may also be designed coming from furan or isosorbides. Furanyl building blocks prepared from pentose, hexose, or polysaccharides could replace petroleum-based phenyl building blocks in thermoset resins, while epoxidized isosorbide has already been shown to be a suitable and favored substitute of bisphenol A. Beyond the suitability of furan derivatives in epoxy-based resins, carbohydrate derivatives are under investigation as epoxy curing agents (Baroncini et al. 2016).

### Cellulose Derivatives

Cellulosic adhesives are solvent-based thermoplastics. As polyhydroxyl alcohol with access to esterification and etherification reaction, esters and ether derivatives as well as polyblends of cellulose and cellulose graft copolymers provide a wide range of adhesive applications. Cellulose nitrate was the first inorganic ester derivative, and it is still one of the most important adhesives. It advanced to a famous “household” cement as it combines features like transparency, flexibility, and water indelibility with a wide range of solubility. Cellulose acetate butyrate is an ester that can be directly used in hot melt adhesives and is utilized in safety glass manufacture. Another ester, cellulose caprate, is used as hot and liquefied optical cement for the manufacture of compound lenses due to its good resistance against UV radiation and the possession of a refractive index near that of glass. Etherification of cellulose can open up the structure to enable solubility in water. The innate adhesive properties of cellulose ethers have been used as thickeners in adhesive formulations. They are of considerable industrial importance as their usage includes plywood adhesives, wallpaper and library pastes, latex adhesives, paper and textiles, and ceramic adhesives. Especially carboxymethylcellulose (CMC) is popular, because of its properties (nonstaining wallpaper adhesive, ease of slip/non-spoiling, high adhesive efficiency, and ease of makeup). Hence, CMC is appreciated in the ceramic industry due to its ability to act as a binder and to suspend materials during various stages of manufacture (Hon 1989).

For applications in adhesive technology, the polymeric degree and structure of cellulose derivatives, which has a direct impact on the solubility and swelling behavior, have to be considered in the preparation of suitable derivatives. In general the principle is valid: the higher the molecular weight, the higher its bond strength. For cellulosic adhesives, processing the adhesive becomes more difficult for increased molecular weights.

Cellulose is never met in pure form. It is a linear homopolysaccharide made up of glucose molecules. Due to its long linear structure, cellulose can achieve a degree of crystallinity of 60–80% depending on its age: the older the higher the crystallinity. Compared with starch and chitin, it has been revealed that even minor structural differences in the direction of the glycosidic bond (alpha or beta) decide if the

conformation is linear or helical and therefore if it is soluble in aquatic media (Türk 2014). These characteristics are of major interest in terms of water resistance and biodegradation. In sum depending on the modification, cellulose may be available as soft as well as tough solvent-based formulations or as hot melts. It adheres very well to porous materials and exhibits substantial resistance to fouling and oil.

### **Starch and Dextrins**

In the predynastic period, Egyptians treasured the practical use of starch when cementing it together with strips of papyrus. They boiled wheat flour with dilute vinegar to obtain an adhesive. Adhesives made from starch and dextrins are almost solely water based and used mainly in the paper and packaging industry. Especially the increasing sector of cardboard and corrugated board production suggests a rising demand. Also as bookbinder adhesive, it occupies a considerable niche market. Starch is a mixture of linear amylose and branched amylopectin. In contrast to the linear cellulose, starch forms a helix due to its alpha-glycosidic bond, which results in fundamental material differences. The previously mentioned isosorbide is a derivative prepared from starch. Dextrin, too, is processed starch by heat and acid to hydrolyze the polysaccharide in smaller fragments. These fragments undergo a repolymerization and result in a highly branched polymer with good solubility. Dextrins are classified by their solid contents and with respective increases in their molecular weights as canary dextrins, white dextrins, and British gums, the latter possessing the strongest adhesive of these three types. To improve the water resistance of waterborne bio-based starch adhesives is a challenging task. The dry strength of such adhesives is fairly high, but exposure to high moisture causes a significant decrease in “wet strength” (Kumar Patel et al. 2013). Treatments with phenolic compounds like caffeic acid and chitosan indicated promising results. Also a system based on modified starch and chitosan limited the water solubility of the starch adhesive (Karak 2016).

### **Potential of Blends, Gum Dispersions, and Exopolysaccharides**

In the context of intermediate or complete bio-based adhesives, different attempts have led to successes by blends of (i) corn starch with tannins, as substitute for phenol in the resin to get closer to formaldehyde-free wood adhesive, (ii) vinyl acetate grafted onto starch and combined with silica nanoparticles to improve water resistance and physical properties of the binding, (iii) and phenol-formaldehyde with fermented biomass, a co-product from ethanol production, comprising glycocalyx, adherent bacterial cells, and fibers (Kumar Patel et al. 2013). Blends of xylan derivatives with dispersing agents as poly(vinyl alcohol) or poly(vinyl amine) and addition of cross-linkers gave a potential wood adhesive as well.

Gums are exudates that are sweated out as a result of injuries to plant parts (e.g., bark) and solidify in air. Gums consist of hydrophilic and hydrophobic heteropolysaccharides with colloidal properties. Gums are suspension and emulsion stabilizing compounds as they inhibit crystallization. For this reason, they are used in hairsprays or in foods such as ice cream and jellies. Common gums are gum arabic, gum tragacanth (spermicidal gels), gum ghatti (enhanced oil recovery, explosive

additive, and wax emulsifier), gum karaya (denture adhesive cream due to high wet adhesive strength), and guar rubber (explosive additive, “fracfluid” additive).

Gum dispersions are heat resistant and possess an intrinsic tack. They are used in plaster adhesives, pressure-sensitive tape and dentures, paper adhesives, pharmaceutical tablet binders, and label pastes. Locust bean gum additionally exhibits excellent water resistance. The binding is comparable to D2 wood adhesive like poly(vinylacetate). Also comparable to this standard were some candidates of investigated microbial polysaccharides in a study of bacterial derived wood adhesives, except for xanthan (which was also successfully tested for wood applications in a different study); candidates included among others photo-curable dextran urethanes, exopolysaccharides from periphytic marine bacteria and from *Bacillus megaterium*, and pullulan (Karak 2016).

### 54.2.5 Protein-Based Adhesives

Three thousand five hundred years and most likely even longer ago, proteins from milk, egg white, and blood were intuitively used as binders and additives in construction materials. Proteins consist of amino acids which differ in their residues. Depending on their composition, they can be tailored for different purposes ranging from catalysis (enzymes), structuring (collagens), transport (ionic channels, hemoglobins), communication (hormones), protection (immunoglobulins), fixation of nitrogen (nodule bacteria), and movement (actin). Gluten (Latin *glūten* for glue) from wheat is a combination of gliadin (56%, responsible for viscosity due to its low molecular weight) and glutenin (44%, quaternary structures with molecular weights >1000 kDa), in sum an elastic storage protein with exceptional adhesive characteristics. It is the main component beyond water in seitan (meat substitute). Gluten is chiefly used in the baking industry but also in the paper industry, and furthermore as an additive in concrete and mortar, and in adhesives. A protein that obtained significant interest is casein, maintained from milk by lowering the pH; it was already used as paint in caves to bind pigments. It is also known as thermoset, namely, galalith, when cured with formaldehyde. The water resistance of casein paints can be achieved by adding chalk milk to it. Because of the food competition and its high price, casein was replaced widely. Still, it is used even today in the food sector for printing casein inks on sausage casings or for labeling bottles. Indoor paintings and paints in kindergartens are also often casein based (Türk 2014). Casein fibers have most comfortable, excellent water transportation, air permeability, and long-lasting antibacterial effects and have received valid international certifications for ecological textiles. These characteristics are attractive for the fashion sector, but in medical applications they were considered cytotoxic.

As a plethora of interesting, proteinaceous structures exists and corresponding unique properties have been identified, the areas of applications as adhesives have rapidly become extremely complex, as the following review focused on just the three major classics beyond casein shows. Treatment of the marine adhesive proteins is postponed and covered in the section polyphenol-based and bioinspired adhesives.

### **Fibrous Proteins (Collagen, Animal Glues, and Fish Glue)**

Collagen, keratin (wool), silk, and elastin are common fibrous proteins. As structuring molecules some of them are constructed hierarchically just like cellulose. Without pretreatment they can be used as reinforcing agents. Collagen is a by-product from leather manufacturing and is used in foods, pharmaceutical products, and medical devices (wound dressing and tissue engineering). In particular medical applications promise a substantial added value.

Animal glues are obtained by boiling bones (bone glue), skin (hide glue) or swim bladders, and skin and bones from fish (isinglass or fish glue). Cartilage glue, on the other hand, is not based on the same compound as other animal glues, but is made up of chondrin, a protein-carbohydrate complex, with less adhesive power (chondroitin sulfate glue). Boiling of the gelatine leads to a water-soluble substance that consists mainly of partially unfolded collagen, whose composition is similar to that of gelatine. All animal glues are high-polymer proteins and derivatives of collagen that form colloids (NPCS Board of Consultants and Engineers 2017).

Degradation, e.g., by hydrolysis and heating of collagen (mainly type I), results in gelatine, which was already used by the ancient Egyptians as an adhesive. Gelatine is able to swell and to absorb water due to a high content of polar residues (about 65%). It is amphiphilic, which makes it suitable as an additive to stabilize foams (Türk 2014). The sum of excellent properties inaugurates versatile niche applications as, for example, in stucco work as a gypsum additive (delaying hardening and increasing strength), in gas masks as an antifogging additive, in compostable candles on graves, and in gum blends as a smoothener and as barrier adhesive. Currently the price for gelatine is relatively low compared to that of synthetic or plant proteins.

### **Proteins in Tissue Engineering**

Substrates involved in surgeries are challenging substrates that require advanced adhesives and need to obey certain natural concepts: fibrinogen and fibrin are proteins present in blood plasma (see chapters in von Byern and Grunwald 2010) and so is albumin, which is inter alia located in the blood. Both and furthermore collagen possess remarkable properties and excellent biocompatibility. Therefore they are used as medical adhesives with FDA approval (albumin limited to surgical repair of acute thoracic aortic dissections). Albumins are globular proteins with amphiphilic character and a high content of the sulfur containing amino acid cysteine. They have polar domains exposed to the outer site, while the lipophilic ones are directed to the inner sphere. This structural feature enables them to function as transporters of water-insoluble compounds. Albumin-based adhesives are usually cross-linked with glutaraldehyde or similar organic compounds and reach an initial tack in about 30 s. Their bonding strength becomes maximal within a few minutes and ranges between 10 and 40 kPa (Bochynska et al. 2016). Fibrin and fibrinogen belong to the blood clotting system. In combination with thrombin, calcium ions, and factor XIII, they are the most commonly used bio-based tissue adhesives, although their bonding strength (approx. 0.01 MPa) is one order of magnitude lower than gelatine-resorcinol-formalin adhesives (approx. 0.1 MPa) (see chapters in von Byern and Grunwald 2010). Collagen and gelatine, a water-soluble derived form of collagen,

became integral parts of the surgeon's toolbox as well: its applications are established in tissue reconstruction, e.g., after drastic damage from combustion, owing to the high potential as a surgical sealant. The substrate can be enzymatically cross-linked by transglutaminase and gels in less than 5 min with bonding strengths about 15–45 kPa. Gelatine is considered biodegradable, non-immunogenic, and biocompatible. It usually needs a cross-linking agent as well as a polymeric additive (e.g., alginate based), with additional functional groups available for cross-links to achieve sufficient mechanical strengths. But it can also be designed as a two-component adhesive such as photochemically induced cross-linking of oxidized urethane dextran and gelatine (Mathias et al. 2016).

### **Vegetable Proteins**

Vegetable proteins like those of soybeans, maize, peas, or wheat gluten, as described above, are in principle all suitable for adhesion applications. As raw materials of by-products, they bear potential for sustainable substitutes, e.g., in wood adhesives. In contrast to casein, they benefit from mild hydrolysis (enzymatical or chemical) or physical treatment to alter their molecular structure by unfolding into a suitable conformation for adhesional processing. Due to its comparatively low costs and good adhesion characteristics, soy protein has established itself as a binder for fillers and pigments in (paper) coatings. Thus, it gives paper a glossy white surface. It was already used in the USA until the beginning of the last century as a low-budget (0.02 dollar/pound; Weakley and Mehlretter 1965) adhesive composed of soy protein, a nonvolatile starch dialdehyde, and lyophilized blood. Just cross-linked soy proteins are not suitable as pure material; they need to be blended with plasticizers because of their brittleness. Also the water content has a considerable impact on the material properties. Up to now just 0.5% of soy protein is used in industrial applications (Türk 2014).

Nevertheless, strength and water resistance of vegetable proteins are still far removed from commercial adhesives. Their potential, however, can be increased by blending them with poly(vinyl acetate) or poly(vinyl alcohol) but also with other proteins as described for the American low-budget formulation with blood and casein (Mathias et al. 2016).

### **54.2.6 Polyphenol-Based Adhesives**

Polyphenols are natural compounds found in animals and plants. These bulky molecules comprise an aromatic p-system and hydroxyl groups in phenolic groups like catechols. It is assumed that the catechol functionality is responsible for adhesive and cross-linking characteristics. In plywood industry the most common adhesives are phenol based and cross-linked by formaldehyde (phenol-formaldehyde). It stands out with excellent weather and water resistance. Based on the structural similarity, several attempts have been made to replace phenol by lignin derivatives. Lignin is composed out of p-coumaryl alcohols, coniferyl, and sinapyl. These three phenylpropanoid monomers give an amorphous polyphenol linked via a multitude of interunit bonds. Lignin is linked covalently to hemicellulose. It serves

as a waterproof and antimicrobial binder for cellulose fibers in wood and is a highly valuable by-product of the lignocellulosic bio-refinery and pulping industry. The latter is less suitable as the lignin coming from the bio-refinery for the use as adhesion. Lignin coming from the bio-refinery has fewer methyl groups and that enhances reactivity. Therefore the lignocellulosic residues have a high content of reactive lignin with access to condensation reactions with phenol and formaldehyde in alkaline conditions. Lignin can replace phenol up to 50% in the formulation (plywood based of such a formulation reached the outdoor grade pursuant to the Chinese National Standard) (Mathias et al. 2016). Homogeneous and constant batches of lignin can also be obtained directly starting from different biomass sources by environmentally friendly enzymatic processes. These enzymes involving laccases, tyrosinases, and lipoxigenases transform lignin into a reactive biopolymer that can be used, e.g., as prepolymers, in adhesives or coatings. A life cycle assessment explored the environmental sustainability of the production. Laccase-modified and reduced lignin-soy protein adhesives yielded more than half of the strength of a common polyurethane adhesive (Mathias et al. 2016).

Adhesives from marine sessile organisms are well designed for hydrated surroundings. Several mechanisms are responsible for this performance, depending on the purpose of shorter- or longer-lasting adhesions. In many adhesives key compounds in the composition could be identified such as the amino acid lysine, in case of the sperm cells from goby fish (Mathias et al. 2016), hydroxyproline, or 3,4-dihydroxyphenylalanine (DOPA). The marine bacterium *Alteromonas colwelliana* uses L-DOPA, tyrosine, and related quinones beyond exopolysaccharides for moisture-resistant adhesion just like some higher organisms like mussels do. DOPA is very versatile in its reactions that are depicted in Fig. 1. It can act as cross-linker or as initial adherent as well. Due to these abilities to adhere in wet conditions and to build up stable networks, these glues gave inspiration for biomedical applications and other technical uses (see Sect. 4.2).

DOPA is just one representative phenolic compound. Tannins, lignin, urushi, and cashew nut shell liquid (CNSL) are further examples. The shell of cashew nuts contains about 20% of CNSL, which is composed of an allergenic phenolic lipid, mainly anacardic acid (71–82%) and also cardol (4–20%), cardanol (1–9%), and 2-methylcardol (1–4%). Anacardic acid is a potent skin irritant, similar to the allergenic oil urushiol (toxin of ivy). The extraction process causes decarboxylation of the anacardic acid leading to cardanol (Maiorana et al. 2015). The structural increments are related to the properties of the resins, made up of phenolic compounds: (i) hydroxyl groups are responsible for good adhesion and proper reactivity at moderate temperatures; (ii) a long aliphatic side chain gives resistance to water, good anticorrosive properties, low viscosity, long open/application time, and flexibility; and (iii) the aromatic ring ensures excellent chemical resistance.

The oldest adhesive used by mankind, birch tar, is also considered to be a polyphenolic representative. Another well-known tar is bitumen, whose use was documented at the site of Umm el Tlell and Hummal (Syria). It dates back to about 70,000 years to the Middle Paleolithic (Boëda et al. 2008). Even though it cannot be considered as actually renewable, it is a natural petroleum tar, consisting of

**Fig. 1** Catechols can act as chelating ligands and complex metal ions (a), the hydroxy group is capable of interacting by hydrogen bonding (b), the phenol can use its  $\pi$ -system for interactions with  $p$ -Orbitals and  $\pi$ -Orbitals (c). Quinones can form covalent bonds by reactions with thiols (d); form Schiff bases and undergo a

macromolecular chains that become solid by entanglement without any cross-linking, a natural hot melt. Resins (see Sects. 2.1 and 2.3.1) and tars have widespread uses as adhesives. Bitumen is available in liquid form, as water emulsion or in solvents, and also in solid form like hot melts. Additives like proteins or thixotroping agents are used in bitumen formulations to adjust their viscosity, tack, and mechanical strength. The tack can be improved by an addition of ionomeric elastomers and flexibility benefits from rubber latex in the formulation. Cigarette butts encapsulated with bitumen are used in construction and combine recycling with improving the mechanical properties of asphalt concrete by reducing thermal conductivity. This reduces the feared Urban Heat Island effect and also hot spots on roads caused by sunlight (Mohajerani et al. 2017).

### 54.3 Biological Adhesives

Bioadhesives from bacteria, plants, and animals have proven their efficacy for 500 million years and become adapted to suit the needs and requirements of the organisms producing them. However, still very little is known about the composition, production, secretion, and mechanical properties of the vast majority of these systems. Generally speaking, biological adhesion tends to be based on two principles:

- (i) Attachment via mechanical systems and interfacial forces, i.e., by van der Waals forces or capillary interactions as seen in geckos, flies, beetles, tree frogs, and ivy or by reduced-pressure systems as given in cephalopod suckers (see ► Chap. 55, “Biological Fibrillar Adhesives: Functional Principles and Biomimetic Applications”). Among these systems, hairy and smooth toe pads have been studied most extensively, and the structures present on the feet of gecko and tree frog species have become model systems with successful prototypes and applications.
- (ii) Usage of chemical bonds based on, e.g., proteins or other macromolecules. These secretions are released through specialized glands and serve not only for solitary attachment and locomotion as for mechanical system but also for other purposes such as construction or defense.

Around 100 marine and terrestrial organisms are known to secrete adhesives (see Graham 2005; Hennebert et al. 2015; von Byern et al. 2018 and contributions in Smith and Callow 2006; von Byern and Grunwald 2010; Smith 2016), but of these only a few organisms have already been characterized in detail or implemented into functional prototypes (see Tables 1, 2, 3, 4, 5). However, as even closely related

**Fig. 1** (continued) kind of Michael reaction (e) or by radical addition forming a aryl-aryl-coupling (f). The DOPA-quinon can also tautomerise to a melanin precursor (g) Image from Rischka et al. (2010) and republished with permission

**Table 1** Compilation of organisms using biological adhesives mainly for predation (no claim is made to completeness)

Bioadhesive main function	Phylum (zool)/order (bot)	Genus	Glue production	Chemical composition	Bonding properties	Major references
Predation	Ericales, Nepenthes, Lamiales	Carnivore plants ( <i>Drosera</i> , <i>Byblis</i> , <i>Pinguicula</i> )	Glue droplet on stalked gland, situated on the leaves	4% aqueous solution of single polysaccharide and chemical elements (Ca, Mg, K, Na)	Viscoelastic ( $10^2$ N/s/m <sup>2</sup> ), hygroscopic, bonding lost <70% rH	See contribution in von Byern and Grunwald (2010)
	Ctenophora	Comb jelly ( <i>Pleurobrachia</i> )	Conical cell with spiral filament (colloblast) in tentacles, projected against predators	Histochemical confirmation of basic proteins (pK <sub>S</sub> ≈ 8) and sugars	Not determined (n.d.)	von Byern et al. (2017b)
	Onychophora	Velvet worm ( <i>Principapillatus</i> , <i>Euperipatoides</i> )	Slime gland ducts in body cavity, glue ejected through slime papillae at the head	84–90% water, 55% protein (8–1300 kDa, major protein Et <sub>p1</sub> = 250, 350 kDa), major amino acids Gly (27 mol%) and Pro (13 mol%), 1.3% sugar (mannose, galactose), lipids, no toxin	n.d.	von Byern et al. (2017b) and von Byern et al. (2017a)
	Mollusca	Worm snail ( <i>Vermetus</i> , <i>Dendropoma</i> )	Sticky mucus net, produced by modified pedal gland system	Mucopolysaccharides and glycosylated proteins, toxic components	n.d.	Klöppel et al. (2013)
	Arthropoda	Orb-weaver spider ( <i>Leucage</i> , <i>Araneus</i> )	Glue droplets on viscid silk capture thread, produced by aggregate glands at abdominal spinneret	Proteins (>65 kDa), major amino acids Gly (22 mol%) and Pro (16 mol%), sugars (N-acetylglucosamine), lipids, choline, GABAmide, isethionate, elements (KNO <sub>3</sub> , H <sub>2</sub> PO <sub>4</sub> <sup>-</sup> , Na, Cl, Ca)	Resistant to UV irradiation, temperature (18–30°), high humidity range (20–90%), tensile strength 5–32 μN/mm	Graham (2005) and Sahni et al. (2014)

t.8	Fungus gnat larvae ( <i>Arachnocampa, Keroplatus</i> )	Glue droplets released through the mouth and attached to silk threads	Water (99%), proteins (58–62 kDa), chemical elements (P, S, K, Ca), free fatty acids, no sugars	Hygroscopic, bonding lost <80% rH, low bonding strength	von Byern et al. (2017b), Eberhard (1980), and Yeargan (1994)
t.9	Spitting spider ( <i>Scytodes</i> ) Bola spider ( <i>Mastophora</i> )	<i>Scytodes</i> : glue and toxin produced in cephalothorax (prosoma) and ejected through chelicera (mouth area) along a silk thread. <i>Mastophora</i> : silk thread with adhesive droplets produced from spinnerets, bola swung against prey (attracted by pheromones)	<i>Scytodes</i> : presumably small (3.5–7.0 kDa) glycine-rich and diglutamine-/dityrosine-containing peptides, high amount of toxins <i>Mastophora</i> : n.d.	<i>Scytodes</i> : contraction and shortening during hardening (force 0.1–0.3 mN) <i>Mastophora</i> : low viscosity liquid. Mass of folded threads within the sticky ball	
t.10	Harvestmen ( <i>Mitostoma</i> )	Pedipalps with clavated setae, secreting glue droplet	Triglycerides, oleic fatty acids, high water content	Pull-off force 7μN, dehydration, no solubility in 70% ethanol	See contribution in Smith (2016)
t.11	Rove beetles ( <i>Stenus</i> )	Glands located in the head, sticky labium catapulted toward prey	Proteins, sugars, and lipids	n.d.	See contribution in von Byern and Grunwald (2010) and Koerner et al. (2012)

**Table 2** Compilation of organisms using biological adhesives mainly for defense (no claim is made to completeness)

Bioadhesive main function	Phylum (zool)/ order (bot)	Genus	Glue production	Chemical composition	Bonding properties	Major references
t.1 t.2 Defense	Mollusca	Slug ( <i>Arion</i> ) and snails ( <i>Cornu</i> )	<i>Arion</i> , dorsal foot glands <i>Cornu</i> , defensive foamlike secretion, released through mantle cavity	<i>Arion</i> , matrilin- and lectin-like proteins, interpenetrating a sulfated polysaccharide network, chemical elements (Ca and Mg) <i>Cornu</i> , proteins (30, 50 and >120 kDa) (unpubl.), other molecules and elements not characterized yet	n.d.	See Wilks et al. (2015) and contribution in Smith (2016)
t.4	Echinodermata	Sea cucumber ( <i>Holothuria</i> , <i>Actinopyga</i> )	Sticky Cuvierian tubules, released through cloacal orifice. Glands located in the tubules	60% protein (17–220 kDa), major amino acids Gly (12–30 mol%) and Glx (9–16 mol%) depending on the species, 40% neutral sugar, toxin holothurin	Excreted tubules elongate 20x to original length, sticks within 10 s. Tensile strength >135 kPa	See contributions in von Byern and Grunwald (2010), Smith (2016), and Graham (2005)
t.5	Arthropoda	Chilopoda ( <i>Henia</i> , <i>Geophilus</i> )	Sternal glands (multicomponent system) located on the ventral body side	Two major proteins (12 and 130 kDa), some species additionally contain hydrogen cyanide (HCN); species-specific pH range	Hardening in the moment of release	von Byern et al. (2017b)
t.6		Termites ( <i>Tenuirotritermes</i> , <i>Nasutitermes</i> )	Gland in the head capsule ejects the glue through a modified pore (named fontanelar gun)	<i>Tenuirotritermes</i> resin composed of 62% $\alpha$ -pinene, 27% myrcene, and 11% limonene; some species also contain toxins and pheromones	Hardening within 10 s	Nutting et al. (1974) and contribution in von Byern and Grunwald (2010)

t.7	Chordata	Salamander ( <i>Ambystoma</i> , <i>Plethodon</i> )	Milky secretion from dorsal and ventral skin glands (two-component system)	70% water, 78% protein (15–120 kDa), 0.41% sugar (mannose, $\alpha$ -L- fucose, N-acetyl-D- glucosamine), lipids, chemical elements (Na, Cl, K, S); some species secrete distasteful substances with its glue	Hardening within seconds, tensile strength >1.7 MPa (unpubl.), hydrophobic in cured stage	von Byern et al. (2017b) and von Byern et al. (2017a)
t.8		Burrowing ground frog ( <i>Nothaden</i> )	One dorsal skin gland (granular gland)	85–90% water, 55–60% protein (13–500 kDa, dominant Nb-1R), major amino acids Gly (16 mol %) and Pro (9 mol%), 0.75 % sugar	Tensile strength >70 kPa (within 24 h), shear stress >2800 kPa (cured 1 week on wood)	See contributions in von Byern and Grunwald (2010), Smith (2016), and Graham (2005)
t.9		Hagfish ( <i>Eptareteus</i> , <i>Myxine</i> )	Lateral slime glands (two-component system), secreting proteinaceous threads and mucin vesicles	99.9% water, 0.002% thread (proteins) and 0.0015% mucin (acidic sulfated glycoproteins), chemical elements (Na, Cl, K)	Elastic and coherent soft hydrogel, high extensibility. No adhesiveness	von Byern et al. (2017b)

**Table 3** Compilation of organisms using biological adhesives mainly for construction (no claim is made to completeness)

t.1	t.2	Phylum (zool.)/ order (bot.)	Genus	Glue production	Chemical composition	Bonding properties	Major references
t.1	t.2	Arthropoda	Eusocial wasp ( <i>Polistes, Vespa</i> )	Salivary secretion used as binder for organic material to build papery nest. The number of glands varies between species	Species dependent: presumably mostly proteinaceous (>73%, siliklike) and insoluble polysaccharides, major amino acids (Ala, Ser, Gly), chemical elements as K, S, Zn, Fe	Water resistant, light weight (thickness 43 µm), tensile strength (0.25–1.02 MN/m <sup>2</sup> )	McGovern et al. (1988), Singer et al. (1992), and Cole et al. (2001)
t.1	t.2	Arthropoda	Honeybee ( <i>Apis</i> )	Wax glands (three cell types) located ventrally on the 4–7 abdominal segment	Mixtures of wax esters, hydrocarbons, free fatty acids, and alcohols	Mechanical manipulation at 35 °C, melting point at 62–64 °C, fragile at low temperature, not adhesive	Tulloch (1970) and Hepburn et al. (1991)
t.1	t.2	Arthropoda	Huntsman spider ( <i>Cebrennus, Leucorchestris</i> )	Sticky silk threads secreted from the abdominal spinneret to line and stabilize the burrow in the desert sand	n.d.	n.d.	Foelix et al. (2016) and Henschel (2017)
t.1	t.2	Arthropoda	Caddisfly larvae ( <i>Hesperophylax</i> )	Salivary gland secretions (silk and glue coat) as binder for organic/inorganic material constructions Silk as double fiber with 5 µm diameter, core (<100 nm), coating >0.5 µm thick	Silk core: H- and L-fibroin (>350 and 25 kDa); major amino acids Pro, Glu, Cal, Lys; chemical element as Ca Glue coat: neutral and acid glycoproteins, heme peroxidase	Stress 4.5 MPa (pH dependent), elongation up to 120%, recovery biphasic and Ca <sup>2+</sup> dependent	See contribution in Smith (2016)

t.7	Annelida	Sandcastle worm ( <i>Phragmatopoma</i> ) Tube worm ( <i>Sabella</i> )	Four distinct secretory cell types in the building organ release the cement to stick sand grains toward a tube	Proteins rich in DOPA, major amino acids Ser (29 mol%), Gly (26 mol%), Ala (10 mol%)	Tensile strength >2.4 MPa	See contributions in Graham (2005), Smith (2016), Graham (2005), and von Byern et al. (2017a)
t.8	Chordata	Swiftlet ( <i>Collocalia</i> )	Salivary secretions used as binder or solitary for bird nest building	Two glycoproteins, sialic acid-rich O-glycosylproteins		Oda et al. (1998)
t.9		African lungfish ( <i>Protopterus</i> )	Three types of goblet cells, which differ morphologically and histochemically Skin secretions form a protective outer cocoon against dry periods in the soil	Positive staining for sugars (PAS)	n.d.	Kitzan and Sweeny (1968) and Greenwood (1986)
t.10		Stickleback fish ( <i>Gasterosteus</i> )	Nest construction with organic material. Glue produced in the kidney, stored in the urinary bladder	Protein (Spiggin, 203 kDa), major amino acid Cys (8 mol%)	Highly elastic thread, silklike appearance	Van Iersel (1953) and Jakobsson et al. (1999)

**Table 4** Compilation of organisms using biological adhesives mainly for attachment (no claim is made to completeness)

Bioadhesive main function	Phylum (zool)/ order (bot)/ kingdom	Genus	Glue production	Chemical composition	Bonding properties	Major references
t.1 t.2 t.3	Bacteria	<i>Pseudomonas</i> , <i>Caulobacter</i>	Extracellular matrix, synthesized by three different mechanisms: ABC transporter, Wzx/Wzy dependent, synthase dependent. Attachment via fimbria/pilus	Adhesin (i.e., FimH) and exopolysaccharides as mannose, N-acetylglactosamine, rhamnose, etc.	Binding partly effected by acidic pH (4–5), adhesion µN range	See contribution in Smith (2016)
t.4	Fungi	Yeast ( <i>Candida</i> )	Depending on function (substrate or spore bonding), i.e., appressorium, hyphodium, conidia, epithelial cells	Species-specific macromolecules (EapI, 110 kDa protein, 90 kDa mannoprotein, etc.), mucilaginous matrix (containing mycosporine- alanine, cutinase, esterase, etc.), sugars (i.e., mannose, galactose)	Appressorium turgor pressure up to 8 MPa and force of 17 µN	See contribution in Smith (2016)
t.5	Ochrophyta	Diatom ( <i>Toxarium</i> )	Glue secreted through slit in the silica cell wall (termed raphe)	Protein (single >220 kDa), major amino acids (Gly 22 mol%, Asx 14 mol%, His 11 mol%), sulfate, chemical elements as Ca, Mg, sugars (mannose, xylose, etc.)	0.8 nN, self- healing properties	See contribution in Smith (2016)

t.6	Malvales Santalales	Flowering plant ( <i>Tilia</i> ) Mistletoe ( <i>Viscum</i> )	Pollen: 1. Pollenkitt produced by anther tapetum 2. Viscid thread is part of the ectexine	Pollenkitt: lipids, carotenoids, protein Viscid thread: polymer bases on sporopollenin Viscin: polysaccharide only	Viscid threads are flexible but not elastic threads	See contribution in von Byern and Grunwald (2010)
t.7	Asparagales	Orchid ( <i>Catasetum</i> )	Viscid disc, attachment of pollinarium to pollinator. Temporary attachment	Glycoprotein including sucrose, glucose, fructose	n.d.	Schlee and Ebel (1983)
t.8	Alismatales	Arrowhead vine ( <i>Syngonium</i> )	Aerial root hair, permanent attachment to all types of substrata	Proteins and polysaccharides	n.d.	Yang and Deng (2017)
t.9	Apiales	English ivy ( <i>Hedera</i> )		Arabinogalactan proteins, pectic polysaccharides, chemical element (Ca)	Combination of physical contact, chemical secretion, and shape modification. Tensile strength, 3.4 MPa (single root hair)	Melzer et al. (2010) and Huang et al. (2016)
t.10	Ulvales	Sea lettuce ( <i>Ulva</i> )	Vesicles with adhesive content in free-swimming zoospore	Protein (110 kDa), glycan moieties	Vesicle discharge and curing within 1 min, $\text{Ca}^{2+}$ - involvement	See contribution in Smith and Callow (2006)
t.11	Laminariales	Giant kelp ( <i>Macrocystis</i> , <i>Durvillaea</i> )	Vesicles (physodes) released from fertilized zygote for permanent attachment	Phlorotannin with phloroglucinol monomer. > 150 compounds with MW from 126 Da to 650 kDa, cross-linked Ca alginates	Tissue adaptation, thallus breakage, shear stress > 0.3 MPa	See contributions in Stevens et al. (2002), Smith and Callow (2006), and Graham (2005)

(continued)

t.12 **Table 4** (continued)

Bioadhesive main function	Phylum (zool)/ order (bot)/ kingdom	Genus	Glue production	Chemical composition	Bonding properties	Major references
t.13	Porifera	Demosponge ( <i>Lubomirskia</i> )	Baso-pinacocyte secreting spongins for permanent attachment. Chitin glands not determined yet	(a) Spongins (collagen-like protein) (b) Chitin (close to $\alpha$ -chitin)	n.d.	Evans (1977) and Ehrlich et al. (2013)
t.14	Cnidaria	Freshwater polyp ( <i>Hydra</i> ) Beadlet anemone ( <i>Actinia</i> )	Gland cells at the basal disc part of the peduncle for temporary bonding	<i>Hydra</i> : proteins (presumably glycosylated), protein characterization in progress <i>Actinia</i> : 96% water, 24% protein (12–200 kDa), 8% carbohydrate, 1% lipid, 67% chemical elements (Cl, Na, Mg), equinotoxins	Muscle-mediated detachment	Stabili et al. (2015) and Rodrigues et al. (2016)
t.15	Mollusca	Mussel ( <i>Mytilus</i> )	Byssus threads with distal adhesive plaque, originated from glands in the foot organ. Permanent bonding but mobility given by thread breakage and re-anchorage	6 foot proteins (115, 42–47, 5–7, 79, 9.5, 11.6 kDa) with different amounts of DOPA, collagenous core	Mussel plaque tensile strength >0.85 MPa (with seasonal variation), plaque area varies to surface energy	See contributions in von Byern and Grunwald (2010), Smith (2016), and Graham (2005)
t.16	Violet sea snail ( <i>Janthina</i> )	Violet sea snail ( <i>Janthina</i> )	Anterior part of the foot (propodium), mucus used as float, >12 cm long, >2 cm width	n.d.	Quick curing. Enclosure of gas to a foamlike buoy. Clear glue color	Laursen (1953)

t.18		Cephalopoda ( <i>Nautilus</i> , <i>Idiosepius</i> )	Adhesive glands on digital tentacle ( <i>Nautilus</i> ), dorsal mantle ( <i>Idiosepius</i> ), other body regions. Temporary attachment	Histochemical confirmation of acidic (1.0–2.5) and basic proteins (pH $\approx$ 8.0) and sugars	Weak bonding, fast release, for some species a mechanical detachment is assumed	See contribution in von Byern and Grunwald (2010)
t.19	Platyhelminthes	Flatworm ( <i>Macrostomum</i> )	Adhesive organ at the tail. Duo-gland system (one gland for attachment, other for release). Temporary attachment	Proteins (characterization in progress) and carbohydrates (PNA lectin); transcriptome	n.d.	Lengerer et al. (2016) and Lengerer et al. (2017)
t.20		Ectoparasite ( <i>Entobdella</i> )	Anterior adhesive pad with two gland types, with rod- or spheroid-like content	Protein, lack of sugars, lipids, and L-DOPA, similarities in amino acid composition to sea star, limpets, and barnacles	Cement-like glue, resistant to shear force from water current, temporary bonding	Kear and Evans- Gowing (1998) and Hamwood et al. (2002)
t.21	Arthropoda	Ticks ( <i>Dermacentor</i> , <i>Amblyomma</i> )	Salivary gland. Used as temporary attachment in the skin as a dowel	Two proteins (RIM36, 64P), major amino acids Gly, Pro, Tyr. Proteins similarity to keratin, collagen, glutenins. Protein 64 P homology to <i>Phragmatopoma</i> (see Sect. 3.3)	Glue with quick- hardening core and slow-hardening cortex, high bonding strength	Kemp et al. (1982), Graham (2005), and Hennebert et al. (2015) Johannes
t.22		Acom barnacle ( <i>Balanus</i> , <i>Megabalanus</i> )	Unicellular gland type in the body secrete cement for permanent bonding	84–90% protein (majors from 16–110 kDa), 1% sugar, major amino acids Ser (9–11 mol%), Leu 8–9 mol%), Pro (8 mol%)	Tensile strength >2 MPa (cyprid larva and adult)	See contributions in Smith (2016), Graham (2005), and von Byern et al. (2017a)

**Fig. 2** Biological adhesives used for different purposes such as for protection (1 barnacles), locomotion (2 starfish), defense (3 sea cucumber), and attachment (4 mussels)

species can differ with regard to gland morphology and/or adhesive composition and the secretions have become optimized for different purposes or environments, there are still a huge number of species whose adhesive secretions have not been investigated yet.

Biological adhesives are not exclusively used for settlement, but often also fulfill other purposes in connection with defense, predation, locomotion (Fig. 2), or nest construction and are superbly adapted morphologically, chemically, and physically to the needs and requirements of the organisms that produce them. Different from man-made synthetic systems, biological adhesion works over a wide range of temperatures, in different environments (aquatic, terrestrial, subterranean, arid), and under changing physicochemical conditions. Bonding can occur irrespective of texture or biological interference within milliseconds to all sorts of surfaces, be they natural, synthetic, biological, hard, or soft and with irregular or of complex substratum chemistry. Some organisms form permanent bonds for predation, attachment, or constructions; others use temporary adhesives to enable a holdfast on demand or for locomotion.

This diversity of organisms and variety of adhesive systems as well as the low amounts of secretion available make bioadhesion research challenging, but with access to advanced technological approaches, considerable progress in its characterization has already been made.

In particular most animal-based biological adhesives have been found to be typically polymers, formed by proteins and polysaccharides, which provide robust cohesion strength between the molecules and strong interaction with the contact area. In most animal glues, a high protein content is present (up to 90%), and technical progress has been made in some species, reaching full-length sequences of key proteins involved (Hennebert et al. 2015).

For many other biological adhesives listed in the tables below, a rough estimation of protein number, molecular mass (i.e., 4–650 kDa), and major amino acid residues (in particular serine, glycine, proline, and/or leucine) are available. Difficulties still appear in view of the carbohydrate characterization, as many adhesives contain a relatively low sugar fraction (<3% dry weight) (von Byern et al. 2017). For a few species, glycosidic protein bonds have been characterized in detail (Hennebert et al. 2015), and for most of the others, information on their sugar residues through lectin affinity tests is available. To the best of our knowledge, to date lipids have only rarely been characterized in adhesive secretions (e.g., permanent adhesive of barnacle larvae; Gohad et al. 2014). There is also some information available on the presence of chemical elements such as calcium, zinc, and iron. These kinds of ions serve as cross-linker and stiffen the protein-polysaccharide complex. Rare amino acids such as L-DOPA (L-3,4-dihydroxyphenylalanine) is prominent in the literature being the best characterized key compound in marine adhesive proteins but has been confirmed only in a few marine species (*Mytilus*, *Phragmatopoma*, *Sabella*). Beyond bioadhesion, L-DOPA also plays an important role in insect cuticle sclerotization and mechanical stability of cephalopod beak and polychaete jaws (Miserez et al. 2008).

Despite these technical obstacles, the natural biodiversity is clearly a blessing from a bio-prospecting perspective, providing countless opportunities to identify commonalities and functional principles, thereby developing a better understanding of adhesive mechanisms, evolutionary origins, and adaptations to specific environments and tasks. The key to unlock bioadhesion principles lies in comparative analyses with innovative research approaches based on intellectual and technical exchange as given by EU network projects such as COST Actions TD0906 and CA15216.

### 54.3.1 Predation

For prey capture through passive trap mechanisms, the glue is initially secreted externally and then attached as droplets or coating on silk threads (e.g., orb-weaver spider *Araneus* and fungus gnat larva *Arachnocampa*), a mucus web (worm snail *Vermetus*), tentacles (comb jelly *Pleurobrachia*), leaves (carnivorous plants *Drosera* and *Pinguicula*), or other prey capture devices. These traps are mostly exposed for days to weeks to varying habitat conditions (UV radiation, humidity, temperature, salinity, wind, rain) but still exhibit a bonding ability at prey contact. To minimize prey escape, the glue-containing parts are closely arranged to increase the number of contact points and to ensure that the tangling prey is rapidly entrapped by the sticky secretion. Observation in *Pleurobrachia* indicates that the animals could discard too

large prey items (von Byern et al. 2018) and also for *Arachnocampa* a defined breaking mechanism is discussed (von Byern et al. 2018). Orb-weaver spiders are known to cope with large prey items by forming high tensile silk threads (up to 0.5 GPa for the viscid silk) (Gosline et al. 1999). Gluing traps in animals/plants are not reused; instead new threads/leaves are formed and exposed. In carnivore plants like *Drosera* and *Pinguicula*, the prey is lured by glistening droplets and optic or odor signals (see respective contribution in von Byern and Grunwald 2010), while the cave-dwelling *Arachnocampa* attracts the prey by a specific light organ (Meyer-Rochow 2007). Also in view of their chemical compositions, the different biological adhesives vary strongly, being often highly adapted to specific habitat conditions and prey (or predator) type as recently shown for *Arachnocampa* (von Byern et al. 2018).

A few arachnid species as *Mitostoma* are known to actively capture prey by means of adhesives. While *Mitostoma* directly attaches the prey with its pedipalps, *Scytodes* and *Principapillatus* expel its secretion from a certain distance (up to 2 cm in *Scytodes* or 4 cm in *Principapillatus*) and within milliseconds onto the prey. Both use canalized structures in the head region (slime papillae, chelicerae) to build up a certain pressure and to control the flow direction (von Byern et al. 2018). Up to two separate jets are used, which run a zigzag pattern over the prey and substratum. Immediately after its release, the glue hardens and partly shrinks to tightly entangle the prey. The predators are able to control the glue amount and use more spit, if the prey is still struggling. While in *Scytodes* the glue is released with silk threads, in *Principapillatus* the ejected glue appears as translucent threads but does not contain silk. It remains questionable if the *Scytodes* glue is toxic itself, but it is known that the trapped prey is paralyzed by injecting toxin afterward. The glue of *Principapillatus* lacks a toxin, so instead digestive saliva is released with a bite to immobilize the prey. In addition to the prey capture, *Principapillatus* also uses its glue for defense against predators.

### 54.3.2 Defense

Besides, also other species are known to use adhesives as defense. However, while being very effective against the predators, it yet remains unclear for most of these species how they avoid being trapped by its own sticky secretion. Most of these secretions are located in particular epithelial glands (i.e., dorsally in the slug *Arion subfuscus* and burrowing ground frog *Notaden*, ventrally in chilopods as *Henia* or specific body regions in salamanders as *Plethodon*) (von Byern and Grunwald 2010; Smith 2016) to ensure a fast release onto the body surface.

Sea cucumber as *Holothuria* in contrast expels sticky threads (named Cuvierian tubules) when stressed by a predator (see respective contribution in von Byern and Grunwald 2010; Smith 2016). Termite soldiers as *Tenuirostritermes* fire their secretion in large distance (>3 cm), while spitting spiders and onychophorans (see paragraph in Sect. 3.1) use an oscillating behavior toward the predator or prey. Helicid snails as *Cornu* not only retract in their shell to protect themselves from predators but also secrete a foamlike slimy secretion through the shell opening. The

defensive glue of the American slug *Arion subfuscus* is formed by the matrilin-like proteins, heparan sulfate-like polysaccharides, and metal ions and currently used as template for medical sealant (Li et al. 2017).

Although the secretion of the hagfishes as *Eptatretus* is not adhesive (von Byern et al. 2018), the mucus they release from lateral skin glands strongly swells and clogs the gills and mouths of the predators. In general, the most defensive secretions are released during contact with the pesterer and dispersed over its body and in particular mouth only a few fires directly toward the predator. Exposure to air causes in *Henia*, *Tenuirostritermes*, and *Plethodon* an immediate hardening of the glue (von Byern et al. 2018), while the adhesives of *Arion*, *Cornu*, and *Eptatretus* remain viscoelastic for a certain time (von Byern et al. 2018; Smith 2016). The Cuvierian tubules in *Holothuria* in contrast remain sticky and form a large web, entangling the predator. In many defensive secretions (sea cucumber, salamander, chilopoda, termites), also toxic, distasteful, or noisomely components could be determined, serving to distract the predator additionally (see respective contribution in von Byern and Grunwald 2010; Smith 2016 von Byern et al. 2018 as well as Nutting et al. 1974), while other bioadhesives (e.g., *Notaden*, *Plethodon*) confirm its biocompatibility in cell culture and medical tests (see Sect. 4.2).

### 54.3.3 Construction

Biological adhesion and mucus are mainly used as binders for constructions incorporating inorganic/organic materials; a few species also use the secretions for other functions. Annelids as the sandcastle worm *Phragmatopoma* and the tube worm *Sabella* build permanent tubes, in which they reside (see respective contributions in Smith 2016). As given for mussels (see below), also these annelids use the amino acid L-DOPA as binder to stick the sand grains together and by this form strong and stable tubes (up to 40 cm) (Smith 2016). As the animals lift themselves from the soil with increasing tube length and thereby lose the possibility to uptake new construction material from the ground, suspended sand grains are collected, selected, and used for tube repair and partial increase.

In relation to sabellids, other animals form with their secretions temporary architectures. Stickleback fish as *Gasterosteus* build in the spring a tunnellike nest of plant origin for breeding. The threadlike glue is secreted from the kidney and dispersed by the fins on the nest material (Van Iersel 1953). Caddisfly larvae and hunting spiders combine silk and adhesives to form stabile cases/burrows; however, differences are given in the production site. The hunting spider *Cebrennus* releases the sticky silk threads from its abdominal spinneret to line and stabilize the burrow in the desert sand (Foelix et al. 2016). The caddisfly larva instead secretes its silk and glue from the salivary glands and uses all kinds of inorganic and organic material to build portable or substrate-bonded cases; some species even design multilevel cases. Most caddisflies are not as selective as the sabellids (see above) in view of its construction material and case design; some species use all types of material and design their bizarre-looking cases.

Salivary liquid and organic material is also used by social wasps as *Polybia* and birds (i.e., *Delichon*) as nest-cementing substance (Oda et al. 1998). Although the nest constructions may not appear as stable as the caddisfly case, the papery constructions of wasps are quite long-lasting (even after the inhabitant leave) and have very good stability and even water-resistant properties (McGovern et al. 1988). Besides its binder function, adhesives are also solitary used for constructions. Swiftlets build with their concentrated salivary breeding nests (also known as Edible bird's nests), while the African lungfish *Protopterus* (Greenwood 1986) form with its mucus protective cocoons to survive dry periods. The waxlike secretion of honeybees provides not only the basis for the honeycombs in nature but is also commonly used in cosmetics, food, and pharmaceutical industry. Besides bee wax, also other secretions as fish slime (Antony 1954, see Sect. 2) and the *Phragmatopoma* adhesives are known to have a high potential for medical applications, e.g., in the field of fetal membrane defect sites (Mann et al. 2012; Papanna et al. 2015) and spina bifida repair (Papanna et al. 2016) (see Sect. 4.2).

#### 54.3.4 Attachment

The usage of adhesives as a support for surface bonding is surely the most common purpose, used by bacteria, plants, and animals. Especially aquatic organisms use such secretions to withstand currents and avoid drifting. Some seal themselves or their eggs permanently to the substratum or biological surfaces (i.e., *Ulva*, *Macrocyctis*, *Lubomirskia*, *Mytilus*, *Balanus*, *Lepas*) and developed cement-like binders with high adhesive strength (up to 2 MPa), adapted to the strong hydrodynamic forces typical of the intertidal regions. Others like *Hydra*, *Nautilus*, *Idiosepius*, *Macrostomum*, *Entobdella*, and *Spadella* adhere only temporarily, "on demand." Detachment is presumably achieved mechanically through muscle contractions or body movements except for the case of *Macrostomum*, where a second gland type (so-called duo-gland system) secretes a detachment enzyme. *Janthina* and *Dosima* release a foamlike glue, enabling them to float on the water and in the water flea *Simocephalus* (Meyer-Rochow 1979); suction in combination with an adhesive may be employed for temporary attachments.

Terrestrial and in particular epiphytic plants (*Syngonium*, *Hedera*) use adhesives for attachment; furthermore a large number of flowers use pollenkitt or viscid threads for pollen binding and transport (*Catasetum*, *Tilia*, *Viscum*). Many insects as *Dinocras*, *Drosophila*, and *Liris* in particular use glues for egg anchorage; animals itself in particular use mechanical tools (see ► Chap. 55, "Biological Fibrillar Adhesives: Functional Principles and Biomimetic Applications") for attachment and bonding. Ectoparasites as *Entobdella* or ticks (*Dermacentor* or *Amblyomma*) secure themselves in the host tissue with an adhesive called cement. The cement portion is secreted after insertion of the mouthparts and solidifies almost immediately to tightly anchorage the animal in the tissue during the feeding phase (Kemp et al. 1982). The secretion of the second portion takes up to several days. After

753 feeding, ticks detach from the cement cones, which remain attached in or on the  
754 host's skin (Kemp et al. 1982; Suppan et al. 2017).

### 755 54.3.5 Locomotion

756 Also the here listed animals use glue or mucus to bond temporary to the substratum  
757 as given for temporary bonding species (see Sect. 3.4). However, the glue is  
758 synthesized and released mostly through structures, specialized for locomotion,  
759 i.e., the podia of *Tethya*, the gastropod pedal sole, or the tube foot of sea stars and  
760 sea urchins. Best known are surely the gastropods, which produce a highly effective,  
761 hydrogel-like mucus, enabling the animals to cross any smooth, sharp (razor blades),  
762 and even extreme superhydrophobic, anti-adhesive surfaces as poly-  
763 tetrafluoroethylene (PTFE, commonly known as Teflon) (Shirtcliffe et al. 2012).  
764 The mucus acts as glue, allowing the animals to adhere and push themselves forward  
765 mechanically by means of wavelike movements of the sole (Miller 1974). In  
766 contrast, *Paracentrotus* and *Asterias* likewise use a duo-gland system as *Macro-*  
767 *stomum* (see Sect. 3.4), in which one gland produces the glue and another secretes  
768 enzymes to break the bonding and enable movement. In particular the viscous  
769 gastropod mucus and its bonding ability on any surface make this secretion inter-  
770 esting not only for new bioinspired wound sealants (Li et al. 2017) but also to  
771 design anti-adhesive surfaces for medical implants and superhydrophobic paints  
772 (see Sect. 4.1).

---

## 773 54.4 Bioinspired Applications

774 Despite the diversity and superiority of biological adhesives (biocompatible, biode-  
775 gradable, lack of heavy metals, or absence of volatile organic compounds), synthetic  
776 adhesives in particular (e.g., phenol/resorcinol/urea-formaldehyde) dominate today's  
777 adhesive market and are used as ingredients in many sealants, furniture products, and  
778 cosmetics.

779 Although many synthetic adhesives offer necessary features for specific applica-  
780 tions such as for wood manufacturing or in microelectronics, as well in dentistry, their  
781 performance is far from optimal and they can have unacceptable properties with  
782 respect to their suitability as an essential biomedical tool (harmful, toxic, not biode-  
783 gradable, low adhesive strength, microbial contamination). Technological advances  
784 in the area of superior bioinspired materials have been made with scientific progress  
785 in biological adhesion, e.g., the ability to produce key elements like L-DOPA  
786 recombinants. Such key components enabled the development of tissue adhesive  
787 like Cell-TakTM (USA), the first example (year 1986, TM-No. 73604754) of a  
788 marine-derived sealant, based on mussel adhesive proteins only; other biomimetic  
789 analogues are currently in the research focus. As a result of our increased understand-  
790 ing of the interrelationships between biological adhesives and underlying mecha-  
791 nisms or similar boundary conditions, it is increasingly possible to transform this into

biomimetic solutions. In contrast to the desired copies in the field of bonding according to biological models, these perfectly adapted organisms cause extensive economic loss due to their adhesive powers. For this reason, the progress made in the course of clarifying adhesive phenomena also serves not least to prevent fouling.

#### 54.4.1 Antifouling

Bacterial biofilms are prevalent and possess benefits and damage at once. They cause problems, e.g., by inducing biocorrosion and biofouling in drinking water supplies, and they are liable for impaired safety in surgery and wound healing. But they are also used for waste water treatments (van der Kooij and Van der Wielen 2014). In contrast to nonadherent bacteria, these microorganisms use biofilms as matrices for cooperation and to establish synergistic interactions like preventing the washaway of enzymes and nutrients or in order to survive in hostile environments. Biofilm formation allows them to withstand periods of starvation by quorum sensing. Consequently the vast majority of microorganisms exist in nature in the form of biofilms. They adhere mostly on wet solid surfaces. Within the process of biofilm formation, several steps are distinguished, whereby the first two are interesting in terms of bioadhesion: (1) adsorption to the substrate by cell adhesion (this initial step can last from a few minutes to one hour of exposure and is based on proteins) and (2) formation of extracellular polymeric substances (EPS) composed of polysaccharides to achieve irreversible attachment by polymer bridging (Vandevivere and Kirchman 1993). A well-known example for bacteria attached to teeth and aggregated in a self-made hydrated polymeric matrix is dental plaque.

Micro- and macrofouling (Fig. 3) are causes of considerable economic damage. A 5% increase in biofouling has been shown to increase ship fuel consumption by 17%, with a 14% increase in greenhouse gas CO<sub>2</sub>, NO<sub>x</sub>, and SO<sub>2</sub> emissions. Biofouling of marine energy turbines is regarded as the primary and most persistent source of failure among these devices. Control of biofouling for aquaculture and fishery operations can account for up to 15% of total annual operating costs. Beyond that is biofouling of sensors a significant barrier to technology advancement due to the impact on data quality (Chapman et al. 2014). Consequently, preventive measures are a challenge for material science. To avoid biofouling is *inter alia* the purpose for the findings on the principles of action of biological adhesives. Different approaches ranging from the use of “confusing surfaces” – to prevent (micro) organisms from adaption – like dendrimer-based coatings to antimicrobial concepts or surface modifications with baretin have proven their potential. Also surface topology mimicking the skin of a shark has been shown to be effective.

#### 54.4.2 Biomimetic Adhesives

Today plenty of commercial adhesive agents are biomimetic. The most prominent representative is the gecko tape. The production of such kinds of adhesives is

**Fig. 3** Macrofouling caused by tough adherent organism, e.g., mussels and barnacles on different surfaces under harsh conditions (salinity, marine current)

estimated to account for 25 billion m<sup>2</sup> (Schwotzer et al. 2012). But for medical issues the market is attractive as well, as the modern surgery is affected by two major factors: cost containment and an aging population (Spotnitz and Burks 2008). Stopping bleedings or sealing and reconnecting tissues after surgical procedures are challenging subjects. The bonding technology emerged as a convenient alternative for wound closure instead of sutures and other tissue applications (Annabi et al. 2015). Recently the slime of slugs (genus *Arion*) was successfully used as an adhesive and sealant for a porcine heart (Li et al. 2017). Many biomimetic tissue adhesives are based on secretions from marine organism, e.g., mussels and algae, but also from terrestrial organism like snails and frogs. Their performance in aquatic conditions is acceptable but requires polymeric additives to adjust the three-dimensional network.

These glues received much attention during the last few years and ended up in mimetics of natural structures like DOPA-containing co-polypeptides and DOPA-functionalized poloxamers or catechol-modified alginate hydrogels (Lee et al. 2013; Bochynska et al. 2016). Red and brown algae also use a mechanism based upon phenolic compounds. Under hydrated conditions their secretions are able to adhere to hydrophilic as well as hydrophobic surfaces. An enzyme (vanadate-peroxidase) induces the cross-link between the polyphenol and the extracellular carbohydrate fibers and causes adhesion to the surface. Hence carbohydrate-based adhesives are worth imitating. Thus, an alginate-polyphenol hybrid adhesive, mimicking *Fucus serratus*, showed higher adhesion to Teflon<sup>TM</sup> than to glass (Kumar Patel et al. 2013).

As promising candidate the Australian frog *Notaden* was also identified as it exhibited five times stronger adhesive strength than fibrin glue on sheep meniscus tissue (Graham et al. 2005).

Various types of medical adhesives are in use as hemostats to form a barrier and stop bleeding (protein and polysaccharide based) or as sealants in order to establish an impervious barrier to gas and many body liquids (fibrin sealant, polyethylene glycol, albumin, and glutaraldehyde) or as adhesives to connect tissue or medical devices (cyanoacrylates, albumin, glutaraldehyde, and fibrin sealant) (Spotnitz and Burks 2008; Ferguson et al. 2010). This classification refers to their function in surgical context. With respect to the former sections, a division could also be used to summarize the medical adhesives according to the compounds' origins:

- (i) Natural or biological adhesives (protein based, sprayable foams or dry fibrin sealants, collagen, gelatine; polysaccharide based, chitosan, alginates, dextran, chondroitin sulfate glue)
- (ii) Synthetic and semisynthetic adhesives (albumin and glutaraldehyde, cyanoacrylates, polyurethanes, polyvinyl alcohol, polyethylene glycols, dendrimers)
- (iii) Biomimetic adhesives (mussel, sandcastle worm, frog, slug)

The development of high-performance adhesives for use with living tissue as shown in Fig. 4 keeps the surgical toolbox expanding (Spotnitz and Burks 2008). More insight is given in ► Chap. 58, "Adhesion in Medicine."

**Fig. 4** Investigation and characterization of biological adhesives by MALDI-TOF MS, application of a biomimetic adhesive to soft tissue and testing the joints (Images from Ingo Grunwald, Fraunhofer Institute for Manufacturing Technology and Advanced Materials (IFAM), Bremen, Germany, and reproduced with his permission)

## 54.5 Challenges and Opportunities

Each of the reviewed bioadhesives has advantages and drawbacks. In terms of *bacterial adhesion*, approaches for a forensic usage are in discussion. Considering that everyone's microbiome is highly individual like DNA is, the microbial fingerprint is a valuable hint in criminal investigations. But depending on the kind of test and recognition of the microbiome, this approach can be risky: in case of sequencing the genetic material, the latter can be manipulated by malicious software encoded into the physical nucleic acid strand. The resulting data can corrupt gene-sequencing software and take control of the underlying computer-aided analysis (<https://www.wired.com/story/malware-dna-hack/>). Adhesion at this minor scale in crime context as well as with regard to antifouling efforts reveals its high potential. So does the use of some algae and their adhesion to surfaces triggered by certain wavelengths of the light. Based on such knowledge, adhesion could be prevented by manipulations involving intelligent materials, for instance, modified materials in bioreactors.

Referring to carbohydrates chitosan displays impressive potential as fully bio-based adhesive (5 MPa shear strength on pine wood) (Kumar Patel et al. 2013). Microbial polysaccharides blended with surfactants showed trendsetting results as well. However, as with sugars, there is an increasing tendency to abandon starch solutions in choosing binders for clay and pigments. Preferable would be combinations of synthetic latexes with casein or vegetable proteins instead of starch dispersions.

Coming to proteins, many investigations in terms of constructional applications have indicated potential: gluten as a substituent (25%) in phenol-formaldehyde resin masses for use in particleboard production (medium-density fiberboard, MDF) did not affect the mechanical performance. As gluten is a by-product from the glucose syrup production, the costs (about 300 euros/t referred to protein desiccant) are more than one sixth less than urea-formaldehyde resins (363 euros/t) (Türk 2014). Assuming that the cost of such binders contributes about 25% to the production costs, a substitution might be more economic, even if more process time is required. Native proteins are mostly insoluble due to their tertiary or quaternary structures. Processing like degradation or reduction can impart the solubility for its use in adhesive formulations. In general proteinaceous adhesives combine biodegradability more favorably and are much more water resistant compared with carbohydrate-based adhesives. Except for chitosan "bio-based" mostly have a positive impact to any life cycle assessment as a substitute to petrochemical compounds, and they show just a few or no emissions.

Complete substitution of synthetic components to compete with commercial adhesives still needs to be realized. Intermediate bio-based adhesives are therefore just a compromise.

The construction and building sector remains as one of the most significant markets for adhesives. Their uses of adhesives range from flooring to structural purposes or building envelopes.

The family of medical adhesives represents another relevant market. Although "classical" medical adhesives and those specific for medical as well as dental devices

are rather heterogeneous, they can be grouped into one family. The global market for medical adhesives and sealants is estimated to reach over 15 billion US dollars in the year 2022 ([http://www.strategyr.com/MarketResearch/Medical\\_Adhesives\\_and\\_Sealants\\_Market\\_Trends.asp](http://www.strategyr.com/MarketResearch/Medical_Adhesives_and_Sealants_Market_Trends.asp)). Driven by an aging population, increasing surgical operational interventions, the rise in healthcare needs, and new treatment methods like the preferences for minimal invasive methods or the use of new tissue scaffold applications, the CAGR (compound annual growth rate) in the area of medical adhesives will reach top values of about 10% until 2021, with even higher values expected for the Asia-Pacific area ([http://www.strategyr.com/MarketResearch/Medical\\_Adhesives\\_and\\_Sealants\\_Market\\_Trends.asp](http://www.strategyr.com/MarketResearch/Medical_Adhesives_and_Sealants_Market_Trends.asp)).

The consciousness of the benefits involved by using bioadhesives in multiple areas (e.g., health, environmental, ethical) is evolving. Bioadhesives are popular; six billion US dollars have been estimated for the global market in 2019. It is possible to increase the sustainability of industrial processes while maintaining or increasing the competitiveness of enterprises. As long as the legislatures are aware of the need to go ahead with the development of bioadhesives and the technologies of second-generation biofuels, the development of bioadhesives will lead to products that can cope with commercial adhesives. Last but not least, the requirements for reducing the emissions of volatile organic compounds (VOCs) and the requirement for recyclable materials push the development of bioadhesives (Mathias et al. 2016).

The classical medical adhesives are normally grouped into (depending on the classification system) hemostats which stop bleedings, sealants which seal leakages (gas and nonclotting liquids), or adhesives that “glue” two tissues together.

This segment of classical medical adhesives alone will have a market size of about three billion US dollars in 2021 (markets) – indicating a highly attractive field of application for medtech companies today and in the future. The market is dominated by the USA and Europe, but emerging markets like those of South America and Asia offer quite significant growth opportunities. The growth rate is observed and checked, for instance, by the process of regulatory affairs (the USA with the FDA, Europe with CE marking) for the certification of new medical adhesives. At least in the EU, the process of the approval of medical devices like adhesives will be tightened due to new regulations. Regardless of this situation, the medical adhesive market and the research associated with it are expected to have a bright future.

---

## 54.6 Conclusion

Biological and microbiological adhesives have an enormous potential for industrial applications. The most prominent ones are constructional, packaging, and medical applications. Sustainable packaging will prevail. There is, however, also a need for manipulating and adapting biological adhesion for healthcare or food safety issues. On account of their impressively efficient and precise way to adhere to industrially challenging substrates, these materials need to be studied and the conditions under which initial adhesion occurs want to be understood. Thus, any activity furthering

insights into the principles of these compounds is significant, reflecting, for instance, the current worth of the stem cell industry 3.5 million pounds in the UK alone (Waugh et al. 2016).

Developing biocompatible adhesives with strong adhesive properties for medical applications is highly desirable, but the delicate balance between adhesive performance and biocompatibility is crucial and part of the legal and technical requirements. Although “tissue adhesives are far from ideal” (Li et al. 2017), there are many promising approaches under investigation (Balcioglu et al. 2016; Li et al. 2017).

Nearly all of the reviewed adhesive classes are important subjects of research to develop alternatives for petroleum-based materials, and the quest exists to develop bioinspired solutions and to achieve tailored adhesives for specific tasks including the prevention of fouling. As carbohydrates and vegetable proteins can be obtained from waste streams of renewable resources and may be produced in great abundance, they do not have to compete with food production and can be considered as a sustainable option. Nature is a prime candidate for inspiration and provides raw materials for applications in adhesives. Bioadhesives can be converted into a variety of useful adhesive products with a promising future, even if natural variations in quality are weaknesses. The interdisciplinary approach with inputs from chemistry, physics, bionics, biology, and engineering offers a wide range of possibilities. Thus, outstanding adhesive performance in nature can be elucidated on a molecular level and translated into technical concepts. Mechanical discrepancies can be bridged with hybrid materials from biological concepts in combination with synthetic components. Looking just at the largest market for adhesives (construction), a fast-growing market (packaging), and the exclusive market (medical adhesives), the future prospects for bioadhesives are positive. This trend is clearly evidenced by the increase in relevant publications covering the field over the last few years (Babu et al. 2013).

## Abstract

Specific mechanisms of adhesion found in nature are discussed in the previous chapter (► Chap. 54, “Bioadhesives”). One of the most discussed biological systems in the last decade are the so-called fibrillar adhesives of insects, spiders, and geckos. These systems are adapted for dynamic adhesion of animals during locomotion and, therefore, have some extraordinary properties, such as (1) directionality, (2) preload by shear, (3) quick detachment by peeling, (4) low dependence on the substrate chemistry, (5) reduced ability to contamination and self-cleaning, and (6) the absence or strong reduction of self-adhesion. In the present chapter, we review functional principles of such biological systems in various animal groups with an emphasis on insects and discuss their biomimetic potential.

S. N. Gorb (✉) · L. Heepe

e-mail: [sgorb@zoologie.uni-kiel.de](mailto:sgorb@zoologie.uni-kiel.de); [lheepe@zoologie.uni-kiel.de](mailto:lheepe@zoologie.uni-kiel.de)

The data on ultrastructure and mechanics of materials of adhesive pads, movements during contact formation and breakage, the role of the fluid in the contact between the pad and substrate are presented here. The main goal is to demonstrate how a comparative experimental approach in studies of biological systems aids in the development of novel adhesive materials and systems. The microstructured adhesive systems, inspired by studies of biological systems of insects, spiders, and geckos, are also shortly reviewed.

## 55.1 Introduction

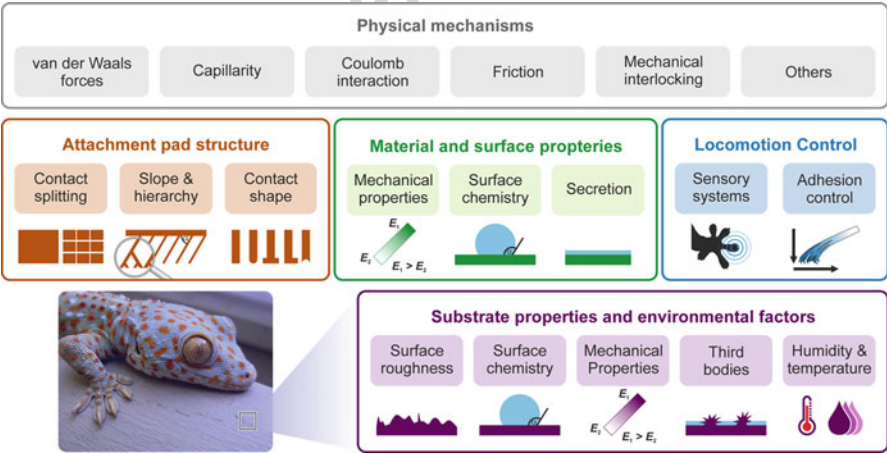

Representatives of several animal groups, such as insects, arachnids, tree frogs, and lizards, are able to attach to and walk on smooth vertical surfaces and even on the ceiling (reviews by Gorb 2001; Scherge and Gorb 2001; Autumn 2006; Wolff and Gorb 2016). This ability is due to highly specialized attachment devices located at different parts of their legs. Biomimetic transfer of such systems into industrial applications is a very challenging task, and several working groups of materials scientists worldwide are currently attempting to reach this goal by applying various approaches of microfabrication and surface science in general. However, biological systems are far too complex for copying them exactly. That is why intensive structural and experimental comparative studies are required to find out which structural and mechanical features of real biological systems are essential for biomimetics. In order to understand functional principles of animal attachment devices, it is not enough to have information about external morphology of the structures. An integrative approach is necessary to combine data on ultrastructure and mechanical properties of materials, arrangement of muscles, joint design, movements during contact formation and breakage (motor control), sensorics, forces and their directionality, contact mechanics at micro- and nanoscale, potential substrates (surface profile and surface energy), and the presence and properties of the fluid in the contact between the pad and the substrate (chemical composition, viscosity, transporting system).

Two important questions have to be answered in order to select the right biological prototype for particular technological requirements. The first question is which product has to be developed, and the second one is which biological system possesses the ability we are going to mimic. Normally, the first and most important requirement from the industry of adhesives is that the new material has to be as sticky as possible. If this is the only requirement, one has to select a prototype among animals and plants using glue-like systems for permanent or long-term adhesion to the substrate (for review, see Gorb 2009 and this book ► Chap. 54, “Bioadhesives”). However, if the requirement for the new material is its ability to allow multiple adhesive cycles, for example, in robotic applications for robot locomotion on smooth walls and the ceiling, with the ability (1) to build and break the contact as fast as possible, (2) to attach to unpredictable surfaces, (3) to have lifetime of millions of attachment-detachment cycles, and (4) to not attach to itself, then we definitely have to search for prototypes among locomotory attachment devices of animals.

To understand principles, at which biological systems operate, detailed studies on ultrastructure, material properties, force range, and motion pattern during locomotion are necessary. Such studies became possible during the last years, because of new developments (1) in microscopical visualization techniques (atomic force microscopy, freezing and environmental scanning electron microscopy), (2) in the characterization of mechanical properties of biological materials and structures in situ and in vivo (measurements of stiffness, hardness, adhesion, friction) at local and global scales, and (3) in computer simulations.

In general, there are two different working strategies that aid in extracting structural and mechanical features of biological objects for further development of bioinspired systems. The first strategy deals with a careful detailed characterization of one particular biological system defined as a model object (one of the most prominent examples for fibrillar adhesives is the gecko toe). The second strategy is focused on a comparative study of a large variety of biological objects, which possess similar functional systems that appeared independently in the course of biological evolution. In our opinion, the second approach is more promising for biomimetics, because structural similarities, which evolved independently in different lineages of organisms, may indicate some kind of “optimal” solution for this type of system. Moreover, a comparative approach aids in extracting essential features and abandoning less important ones for designing artificial prototypes. Although different, these two approaches are complementary and help in the course of the biomimetic process.

Figure 1 provides a summary and categorization of essential features that contribute to the so-called gecko effect. In this chapter, along with this categorization,

**Fig. 1** Summary and categorization of essential features that contribute to the so-called gecko effect: physical mechanisms, attachment pad structure, material and surface properties, and locomotion control. Various substrate properties and environmental factors may influence the adhesive performance of climbing animals (Adapted from Heepe and Gorb 2014. Photo copyright by Alex Mortillaro)

we report on our 15-year-long experience in studies of locomotory attachment devices in various animal groups with an emphasis on insects. The main goal is to demonstrate how a comparative experimental biological approach can aid in understanding biological attachment systems and derive design rules for the development of novel adhesive materials and systems.

## 55.2 Dynamic Adhesion for Locomotion

The adhesive contact between the leg and the substrate is mostly important for a rather short period of time of the stance phase and must be released during the swing phase (Fig. 2). These phases repeat infinitely in step cycles during locomotion. Therefore, adhesive structures of animal legs must fulfill several tasks, sometimes opposite to each other and reversibly executed in repeated step cycles (Gladun et al. 2009). (1) The sticky surface of the leg must be ready to immediately build adhesive contact with the substrate. The contact formation must be fast and established with minimal load on the ceiling. (2) Adhesion of few legs must be strong enough to hold the animal on the inclined and even on the overhanging substrate (reliability). (3) At the same time, adhesion must be low enough to allow smooth and quick detachment of the swinging leg. In other words, adhesion must be reversible. (4) The adhesive surface of the pad must be sticky enough to generate sufficient adhesive force to the substrate, but it should be secured from adhering to itself, to prevent disability of the adhesive surface for the next step cycle.

**Fig. 2** Ceiling situation. If the mass  $m$  of the animal is in the center of gravity, then its weight is  $W = m g$ , the angle of the ground reaction is  $\alpha$ , the normal pull-off force component is  $F_n$ , and the shear force component is  $F_s$ . Thus, the weight of the animal walking on the ceiling should be counterbalanced by two forces: friction ( $F_f$ ), which prevents leg sliding along the substrate, and adhesion ( $F_a$ ), which prevents leg separation from the substrate. In order to walk on the ceiling, it is not sufficient just to generate strong adhesive bond between the leg and substrate. Two additional problems have to be solved: (1) contact formation must be fast, reliable, and performed with the minimal load on the ceiling and (2) contact must be released in the fast manner and with the minimum of the applied load (From Gladun et al. 2009)

### 55.3 Pad Structure

To date, both the morphological and ultrastructural bases of the ability of animals to dynamically adhere to vertical surfaces have been studied in detail only in representatives of selected taxa, including insects (reviews by Gorb 2001, 2005; Federle 2006), arachnids (Homann 1957; Kesel et al. 2003; Niederegger and Gorb 2006; Wolff and Gorb 2016), tree frogs (Barnes 2006; Smith et al. 2006), and lizards (Hiller 1968; Autumn 2000, 2002; Huber, 1995a, b). In their evolution, animals have developed two distinctly different mechanisms to attach themselves to a variety of substrates: smooth pads and fibrillar (hairy, setose) pads. Due to the flexibility of the material of the attachment pads or fine surface outgrowths, both mechanisms can maximize the possible contact area with a wide range of substrate profiles (Gorb and Beutel 2001; Gorb 2005).

Interestingly, in different lineages, both types of attachment pads can be found. For example, within insects, such groups as orthopterans, hymenopterans, and thysanopterans bear smooth pads, whereas dipterans, coleopterans, and dermapterans possess mainly fibrillar pads. Within arachnids, representatives of Solifugae have smooth pads, whereas Araneae are characterized by fibrillar ones. Among reptiles, Gekkonidae and Anolinae have fibrillar pads, and some skinks have smooth ones. Additionally, these highly specialized structures are not restricted to one particular area of the leg. For example, in insects, they may be located on claws, derivatives of the pretarsus, tarsal apex, tarsomeres, or tibia. Recent phylogenetic analyses of hexapods based on the pad characters, processed together with characters of other organ systems, aided in resolving the question of the attachment pad evolution in hexapods and showed that these structures have evolved several times, independently (Gorb and Beutel 2001; Beutel and Gorb 2001, 2006).

Fibrillar systems always contain cuticle protuberances on their surfaces (Fig. 3). Protuberances on the fibrillar pads of Coleoptera, Dermaptera, and Diptera belong to different types. Representatives of the first two lineages have socketed setae originating each from two different cells. Setae range in their length from a few micrometers to several millimeters. Dipteran outgrowths are acanthae: single sclerotized protuberances originating from a single cell (Richards and Richards 1979). Structural features of adhesive outgrowths have been previously reported, for example, for flies, the acanthae are hollow inside (Bauchhenss 1979), and some of them contain pores under the terminal plate (Gorb 1998). These pores, presumably, deliver an adhesive secretion directly in the contact area. Pore canals at the base of the shaft may additionally transport secretions to the surface. In beetles, the setal bases are embedded in rubberlike material, which provides flexibility to the supporting material and helps the seta to adapt to various surface profiles.

Gecko setae are multibranching, hierarchical structures of 80–100  $\mu\text{m}$  in length (Ruibal and Ernst 1965; Stork 1983; Schleich and Kastle 1986; Roll 1995; Huber et al. 2005a; Rizzo et al. 2006). In anole lizards, setae are smaller and unbranched (ca. 20  $\mu\text{m}$  long) (Ruibal and Ernst 1965; Stork 1983; Rizzo et al. 2006). The gecko setae are not hollow inside. They are formed by proteinaceous fibrils held together by a matrix and surrounded by a proteinaceous sheath. Ordered protein constituent in these structures exhibits a diffraction pattern characteristic of  $\beta$ -keratin. Raman microscopy

**Fig. 3** Wet fibrillar adhesive system of the fly (a–c) and dry fibrillar adhesive system of gecko (d–g). (b, c, e, g) Scanning electron microscopy images of adhesive setae. Both systems are similar according to the contact mechanics but differ in relative contribution of different physical forces to the overall adhesion. Insect mainly employ wetting phenomena, whereas gecko system is dominated by intermolecular van der Waals forces

of individual setae, however, shows the presence of additional protein constituents, some of which may be identified as  $\alpha$ -keratins (Rizzo et al. 2006). In anoles, setae emerge from the oberhautchen layer of the epidermal shedding complex into the cells of the clear layer, which act as templates for their growth (Alibardi 1997). The clear layer cells template the formation of spatular terminal elements. This means that setae are fully formed prior to shedding of the external epidermis during the shedding cycle.

### 55.4 Nature of Attractive Forces

There are two different adhesive mechanisms in fibrillar systems: a wet one, primarily based on capillarity, and a dry one, primarily based on intermolecular van der Waals interactions. Wet adhesive systems (insects) generate a thin fluid layer in the contact between single hairs and substrate, whereas dry ones (spiders, geckos)

do not. Pad fluids have been previously reported from fibrillar pads of reduviid bugs (Edwards and Tarkanian 1970), flies (Bauchhenss 1979; Walker et al. 1985), coccinellid (Ishii 1987; Kosaki and Yamaoka 1996), and chrysomelid (Eisner and Aneshansley 2000) beetles. The pad secretion contains nonvolatile, lipid-like substances that can be observed in footprints stained with Sudan Black. Microscopy data combined with gas chromatography and mass spectrometry showed that secretion of smooth pads of ants and locusts is an emulsion containing water-soluble and lipid-soluble fractions (Federle et al. 2002; Vötsch et al. 2002). For fibrillar pads, two chemically different secretion compositions were reported. Tarsal secretions of beetles were mainly lipid based (Geiselhardt et al. 2009, 2010; Betz 2010) with a small water fraction, whereas in flies it is assumed to be a mainly water-based microemulsion (Gorb 2001) with low lipid content. Footprints of secretion in flies, visualized by cryo-SEM, indicate as well an emulsion-like composition (Fig. 4). Detailed fluid evaporation measurements in beetles *Coccinella septempunctata* and flies *Calliphora vicina* by atomic force microscopy supported these observations (Langer et al. 2004; Peisker and Gorb 2012). In flies, a larger volatile fraction was observed, if compared to beetles (Peisker and Gorb 2012). This result is also reflected in the corresponding viscosities of tarsal secretions in flies and beetles. For flies (*C. vicina*) a viscosity of approximately 11 mPa·s was measured by microrheological technique, whereas for beetles (*C. septempunctata*) it was two times higher, and a viscosity of approximately 22 mPa·s was found (Fig. 5) (Peisker et al. 2014). Both secretions showed a Newtonian behavior.

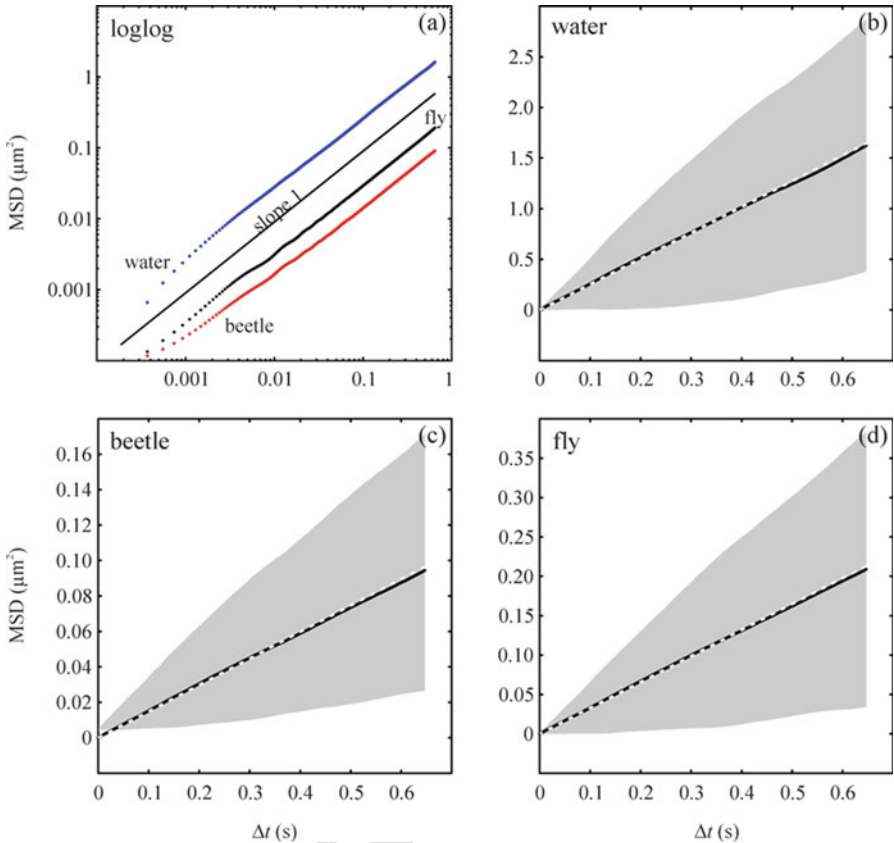

In wet fibrillar systems, numerous experiments showed that the main contribution of attractive forces to the overall adhesion is due to capillarity. When hairy pads of the bug *Rhodnius prolixus* were treated with organic solvents, attachment was impaired (Edwards and Tarkanian 1970). Experiments with freely walking beetles strongly suggested that cohesive forces, surface tension, and molecular adhesion, mediated by the pad secretion, may be involved in the mechanism of attachment (Stork 1980a). Multiple local force-volume measurements, carried out on individual terminal plates of the setae of the fly *C. vicina* by application of atomic force microscopy (Langer et al. 2004), showed that adhesion strongly decreases as the volume of the secretion decreases, indicating that a layer of pad secretion covering the terminal plates is crucial for the generation of strong attractive force. These data provide direct evidence that, beside van der Waals forces, also attractive capillary forces, mediated by the pad secretion, contribute to the fly's attachment mechanism (Langer et al. 2004). Similarly, for beetles, traction force experiments on nanoporous plant (Gorb and Gorb 2002) and nanoporous artificial surfaces (Gorb et al. 2010), capable of adsorbing tarsal secretions, showed strong minimization of attachment ability.

In the hairy attachment system of gekkonid lizards, van der Waals interactions are responsible for the generation of attractive forces (Hiller 1968; Autumn et al. 2000, 2002). Experiments, in which the force-displacement curves were determined for individual spatulae by atomic force microscopy, showed that these smallest elements of the gecko's attachment devices generate forces of about 10 nN. An estimate of adhesion energy ( $\gamma$ ) from Kendall's classical peeling theory (Kendall 1975), which describes the force required to peel a tape of certain width (200 nm for

**Fig. 4** Fluid in wet fibrillar systems. (a, b) Tenent setae of the syrphid fly *Episyrphus balteatus* bearing lumen (LU) filled with the fluid and pores (black arrows) under platelike terminal contact elements (PL). (c) Pattern of microdroplets left by the fly *Calliphora vicina* on the glass surface, as viewed in phase contrast light microscope. (d, e) Same droplets frozen and further replicated with carbon-platinum coating technique and visualized in transmission electron microscope (black arrow indicates direction of coating). gecko spatula) from a rigid substrate in perpendicular direction, gives  $\gamma = 50 \text{ mJ}\cdot\text{m}^{-2}$  (Huber et al. 2005a). This value corresponds well to the range expected for adhesion by intermolecular forces ( $10\text{--}100 \text{ mJ}\cdot\text{m}^{-2}$ ; Israelachvili 1992). Using this value of adhesion energy, we may estimate the order of the theoretical force a gecko can produce, assuming all spatulae readily make intimate contact with the substrate and peel off simultaneously. Assuming an effective total peeling line, which is the sum of widths of all spatulae, of 1.8 km for the tokay gecko (Varenberg et al. 2010) and a peeling angle of  $30^\circ$ , shown to be the critical angle of detachment for gecko setae (Autumn et al. 2000), we obtain a maximum force of order 700 N or correspondingly a maximum supported weight of order 70 kg. This large value indicates that only small portions of spatulae are needed in contact with the substrate at each single step. While these estimates show that van der Waals forces can account for the measured adhesion, we cannot unambiguously exclude contributions from capillary forces (Huber et al. 2005b).

**Fig. 5** Plots of the mean square displacement (MSD) over the lag time for different fluids (Adapted from Peisker et al. 2014). **(a)** Dependence of the MSD on lag time (see *black line* with slope 1) for water (*blue dots*), the fly fluid (*black dots*), and the beetle fluid (*red dots*). The linear relationship in the log-log scale indicates purely viscous (Newtonian) properties of all fluids studied. For the fly and the beetle, all measurements were averaged. Representative MSDs for **(b)** water, **(c)** beetle fluid, and **(d)** fly fluid. *Black solid lines* are the MSD data points; the *gray-shaded area* is the standard deviation in each MSD data point; the *white-dashed lines* are linear fits to the data

### 55.5 Multiple Contacts

Based on the studies of different animal groups, an interesting correlation between the setal density and animal weight was found: the heavier the animal, the smaller and more densely packed are the terminal contact elements (Scherge and Gorb 2001) (Fig. 6). Using contact mechanics theories, this scaling effect was explained by applying the principle of contact splitting to the Johnson–Kendall–Roberts (JKR) contact theory (Johnson et al. 1971), according to which splitting up the contact into finer subcontacts increases adhesion on any substrate profile (Arzt et al. 2003). This

**Fig. 6** Dependence of the contact density of terminal contacts on the body mass in fibrillar pad systems in representatives from diverse animal groups: 1, 2, 4, 5, flies; 3, beetle; 6, bug; 7, spider; 8, gekkonid lizards (Adapted from Scherge and Gorb 2001). The systems, located above *solid horizontal line*, preferably rely on van der Waals forces (*dry adhesion*), whereas other ones mostly rely on capillary and viscose forces (*wet adhesion*)

relationship holds because animals cannot increase the area of the attachment devices proportionally to the body weight due to the different scaling rules for mass and surface area. Therefore, the increase of the attachment strength in hairy systems is realized by increasing the number of single contact points, i.e., by increasing the hair density. It has been shown later that this trend is different within each single lineage of organisms (Peattie and Full 2007). However, a closer look at the terminal contact elements in biological hairy adhesive systems involved in locomotion revealed that they are predominately spatula shaped (Gorb and Varenberg 2007) and cardinally differ from flat-punch- or hemisphere-ended structures (Fig. 7). Therefore, the application of the contact splitting principle to Kendall's peeling model (Kendall 1975) also provides a proper explanation of multiple contact geometry with spatula-like terminal elements. It demonstrates that an animal's attachment ability grows with an overall length of the peeling line, which is the sum of widths of all thin-film elements participating in contact (Fig. 8). This robust principle is found to manifest itself across eight orders of magnitude in an overall peeling line ranging from 64 μm for a little red spider mite to 1.8 km for a tokay gecko, generalizing the critical role of spatulate terminal elements in biological fibrillar adhesion (Varenberg et al. 2010).

Furthermore, other advantages of such hairy adhesive systems have been proposed. For example, in a smooth, continuous adhesive contact, once a crack is initiated at the adhesive interface, the crack may easily propagate over the entire contact area until complete detachment occurs. By contrast, in a fibrillar system, the crack leads initially to the detachment of one seta, and the elastically stored energy in

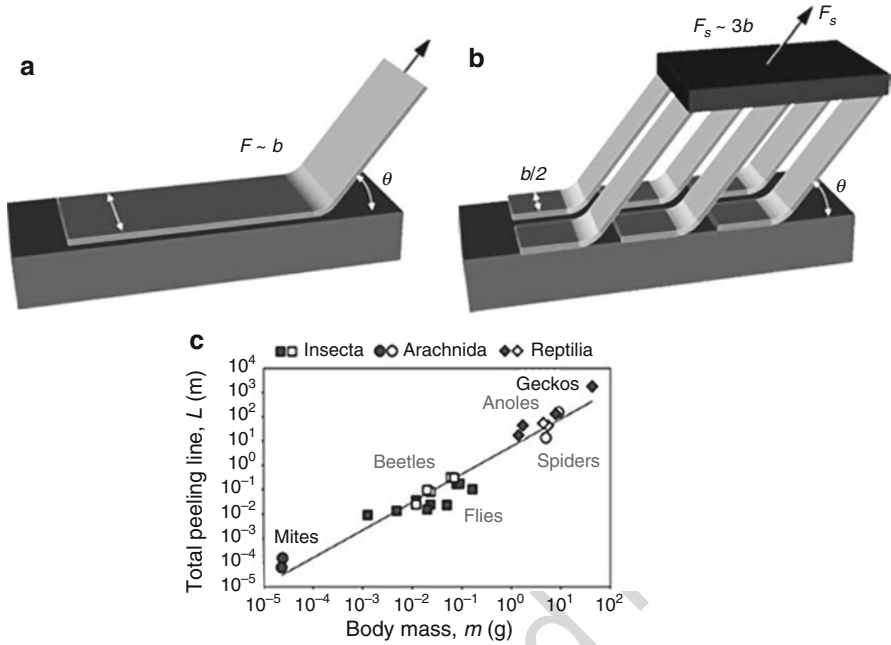

**Fig. 7** Cryo-SEM images of spatula-shaped thin-film terminal elements while in contact with smooth glass, in hairy attachment pads found in animals of evolutionary remote lineages. **(a)** Beetle (*Gastrophysa viridula*). **(b)** Fly (*Calliphora vicina*). **(c)** Spider (*Cupiennius salei*). **(d)** Tokay gecko (*Gekko gecko*). Arrows point in distal direction (From Varenberg et al. 2010)

the seta is released and can no longer contribute to the propagation of the crack (Jagota and Bennison 2002; Hui et al. 2004; Chung and Chaudhury 2005; Tang and Hui 2005). This principle is known as crack trapping. Thus, the crack has to be reinitiated at each individual subcontact. In addition, fibrillar systems adapt better to uneven and rough surfaces (Persson 2003; Persson and Gorb 2003; Kim and Bhushan 2007; Filippov et al. 2011). Because each seta is virtually independent of other neighboring setae, a seta can contact the asperities and valleys of a rough surface without being mechanically influenced by neighboring setae (Fig. 9a). In contrast, in a smooth system, the region around the contact with a surface asperity can be prevented from forming contact (Fig. 9b). Moreover, the effective stiffness of a fibrillar adhesive system is strongly reduced compared with the stiffness of the bulk material of setae. Therefore, the fibrillar system is more compliant to rough surfaces (Persson 2003). Since these effects are based on fundamental physical principles and mostly related to the geometry of the structure, they must also hold for artificial surfaces with similar geometry.

## 55.6 Contact Shape

Real biological adhesive contacts display a variety of shapes and only rarely resemble a hemisphere (Fig. 10). The influence of various contact shapes on the pull-off force for single contacts, as well as their scaling potential in contact arrays, was previously theoretically estimated (Spolenak et al. 2005) and experimentally

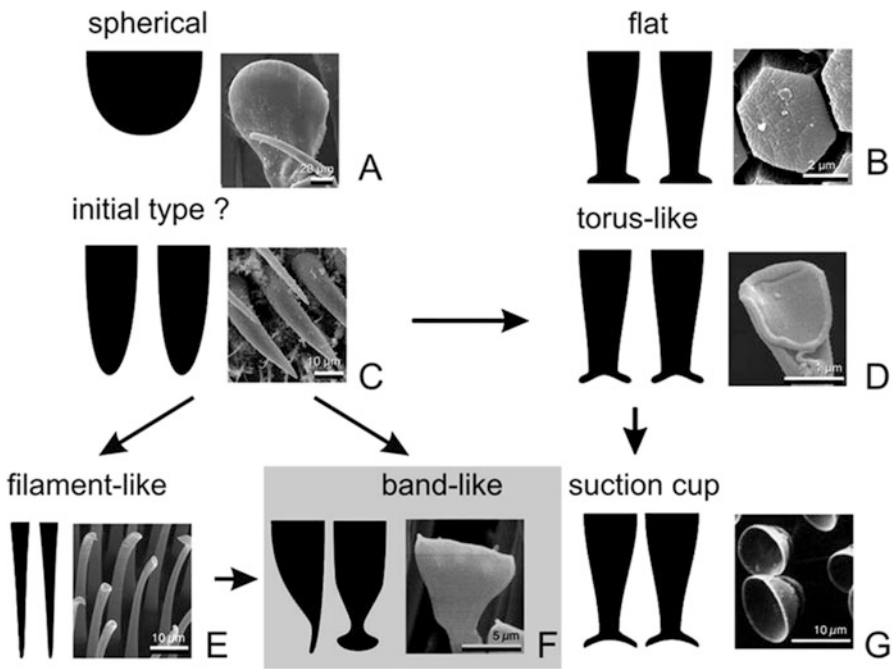

**Fig. 8** Graphical representation of the effect of adhesion enhancement by increasing the peeling line length. **(a)** A single piece of elastic film peeling from a rigid substrate. Peeling force  $F$  is proportional to the film width  $b$  (at constant peel angle  $\theta$  for given pair of materials). **(b)** A series of elastic films covering the same contact area as in **(a)**. Peeling force  $F_s$  is threefold the value  $F$  in **(a)** due to an overall growth of the peeling line length calculated as a sum of individual film widths. **(c)** Total peeling line (the sum of widths of all terminal elements) in fibrillar attachment systems of different animals as a function of their body mass (From Varenberg et al. 2010)

**Fig. 9** **(a)** Fibrillar and **(b)** smooth adhesive systems making contact with a rigid substrate with an asperity. Whereas in a fibrillar system, individual fibers can deform and follow surface irregularities without affecting neighboring setae **(a)**, in smooth elastic pads, regions around the asperity can be prevented from forming contact (arrows; **b**) (From Heepe and Gorb 2014)

demonstrated for artificial fibrillar adhesive systems (del Campo et al. 2007). It was concluded that non-spherical shapes, such as toroid, should lead to better attachment. In insects, spiders, and geckos, as shown in Fig. 7, the topmost hierarchical level of a seta that is responsible for the formation of intimate contact with the substrate

**Fig. 10** Shapes of attachment devices in nature and their hypothetical evolutionary pathways (shown as arrows). (a) Bug *Pyrhocoris apterus*, smooth pulvillus. (b) Grasshopper *Tettigonia viridissima*, surface of the attachment pad. (c) Fly *Myathropa florea*, unspecialized hairs on the leg. (d) Fly *Calliphora vicina*, seta of the pulvilli. (e) Ladybird beetle *Harmonia axyridis*, seta of the second tarsal segment. (f) Beetle *Chrysolina fastuosa*, seta of the second tarsal segment. (g) Male diving beetle *Dytiscus marginalis*, suction cups on the vertical side of the foreleg tarsi (Adapted from Spolenak et al. 2005). Band-like (tape-like, spatula-like) terminal contact elements (highlighted in gray) are most often observed in biological fibrillar adhesive systems capable of ceiling locomotion

resembles thin film-like or spatulae (Stork 1980b; Gorb 1998, 2000; Persson and Gorb 2003; Spolenak et al. 2005). Additionally, spatulae bear a gradient of thickness from the base to the tip of the spatula (fly, Gorb 1998; gecko, Persson and Gorb 2003; beetle, Eimüller et al. 2008) and a gradient in width as they become wider toward its free end. This geometrical property of setal tips can be observed in many animal species (Figs. 3 and 7). In contact, spatulae are aligned and orientated to the distal direction of the pad.

Several hypotheses have been previously proposed to explain the functional importance of such a contact geometry: (1) enhancement of adaptability to the rough substrate (Persson and Gorb 2003), (2) contact formation by shear force rather than by normal load (Autumn et al. 2000), (3) increase of total peeling line due to using an array of multiple spatulae (Varenberg et al. 2010), and (4) contact breakage by peeling off (Gao et al. 2005).

**Fig. 11** The role of the spatula-like terminal contact elements at the tips of adhesive setae in the adaptation to the surface profile (a–c) and in the increasing of the total peeling line. (a) Contact of the spatula of the beetle *Gastrophysa viridula* with the microrough surface. (b–c) Thick elastic material requires additional load to form adhesive contact (b), whereas adhesion interaction pulls the elastic thin film (even made of stiff material) into complete contact with the rough substrate surface (Adapted from Persson and Gorb 2003)

It appeared that the role of highly flexible terminal spatula elements as compliant contacting surfaces is critical (Persson and Gorb 2003). Since the effective elastic modulus of thin plates is very small, even for relatively stiff materials such as keratin or arthropod cuticle, this geometry is of fundamental importance for adhesion on rough substrates (Persson and Gorb 2003), due to the low deformation energy stored in the material during intimate contact formation (Fig. 11).

For adhesion activation, it is well known that the application of a normal load can enhance adhesion (Popov 2010). However, for hairy attachment systems, the adhesion force always remains smaller than the initially applied normal force. This would potentially be not enough to enable walking on the ceiling. Another possibility to activate or enhance adhesion forces is the application of a shear force. We have previously shown that an applied shear force to a particular direction of the spider's spatulated setae results in an increase of real contact area (Niederegger and Gorb 2006; Filippov et al. 2011). Also, flies employ shear movements during contact formation by their attachment devices (Niederegger and Gorb 2003). Previous authors revealed strong shear dependence of measured pull-off force in the gecko attachment system and even called this effect by the somewhat misleading term *frictional adhesion* (Autumn et al. 2000, 2006), which can be simply explained by Kendall's peeling model (Kendall 1975), when the tape is loaded/peeled off at very shallow angles to the substrate. In contrast, by peeling the tape off at very high angles, a very strong reduction in the adhesive force is obtained, which allows for a simple, quick, and energy-efficient detachment mechanism.

## 55.7 Slope and Hierarchy

The observed pull-off force of an adhesive structure may be defined by the difference between attractive forces arising due to, e.g., van der Waals or capillary interaction and the contact reaction forces, arising due to elastic deformation of the adhesive structure during contact deformation (Varenberg et al. 2011). In order to increase the pull-off force, either the attractive interactions have to increase, or the contact reaction forces have to decrease. The attractive forces, e.g., due to van der Waals interactions, reach a natural upper limit as soon as the adhesive structure and the contacting substrate form an intimate contact. In order to form intimate contact, especially to rough surfaces, adhesive structures have to be as soft as possible to enhance real contact area. This in turn, however, would increase the elastic deformations and thus the contact reaction force which would lead to a lower pull-off force. In light of the above, it is clear that there must be a trade-off for the adhesive structure between being soft enough, in order to form an intimate contact, and being stiff enough, to allow for the generation of a sufficiently high pull-off force. Solutions for this problem are either (a) in a hierarchical fibrillar design of the adhesive pad (Fig. 3d–f), (b) in a gradient material in nonhierarchical fibrillar structures (Fig. 12), or (c) in the tilted orientation of hairs relatively to the substrate (Fig. 13). In case of the gecko (see above), the complex hierarchical architecture of the adhesive pad made of relatively stiff  $\beta$ -keratin allows for a relatively low effective modulus (Persson 2003) while simultaneously avoiding setal condensation.

In geckos, there is a higher number of structural levels made of relatively stiff  $\beta$ -keratin (see above): lamella (the first lowermost level), seta (the second one), branching pattern of setulae (third and sometimes fourth level(s)), and spatulae (the uppermost one). Since many natural surfaces (stones, soil, tree bark, plants) have fractal roughness with several overlapping wavelengths, it is not enough to have adhesive pads optimized for one a particular wavelength of roughness. In order to optimize adhesion on a wide range of natural surfaces, biological fibrillar adhesives employed several hierarchical levels, each responsible for contact formation optimization for a particular range of wavelengths. In general, biological adhesive systems represent a kind of mirror structure of the natural fractal world.

Recently, numerous models were developed, in order to explain the role of the hierarchy in the functioning of biological adhesive pads (e.g., Kim and Bhushan 2007; Schargott 2009). While the hierarchical beam model with vertical beams shows the possibility of reducing the effective elastic modulus, the tilted beams are the key to obtaining very soft systems, even when the material employed has a high elastic modulus. In the model combining hierarchy and tilting, elastic and adhesive properties are furthermore enhanced (Schargott 2009). It is shown that when interacting with a rough stochastic surface, the attachment properties are improved with each additional hierarchical layer (Kim and Bhushan 2007; Schargott 2009).

Animals with fewer hierarchical levels have evolved different strategies for the same purpose. In the seven-spotted ladybird beetle (*Coccinella septempunctata*), a material gradient of tanned chitin at the setal base and the rubberlike resilin at the

**Fig. 12** Morphology and material composition of adhesive tarsal setae. Ventral part of the second adhesive pad of a foreleg of a female *Coccinella septempunctata*, lateral view. (a) Scanning electron micrograph. (b) CLSM maximum intensity projection showing an overlay of the four different autofluorescences indicating the material composition. The *arrows* indicate the dorsoventral material gradient in exemplary setae. *S* exemplary spatula-like seta, *P* exemplary seta with a pointed tip. Scale bars, 25  $\mu$ m (From Peisker et al. 2013)

setal tip were recently found (Fig. 12; Peisker et al. 2013). Such a gradient in material properties similarly allows for an efficient adaptation to rough surfaces, due to the soft setal tip, while, at the same time, providing sufficient mechanical stability, due to stiffer base, to prevent clusterization and low contact reaction forces.

Tilted geometry of hairs is responsible for the bending mode of their deformation in contact rather than for the buckling one. It is clear that hairs are much stiffer in buckling than in bending. That is why tilted hair arrays have a much lower structural modulus of elasticity than a non-tilted one, and the adaptability to the surface profile of the tilted array is much higher. In addition, bending as a failure mode leads to lesser material fatigue than the buckling mode.

Additionally, asymmetrical shape of a single contact element in combination with the proper movements may provide the way to switchable adhesives, when contacts formed by fibers are activated and when the structure is sheared in the direction of the slope. The contact can be broken by peeling at high angles, when fibers are sheared in an opposite direction.

**Fig. 13** Slope angle of adhesive setae in the tokay gecko *Gekko gekko* (a, b) (SEM) and in the fly *Calliphora vicina* (c) (semithin section, light microscopy). Arrows indicate distal direction of the pad (From Gorb 2011)

### 55.8 Adhesion Control

Animal locomotion involves simultaneous peeling of many spatulae, at the level of adhesive pads (Fig. 7), at the level of contralateral legs (Fig. 14a, b), and sometimes also at the level of contralateral toe pads within one foot (Fig. 14c). Thus, in climbing animals, the situation is more complex than in Kendall's classical peeling model and resembles a hierarchical multiple peeling configuration (Pugno and Gorb 2009; Pugno 2011; Heepe et al. 2017a). On the macroscale, however, the peeling configuration of climbing animals may be reduced, for simplicity, to the peeling of two elastic tapes loaded at a common hinge (Fig. 14d). This double-peeling configuration has interesting adhesive properties, if compared to the classical single peeling. It exhibits a self-stabilized optimum peeling angle with a maximum in peeling force, i.e., the optimum configuration is reached irrespective of the initial peeling angle configuration of the system. Below the optimum angle, there is no delamination (peeling) but pure elastic deformation of the system. Above the optimum angle, stable delamination is observed. Figure 15 shows experimental results of the double-peeling configuration using an elastic adhesive tape (Heepe et al. 2017a).

When an animal is adhering to the ceiling, its legs tarsomeres are oriented toward the center of the body mass (Fig. 16a). In this orientation, setae are recruited by bending to their tilted direction, and spatulae are set under shear load. Under these conditions, setae are activated to their adhesive state. If five of the six insect legs are ablated, the animal is not able to adhere to the ceiling anymore, even if the average adhesive force of the single leg (measured for all six legs acting in concert and then normalized by the number of legs) should be sufficient to resist the body weight on the ceiling. However, with two intact legs, an animal can perfectly stay on the ceiling

**Fig. 14** (a) A beetle *Gastrophysa viridula* in contact with a glass ceiling (lateral view from behind). The arrow indicates weight force  $W$  acting at the center of mass. (b) Fly *Calliphora vicina* in contact with a glass ceiling (view from above through the glass ceiling). Arrows indicate contralateral leg movement. (c) Foot of a gecko *Gekko gecko* in contact with a glass ceiling (view from above through the glass ceiling). Arrows indicate contralateral toe pad movement. (d) Simplified mechanical model of the ceiling situation (lateral view from behind, similar to (a)). Two elastic tapes are in contact with a rigid ceiling and having a common hinge, where a load  $F$  is applied. The tapes make angles with respect to the substrate of  $\alpha_1$  and  $\alpha_2$  (From Heepe et al. 2017)

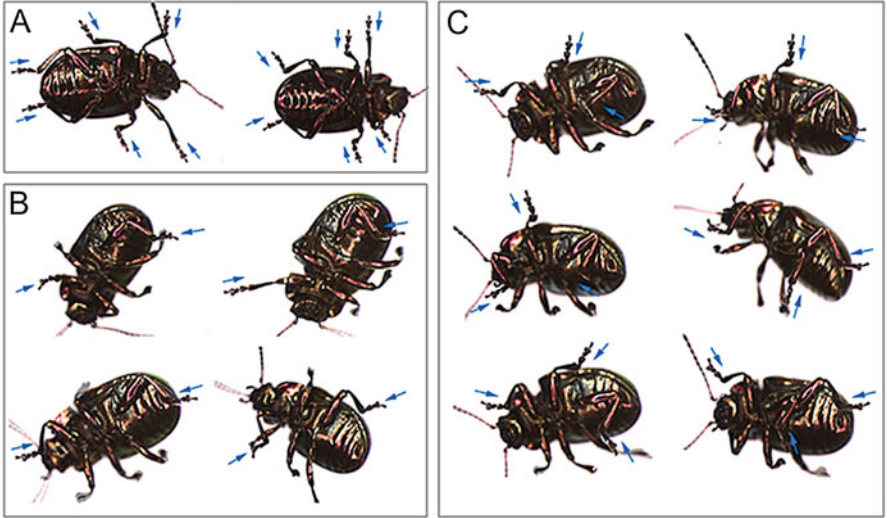

(Fig. 16b). With three remaining intact legs on one body side, an animal can reorient one leg to the other body side and stay on the ceiling (Fig. 16c). In the latter two cases, the adhesive system can be activated by shear force.

In light of the above results, the explanation of this phenomenon is rather simple. The situation of the single leg in contact can be simulated by a piece of sticky tape adhering to the ceiling and holding a certain mass. The peeling angle in such geometry would tend to be  $90^\circ$ , which according to Kendall's model (Kendall 1975) generates a rather low peeling force. When two or multiple tapes are combined, the peeling angle will be generally lower than  $90^\circ$ , due to the self-stabilization effect of such geometry.

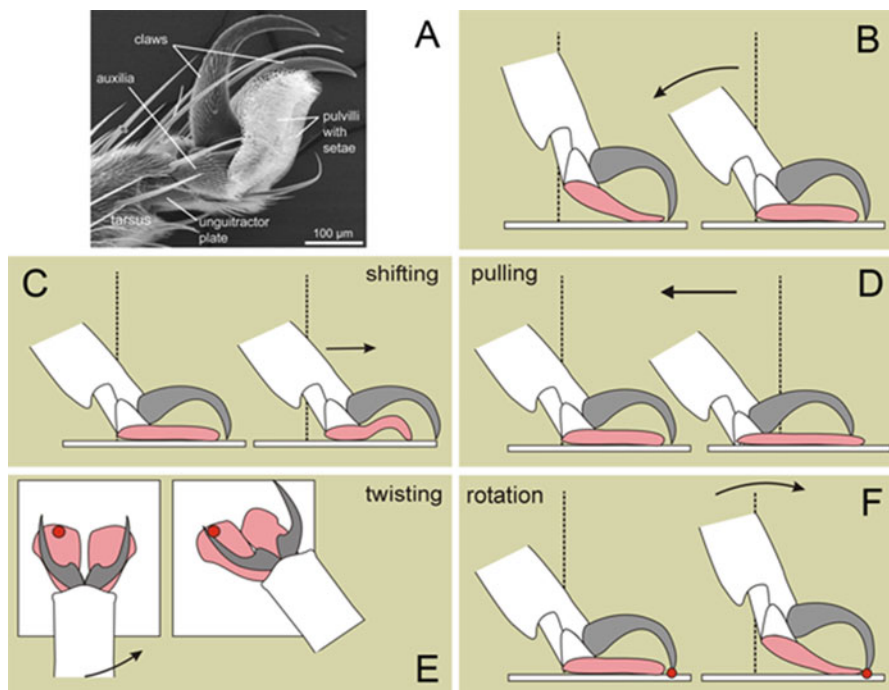

High-speed video recordings of a fly foot attaching to the substrate show that the pulvilli are pressed down to the surface and also pulled towards the body. Through this movement, the claws become spread apart (Fig. 17a, b). During such an action, setae and their spatulae will be activated, and the maximal force will be reached. In order to detach, four different movements may occur (Fig. 17c–f) (Niederegger et al. 2001;

**Fig. 15** (a) Schematic of the experimental setup. Principal double-peeling configuration: the tape (dark gray) is in contact with glass substrates (light gray) and loaded with a force  $F$  at the hinge in the middle of the tape. The tape makes initial peeling angles with the substrate of  $\alpha_0$ . (b) Experimental results (open circles) of the double-peeling configuration using elastic adhesive tape. Experiments were started at initial peeling angles  $0^\circ$  and  $90^\circ$  as indicated by the arrows (Adapted from Heepe et al. 2017a)

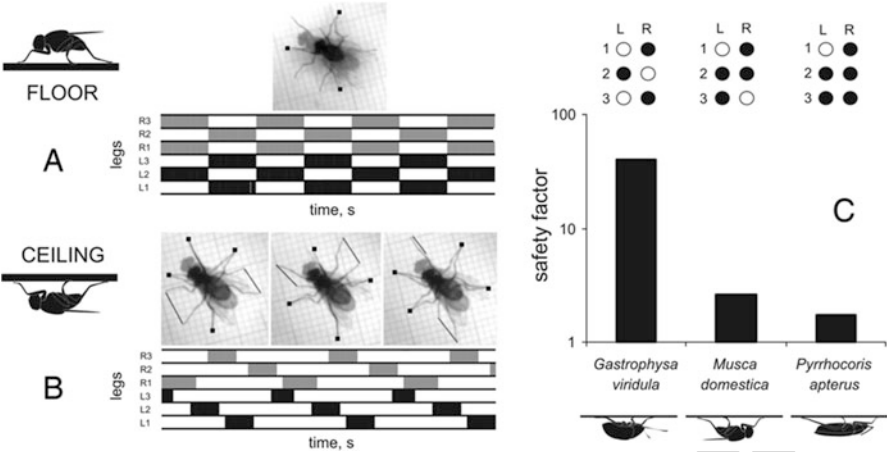

**Fig. 16** (a–c) Posture of the chrysomelid beetle *Chrysolina fastuosa* on the ceiling. (a) Intact beetles. (b) Two-legged beetles (four legs are removed). Arrows indicate orientation of leg tarsomeres. (c) Three-legged beetles (three legs on one body side are removed). Please note rearrangement of leg positions, in order to generate shear toward center of the body mass (arrows) (From Gorb 2011)

**Fig. 17** Attachment and detachment movements of the fly adhesive organs (diagrams are based on the high-speed video recordings under binocular microscope). (a) Side view of attachment organs (pulvilli) in the fly *Calliphora vicina* (SEM). (b) Movement at attachment. (c–f) Movements at detachment by using shifting (c), pulling (d), twisting (e), and rotation (f) (From Niederegger et al. 2001; Niederegger and Gorb 2003)

Niederegger and Gorb 2003). (1) In *shifting* (or *local peeling*), the foot is shortly moved forward. This compresses the pulvilli, which in turn leads to a smaller contact area and thus to a reduction of attachment forces. Additionally, peeling occurred at the level of the spatulae. (2) In *twisting*, the leg is turned by up to 90° and pulled backward. This bends the setae and eventually detaches them from the surface. (3) In *rotation* (or *global peeling*), the foot is lifted from its back to the front, which causes the claws to be passively pressed to the surface. With this force, the adhesion is interrupted by peeling at the level of the whole pad. (4) In *pulling*, the foot is simply pulled backward until the attachment devices detach from the surface. This type of detachment possibly requires quite strong force, but it happens in some behavioral situations, especially when the insect is stressed. In geckos, attachment is activated by proximodistal rolling out of the toe, whereas detachment is provided by distoproximal peeling of it (Gao et al. 2005).

Observations of the gait pattern in flies walking on a horizontal surface revealed that three opposing legs were in the swing phase (moving), whereas the other three legs remained in the stance phase (motionless) (Fig. 18a). Does the gait pattern of the fly change on the wall and ceiling? Using high-speed camera video recordings of

**Fig. 18** Gait patterns of insects on glass ceiling. (a, b) Gait diagram of the house fly, *Musca domestica*, on the floor (a) and ceiling (b) (From Niederegger et al. 2001; Gorb 2001, 2005). (c) Relationship between the safety factor (attachment force divided by the body weight) and the gait pattern on the ceiling in different insects. *Insets* show feet (black dots) that are typically in contact during the walk on smooth ceiling (From Gorb 2011)

flies walking on a vertical surface, it was shown that their gait pattern is not different from the pattern on a horizontal surface. However, the fly walking on the ceiling moved only two legs at once and four remained in the stance phase (Niederegger et al. 2001; Gorb 2001, 2005) (Fig. 18b). This result led us to assume that the gait pattern may contribute to the fly’s ability to adhere dynamically on the ceiling, in providing an optimal relationship between the body weight and the supporting contact area.

Experiments with insect species that have different safety factors (attachment force divided by the body weight) show that insects with a safety factor above 10 can employ tripod gait similar to one observed during locomotion on the floor. Insects with a safety factor in the range of 4–5 change their gait compared to that reported above for the fly. Insects with a safety factor lower than 3 change their gait to that, where only one leg is in the swing phase and the other five remain in the stance phase (Fig. 18c). These results show that dynamical adhesion in insects may also strongly rely on a multiple peeling configuration, especially in ceiling locomotion.

Thus, it is plausible to assume that biological adhesive systems try to actively use changes in their configuration of their tape-like contact geometry, to control and/or maintain adhesion. To securely stay on the ceiling, animals tend to keep their macroscopic peeling angle below the optimum. In this regime, no peeling occurs. Interestingly, in flies clinging to a glass ceiling, it was observed that their feet were in constant slow motion toward the body center of mass (Wigglesworth 1987), potentially due to the tarsal secretions produced in insect adhesive systems (Gorb 2001). After a certain sliding motion of the feet, they were quickly extended and reattached, thereby maintaining a position with a low macroscopic peeling angle. Quick and

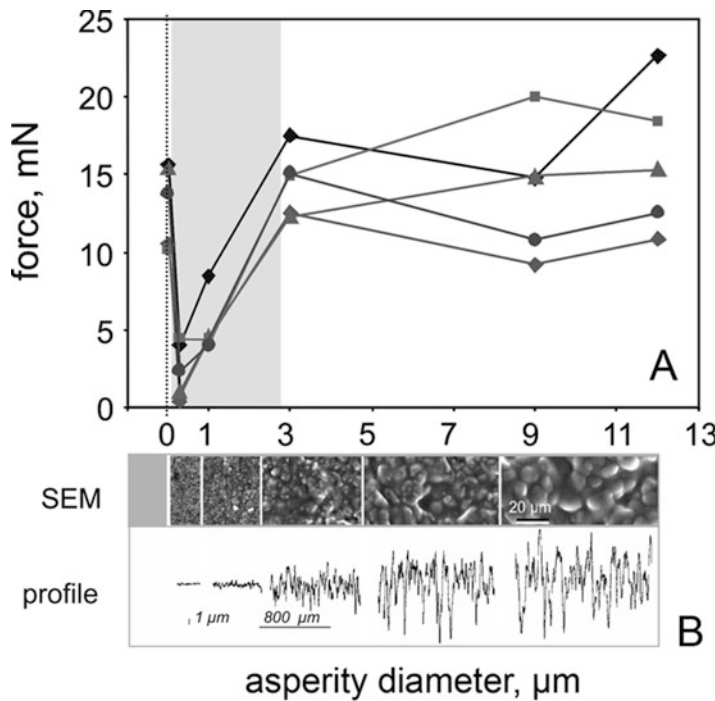

easy detachment may be achieved by a simple active change of the macroscopic peeling angle above the optimum one by, e.g., proximodistal peeling in the case of flies (Niederegger et al. 2002) and distoproximal peeling or digital hyperextension in the case of geckos (Russel 1975). This may be possible, since their available contact area is restricted to the pad area and, thus, only a short peeling distance is necessary before complete detachment of a pad or a foot occurs.

## 55.9 Environmental Conditions Affecting Animal Adhesion

All natural surfaces have surface roughness on many different length scales (Persson 2014) which may strongly reduce attachment of animals (e.g., Gorb 2001; Gorb and Gorb 2002; Peressadko and Gorb 2004b; Huber et al. 2007; Voigt et al. 2008; Wolff and Gorb 2012). The influence of surface roughness on insect attachment has been proven experimentally in several studies (Gorb 2001; Peressadko and Gorb 2004b; Voigt et al. 2008; Bullock and Federle 2011). There seems to be a common trend that insects generate much higher forces on either smooth or rough surfaces with an asperity size exceeding  $3.0\text{ }\mu\text{m}$  than on those with the roughness ranging from  $0.3$  to  $3.0\text{ }\mu\text{m}$  (Fig. 19). This effect has been explained by the specific geometry of spatula-like terminal elements of insect tenent setae that are able to generate sufficient contact, if the surface irregularities are sufficiently large. Worst attachment has been observed on substrates with a roughness of  $0.3$  and  $1.0\text{ }\mu\text{m}$  (Fig. 19). In this case, the spatula-like terminal elements cannot follow the surface profiles with these small asperities, and thus, the area of real contact between these substrates and the tips of insect setae is very small. Since adhesion force depends on the area of real contact, insects were not able to attach successfully to surfaces with such a microroughness.

Interesting examples of natural anti-adhesive surfaces are well known from many plants, which are covered with microscopic wax crystals of different shapes, chemistry, and mechanical properties. To explain the anti-adhesive properties of these plant substrates, four hypotheses were previously proposed (Gorb and Gorb 2002). (i) Wax crystals cause microroughness, which considerably decreases the real contact area between the substrate and setal tips of adhesive pads (*roughness hypothesis*); see above. (ii) Wax crystals are easily detachable structures that contaminate pads (*contamination hypothesis*). (iii) Structured wax coverage may absorb the fluid from the setal surface (*fluid absorption hypothesis*). (iv) Insect pad secretion may dissolve wax crystals (*wax-dissolving hypothesis*). This would result in the appearance of a thick layer of fluid, making the substrate slippery. Recently, only the first three hypotheses were tested.

Contamination of insect pads by plant wax crystals has been demonstrated for several insects and in a series of plant species (e.g., Gaume et al. 2004; Gorb and Gorb 2006). It has been found that plants differ essentially in their contaminating effects on insect pads (Gorb and Gorb 2006). The degree of contamination depends on the micromorphology of waxes (Borodich et al. 2010). The analysis of the relationship between the contamination ability and geometrical parameters of wax

**Fig. 19** Role of the substrate roughness (asperity diameter) in the attachment of biological fibrillar adhesives. (a) Attachment forces of chrysomelid beetles *Gastrophysa viridula* measured on the horizontal surface of the drum of the centrifugal force tester on substrates with different roughness. (b) Surface of the substrate in SEM and measured with the profilometer (From Peressadko and Gorb 2004b)

crystals has shown that the contamination is related to both the largest dimension and the aspect ratio of crystals (Borodich et al. 2010).

The fluid absorption hypothesis was recently tested in an experimental study, where nanoporous substrates with the same pore diameter but different porosity (area of voids in a material surface, normalized over the total area) were used (Gorb et al. 2010). According to this hypothesis, absorption of the insect pad fluid by the porous substrate results in a reduction in the fluid thickness between the terminal plates of the insect pads and the substrate, and this leads to a reduction of capillary interaction in the contact area. Traction force experiments performed on tethered ladybird beetles walking on different porous substrates showed that forces were significantly reduced. The reduction in insect attachment on nanoporous surfaces may be explained by possible absorption of the secretion fluid from insect adhesive pads by porous media and/or the effect of surface roughness. The wax-dissolving hypothesis has not been experimentally tested yet.

A rather long-standing question in animal attachment is which substrate property is most important for the attachment ability: surface roughness or surface chemistry? Since the surface chemistry (here in terms of surface energy) affects the strength of

either van der Waals or capillary interaction, substrates with low surface energy are expected to reduce the overall attachment ability. In a recent experiment, traction forces of ladybird beetles *Coccinella septempunctata* were systematically measured on eight types of substrates, each with different chemical and topographical properties (England et al. 2016). The results clearly showed that surface roughness rather than surface chemistry essentially affected insect adhesion. Surface chemistry had no significant effect on the attachment ability of the beetles (England et al. 2016).

So far, however, the attachment ability of insects and also that of spiders and geckos has been tested on rigid substrates only, whereas the natural habitats of climbing animals may provide a variety of substrate stiffness ranging from rigid rock surfaces to soft, biofilm-covered substrates. Friction force measurements, using a centrifugal force tester, with male and female beetles *Coccinella septempunctata* on smooth silicone elastomer substrates with different stiffness between 2 and 0.3 MPa revealed an overall decrease in attachment ability if compared to a rigid substrate (Heepe et al. 2017b). Within the range of measured stiffness, female's attachment ability was not affected, whereas male's decreased with decreasing stiffness. This sexual dimorphism in attachment ability is explained by the presence of a specialized, discoidal seta type in males, which is not present in females (Heepe et al. 2017b). Substrate properties are not the only environmental factors shown to influence animal adhesion. Also the ambient humidity affects the attachment ability, as it was shown in the dry adhesive pads of geckos (Huber et al. 2005a; Niewiarowski et al. 2008; Puthoff et al. 2010; Prowse et al. 2011) and spiders (Wolff and Gorb 2011) as well as in the wet adhesive pads of beetles (Heepe et al. 2016). In all animals, reduced attachment ability was observed for very low and very high relative humidities, whereas maximum attachment ability was found for intermediate humidities (Heepe et al. 2016). This is particularly interesting since both types of adhesive systems (wet and dry) are supposed to be based on different physical interactions (capillarity versus van der Waals forces).

---

## 55.10 Biomimetic Implications

As mentioned above, fibrillar adhesive systems appeared several times in animal evolution and at least three times independently even in insect evolution. This fact may indicate that design principles of biological fibrillar adhesives must have an advantage for adhesion enhancement not only in biological systems but also in artificial surfaces having similar geometry. Geometrical effects discussed above, such as multiple individual contacts, high aspect ratio of single contact structures, peeling spatula-like tips of single contact elements, are responsible not only for generation of a strong pull-off force in such devices but also for other interesting features, such as adhesion reversibility, contamination reduction, etc. (Fig. 20). The physical background of these effects were intensively discussed theoretically in several publications (for early original work, see, e.g., Jagota and Bennison 2002; Arzt et al. 2003; Persson 2003; Persson and Gorb 2003; Chung and Chaudhury 2005; Gao et al. 2005; and for current reviews, Federle 2006; Autumn 2007;

**Fig. 20** Some functional principles (*FEATURE*) at which biological reversible and biological adhesive systems operate. In the middle of the diagram, the functions (*FUNCTION*) and their relationship to the features are depicted. The resulting effect that is required for optimization is shown at the right-hand side (*arrows* indicate enhancement/reduction of the function). Simultaneous implementation of all these features in one artificial system is desirable but hardly possible. However, one principle or a combination of few of them can be implemented depending on particular requirements for material or system (From Gorb et al. 2007b)

Kampermann et al. 2010; Gorb 2011; Jagota and Hui 2011). For fibrillar biological systems, the following key functional properties can be defined (Autumn et al. 2007; Creton and Gorb 2007).

1. *Anisotropic attachment*: Attachment force variable depending on the setal-spatula orientation with respect to the substrate, normal load, and parallel drag.
2. *High adhesion coefficient*: Ratio of preload to pull-off force, which represents the strength of adhesion as a function of the compressive load.
3. *Low detachment force*: Animals detach their feet in a few milliseconds by different kinds of movement, which lead to peeling of adhesive structures at different levels.
4. *Universality of adhesion*: Van der Waals-based interaction and oil-based capillary interaction with the substrate depend basically on geometry of features (fibrillar shape, spatulae, fluid thickness, etc.) and are less dependent on the substrate chemistry.

5. *Self-cleaning*: The feet of geckos are resistant to the contamination by particles corresponding in size to typical environmental dirt particles (diameter 5–100  $\mu\text{m}$ ). In insects, secreted fluid may additionally contribute to rinsing of dirt particles. Biological fibrillar adhesive systems possess an anti-contaminating property.
6. *Anti-self-adhesion*: Hierarchical fibrillar structure avoids the self-adhesion of individual structural elements.
7. *Nonsticky default state*: Most of the fibrillar structures with an exception of mushroom-shaped setae are nonsticky by default, because only a very small contact fraction is possible without deforming the setal array.

Based on the inspiration from biology and using contact theory as a guideline, artificial surfaces were developed with enhanced pull-off forces in contact with the flat surface, if compared to the flat control. These materials have been produced using various micro- and nanofabrication techniques ranging from laser technology and carbon nanotube packaging to various lithography techniques (for early original work, see, e.g., Geim et al. 2003; Sitti and Fearing 2003; Peressadko and Gorb 2004a; Northen and Turner 2005; Yurdumakan et al. 2005; and for current reviews, e.g., Greiner et al. 2009; Sameoto and Menon 2010; Kwak et al. 2011) (Fig. 21). Independently on the pull-off forces achieved by the surface patterning, these materials are strongly limited in the patterned area. Usually, the overall patterned area was in the best case restricted to few square centimeters, which makes their use for industrial applications rather difficult. Also most bioinspired fibrillar adhesives are just based on the fibers with flat punches at their tips or in most elaborate cases sloped punches (Autumn et al. 2007), without implementation of proper terminal elements in the form of spatula or mushroom, as we know them from the majority of biological systems including insects, spiders, and geckos. So far, the best results of mimicking fibrillar adhesive systems have been achieved with mushroomlike surface microstructures (for early original work, see, e.g., Daltorio et al. 2005; Kim and Sitti 2006; Gorb et al. 2007a; Davies et al. 2009; for a current review, see Heepe and Gorb 2014). Some of these developments may be produced in large-scale industrial processes in the form of square meters large foils (Gottlieb Binder and Co 2017) (Fig. 22). Interestingly, such microstructures can be found in attachment pads of male beetles from the family Chrysomelidae. Although both sexes possess adhesive hairs on their tarsi, only males bear hairs with such extreme specialization for adhesion on the smooth surface and most likely to attach to female's covering wings during pairing (Stork 1980b; Voigt et al. 2008). It has been previously reported that males of the Colorado potato beetle *Leptinotarsa decemlineata* generate such a strong adhesion on the smooth clean glass that they are not able to break off the contact and that is why they have a hard time walking on this surface (Pelletier and Smilowitz 1987). The hairs responsible for this effect have broad flattened tips and narrowed flexible region below the tips. These features, as well as distribution patterns of pillars, were implemented in the design of the patterned polymer structure described here.

The adhesive properties of the industrial micropatterned adhesive foil were characterized using a variety of measurement techniques and compared with those

**Fig. 21** Bioinspired fibrillar adhesives of different dimensions. (a, b) Metallic nanowhiskers. (c, d) Hierarchically branching fiber arrays made of epoxy resin. (e, f) Silicone molds of laser-patterned metal surface. (g, h) Carbon nanotubes. (a–d, g, h) Original micrographs ((a–d, g, h) From Gorb 2010. (e, f) From Peressadko and Gorb 2004a)

of the flat foil made of the same polymer (Daltorio et al. 2005; Gorb et al. 2007a; Varenberg and Gorb 2008a, b, c; Heepe et al. 2011, 2012, 2013, 2014a, b, 2017a; Kovalev et al. 2012; Kizilkan et al. 2013, 2017; Kasem and Varenberg 2013; Denning et al. 2014; Breckwoldt et al. 2015). The foil with the microstructure pattern demonstrates considerably higher pull-off force per unit real contact area and per

**Fig. 22** Patterned insect-inspired polivinylsiloxane surface. (a) Single structures are distributed on the surface according to the hexagonal pattern, in order to reach the highest packaging degree of single pillars (above aspect, SEM image). (b) White light interferometer image of a single pillar head demonstrates almost flat shape of the contacting surface. (c) Side aspect of the pillar array. (d–f) Behavior of structured PVS surfaces in contact with the glass surface (SEM images). Black arrowhead shows a dust particle in contact (From Gorb et al. 2007b)

unit apparent contact area as well. It is also less sensitive to contamination by dust particles, and after being contaminated and washed with soap and water, the adhesive properties can be completely recovered. The foil represents an industrial dry adhesive based on the combination of several principles previously found in biological attachment devices of insects, spiders, and geckos.

This material is a promising candidate for the application in dynamical adhesive systems, such as robot soles adapted for locomotion. Robots that could climb smooth and complex inclined terrains, like insects and lizards, would have many

applications such as exploration, inspection, or cleaning. Walking machines usually use suckers to hold onto vertical surfaces and under a surface. A primary disadvantage of this attachment principle is large energy consumption for vacuum maintenance. The novel biologically inspired materials may enable future robots to walk on smooth surfaces regardless of the direction of gravity. Mini-Whegs™, a small robot (120 g) that uses four-wheel legs for locomotion, was recently converted to a wall-walking robot with compliant, adhesive feet (Daltorio et al. 2005). The robot is capable of ascending vertical smooth glass surfaces using a micropatterned adhesive (Fig. 23a). A new version of this robot (about 22 g) is even able to transverse from the floor to the ceiling without detaching from the substrate (Fig. 23b). Another demonstration of adhesion capability of such material is shown in Fig. 23c, d. A PMMA plate, 20 × 20 cm, covered by the foil is sufficient to support the weight of a man attached to the glass ceiling (Fig. 23c). Using custom-built gloves for hands and feet, the material, in principle, allows climbing a vertical glass wall (Fig. 23d).

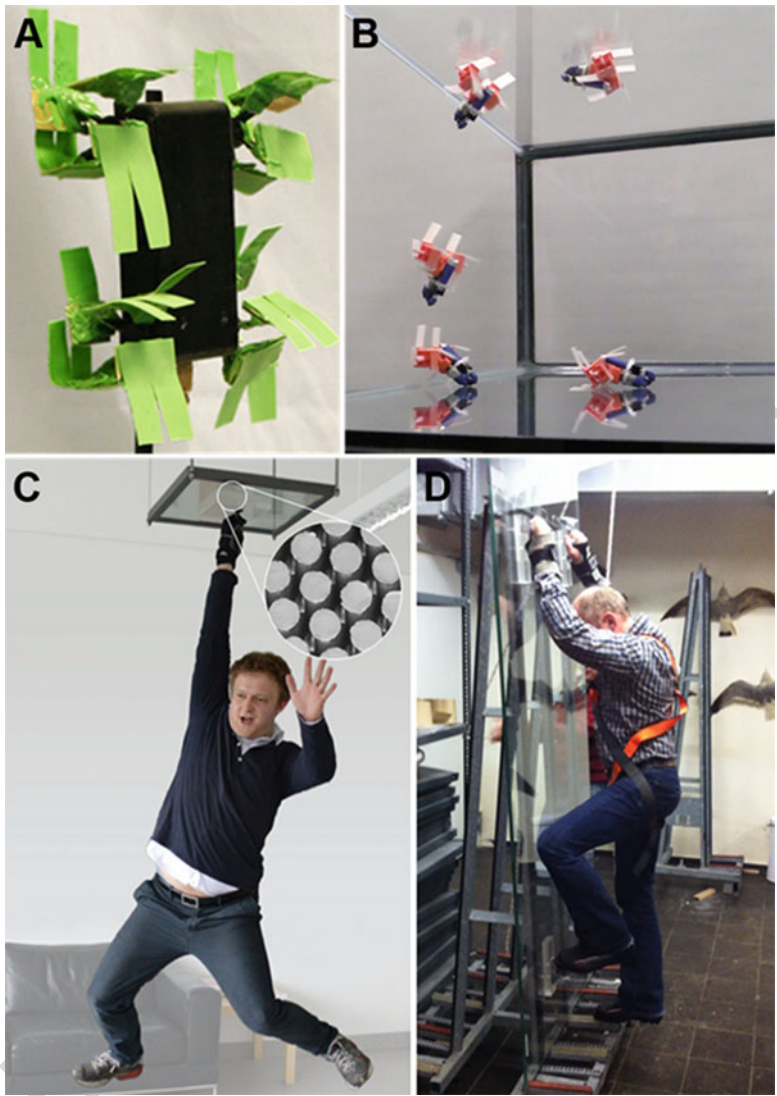

Bioinspired fibrillar materials can be additionally applied to the design of micro-gripper mechanisms with the ability to reversibly adhere and to adapt to a variety of surface profiles and for any kind of reversible adhesive tapes.

---

## 55.11 Conclusions

1. Real biological attachment systems usually rely on the combination of different functional principles based on elaborate micro- and nanostructures.
2. Attachment systems in biology can be subdivided according to their structure and basic physical forces responsible for enhancement of contact forces.
3. Reversible attachment devices used for locomotion may be hairy and smooth. Hairy systems consist of fine microstructures, whereas smooth systems are composed of materials with unusual inner structure. Due to the flexibility of the material of the attachment pads or fine surface structures, both mechanisms can maximize the possible contact area with a wide range of substrate profiles.
4. Recent phylogenetic analyses have shown that similar functional solutions for attachment have evolved several times independently in the evolutionary history of animals (e.g., geckos, anoles, spiders, beetles, flies, etc.).
5. In hairy systems, the density of single contact elements usually increases with increasing body weight of the animal group. From the scaling analysis, it has been previously suggested that animal lineages relying on dry adhesion (lizards, spiders) possess a much higher density of terminal contact elements compared to systems using the wet adhesive mechanism (insects).
6. Lizards' and spiders' attachment systems are mainly based on van der Waals forces, but also wetting phenomena caused by water absorbed on the surface have an effect on the attachment ability. In insects, mainly attractive capillary and viscous forces mediated by the pad secretion are the basic physical mechanism in their adhesion.

**Fig. 23** (a) Mini-Whegs™ on vertical glass with a microstructured adhesive tape (From Daltorio et al. 2005). (b) Inverted Mini-Whegs demonstrating internal transitions from floor to wall to ceiling (From Breckwoldt et al. 2015). (c) Photograph of a man attached to the glass ceiling by a 20 × 20 cm PMMA plate covered by microstructured adhesive tape (see SEM image in the *inset*) (original). (d) Photograph of a man attached to a vertical glass wall by custom-built gloves for hands and feet covered with the microstructured adhesive tape (original)

7. The effective elastic modulus of the fiber arrays is very small, which is of fundamental importance for proper contact formation and adhesion on smooth and rough substrates.

8. Hierarchical organization of surface features in attachment pads may enhance adaptability to real surfaces, which often have fractal roughness.
9. Asymmetrical shape of single contact element (tilted position relative to the support) in combination with proper movements may provide a way to switchable adhesives.
10. Hairy pads show a clearly cut minimum of adhesion at certain ranges of substrate roughness. Such a critical range of roughness depends on the relationship between the diameter of single contact elements of the pad and the length scale of the roughness.
11. During their evolution, plants have developed structures to prevent adhesion of insects. To explain anti-adhesive properties of plants, structured with crystalline waxes, four hypotheses were proposed: (1) roughness hypothesis, (2) contamination hypothesis, (3) wax-dissolving hypothesis, and (4) fluid absorption hypothesis.
12. Since many functional effects found in biological systems are based on fundamental physical principles which are mostly related to the geometry of the structure, they must hold also for artificial surfaces with similar geometry.

## Abstract

The increased commercial availability and the reduced prices of nanoparticles are leading to their incorporation in polymers and structural adhesives. This chapter outlines the principal types of nanoparticles, and the methods that may be used to disperse the particles in a polymer matrix. It discusses how nanoparticles can alter the mechanical properties (e.g., stiffness), electrical properties (e.g., conductivity), functional properties (e.g., permeability, glass transition temperature), and fracture performance of thermoset polymers. The effect of nanoparticles on joint performance is also discussed.

## 56.1 Introduction

### 56.1.1 Nanotechnology

It can be argued that nanotechnology is not new, as the use of nanoparticles to alter the properties of materials is not a recent development. For example, the late Roman (fourth century AD) Lycurgus cup is on display in London at the British Museum. This cup is made of cut glass, and looks green in reflected light, but appears red when light is shone through it. This effect is due to the light being scattered by the colloidal dispersion of gold and silver nanoparticles, which are about 70 nm in diameter, in the glass. Another example is carbon black, as used currently in millions of car tires and printer cartridges per year, which is composed of particles of size 20 nm and above. However, this material was first produced 3,500 years ago in China as lamp black.

Nanotechnology has become a hot topic in science and engineering in recent years. One of the definitive points in the history of nanotechnology came in a lecture by Richard Feynman, in 1959, entitled “There Is Plenty of Room at the Bottom” (Feynman 1959). In this lecture, Feynman highlighted the potential of working at a micro- or nanoscale, and discussed the problem of manipulating and controlling things on a small scale. He issued a challenge to scientists (and engineers) to work at very small scales, and this challenge is now being taken up.

So what is nanotechnology? Nanotechnology could be defined as the combination of existing technologies with the ability to observe and manipulate at the nanometer ( $10^{-9}$  m) scale (Hay and Shaw 2001; Harper 2003). The question is then, why is there so much interest in nanotechnology now? It is linked to (a) the expanding ability to synthesize nanometer-scale materials, and (b) the availability of the tools that enable the imaging of structures at this scale. Thus, it is now possible to characterize how nanoparticles are dispersed and start to understand why the observed effects occur, something that was not possible for the Romans. As the limits of the nanoscale, say at scales of less than 20 nm, are approached then different effects, such as quantum effects, become more significant.

A major concern with the use of nanoparticles is their potential toxicity. Care must be taken not to repeat the health problems caused by exposure to asbestos. Stories of potential catastrophe such as Michael Crichton’s book “Prey” and Prince Charles’ “grey goo” speech have not helped the perception of nanoparticles and nanotechnology

(Radford 2003). Hence, manufacturers are approaching this new technology cautiously. Studies are underway to assess the health effects and some results have been published (e.g., Lam et al. 2004; Warheit et al. 2004; Brown et al. 2007), but as yet there is no real agreement on the real dangers to health due to inhaling nanoparticles. It must be borne in mind that the nanoparticles in cured adhesives are not free in the atmosphere, but are bound into a matrix. Recent studies indicate that even during fracture of a nanoparticle-modified epoxy material, only a few nanoparticles are released into the atmosphere. In contrast, nanoparticles are produced in large quantities by the combustion of fossil fuels, and millions of tonnes of nano- and submicron-particles are already in use by various industries including in paints and toiletries.

### 56.1.2 Nanoparticle Reinforcement

Five basic characteristics of particulate fillers were defined by Rotheron and Hancock (1995). These remain true whether the particles are micro- or nanoparticles:

1. What properties are being sought?
2. What deleterious changes may also occur and can they be tolerated?
3. How easy is the filler to handle and how might it affect processing?
4. Are any special additives needed?
5. What is the true cost of using the filler, is it justifiable and are there more cost-effective alternatives?

Rotheron and Hancock (1995) observed that it is widely assumed that fillers are cheap and that polymers are expensive. Conversely, for nanoparticles it is widely assumed that nanoparticles are expensive and that polymers are cheap. This is not necessarily the case. As the nanoparticle manufacturing industry expands, nanoparticles are increasingly available in large (i.e., tonne) quantities. The prices of expensive nanoparticles such as carbon nanotubes are also being reduced. The price of nanoparticles varies greatly with the type, as well as with the purity of the material. For example, silica nanoparticles supplied dispersed as a masterbatch in epoxy cost about \$20/kg (Nanoresins 2008), and core-shell rubber nanoparticles similarly dispersed cost approximately \$12/kg (Kaneka 2008). Nanoclays can cost as little as \$7/kg (SigmaAldrich 2008). However, a kilogram of carbon nanotubes cost between \$400 and \$98,000 in Autumn 2009 (CheapTubes 2009).

Nanoparticles are, by definition, very small. It must be noted that the interparticle distance for nanoparticle-modified polymers is also very small, especially at high volume fractions. These factors may affect the interaction between a particle and its neighbors, or between a particle and the polymer surrounding it, or may affect the structure of the polymer itself. Hence, the properties of a particle-modified polymer may vary depending whether nanoparticles or microparticles are used.

The addition of nanoparticles can be simply a marketing tool, as the performance benefit that they provide could often be obtained using conventional fillers at a much lower cost. However, some very successful applications that rely on the small size

of nanoparticles have been shown, for example, the addition of ceramic nanoparticles to transparent coatings gives improved scratch resistance without loss of transparency. Nanoparticles have also been used in sporting goods, for example, carbon nanotubes in tennis racket or bicycle frames, and ski poles that use a glass fiber composite with silica nanoparticles.

## **56.2 Nanoparticles**

### **56.2.1 Nanoparticles Definition**

The common definition of a nanoparticle is that it has at least one dimension in the nanometer range. Indeed, the term “nano” has virtually replaced “submicron,” even when the latter is more appropriate. A search of the scientific literature published in the last 5 years yields more than 60,000 articles per year that mention “nano,” but less than 3,000 papers per year that mention “submicro” (of which almost a third mention “nano” as well). Nanoparticles are characterized by a large surface area to volume ratio. They can be made from a wide range of materials – metallic (e.g., gold, silver), ceramic (e.g., silica, alumina, layered silicates, silicon carbide), or organic (e.g., carbon black, rubber particles, graphene, carbon nanotubes, and nanofibers). Due to the small size of nanoparticles, the numbers present in nanoparticle-modified materials are enormous. For example, there are approximately  $10^{17}$  individual particles in 1 kg of 20 nm silica nanoparticles.

As many nanoparticles are smaller than the wavelength of light (about 400–700 nm), they appear translucent when added to a translucent polymer. A consequence of this is that they are too small to be seen using optical microscopy, but can be imaged by high-magnification techniques, such as transmission electron microscopy (TEM), atomic force microscopy (AFM), and field emission gun scanning electron microscopy (FEGSEM). The structure of nanoparticles can also be characterized using X-ray diffraction or other techniques (Wang 2001). Because the particles are so small, it is not normally possible to measure their mechanical properties, and hence these are assumed to be the same as for the bulk material, or equal to those of a similar material. For many applications, such as the prediction of the mechanical properties of nanoparticle-modified materials, this appears to be a reasonable assumption.

As with micron-sized fillers, the particle shape and aspect ratio are important in determining the properties of nanoparticle-modified materials, such as stiffness, flow characteristics, tensile strength, etc. The aggregation and dispersion of the particles are also important, and may also affect the properties. Nanoparticles can be classified by their shape, as equi-axed (e.g., spherical), rod-like, and plate-like. These classes will be discussed in turn.

### **56.2.2 Equi-Axed Nanoparticles**

Most equi-axed nanoparticles are spherical, but irregular particles are also available. The common particles are metallic (e.g., gold, silver), ceramic (e.g., silica, alumina,

titania), or organic (e.g., rubber particles, fullerenes). The ceramic particles are typically prepared by sol-gel or flame-spraying methods; silica and alumina are commonly used with adhesives, see Fig. 1. Rubber particles are typically core-shell particles, with a soft core and a hard shell of a polymer such as poly(methyl methacrylate).

### 56.2.3 Nanotubes and Nanofibers

The rod-like nanoparticles that are commonly discussed in the scientific literature are carbon nanotubes. Carbon nanofibers (CNFs), which have a larger diameter, are also available. They are cheaper and are available in much larger quantities than carbon nanotubes. Ceramic nanotubes (e.g., zirconia, tungsten disulfide) or whiskers (e.g., silicon nitride, silicon carbide, alumina) can also be used.

Carbon nanotubes were first reported by Iijima (1991; Iijima and Ichihashi 1993), and are effectively sheets of graphite rolled into tubes. They are produced by chemical vapor deposition (CVD), electric arc, or laser ablation processes (Harris 1999, 2009). These techniques produce nanotubes with different lengths, straightness, purities, and degrees of entanglement. Hence, the nanotubes require purification to remove the amorphous carbon that is also produced, typically by heating them in a mixture of nitric and sulfuric acid (Gojny et al. 2003). CVD is becoming the most popular method for producing relatively large quantities of nanotubes relatively cheaply. In this technique, the nanotubes are grown on a ceramic substrate,

**Fig. 1** Transmission electron micrograph of silica nanoparticles in epoxy (Courtesy S. Sprenger)

rather like the bristles of a brush. The length of the nanotubes can be controlled, and they have a relatively low degree of entanglement.

There are two principal types of carbon nanotubes. Firstly, single-walled nanotubes (SWNTs) have a single graphene layer rolled into a tube typically 1–2 nm in diameter, with hemispherical end caps (Iijima and Ichihashi 1993; Tjong 2006). Secondly, multiwalled nanotubes (MWNTs) are comprised of a number of coaxial graphene tubes, each with an end cap. The outer diameter of a MWNT is typically 3–10 nm. Under tension, only the outer layer of a MWNT carries the load as the van der Waals forces between the layers are too weak to transfer stress to the inner layers (Lau et al. 2004). Variants such as double-walled nanotubes (DWNTs) are also available. The length of nanotubes varies significantly, but they can be as long as several millimeters (Chakrabarti et al. 2006). Hence, nanotubes can possess very large aspect ratios. Their modulus has been measured to be up to 1 TPa, with strengths of up to 150 MPa (Demczyk et al. 2002), although they are rather flexible normal to their axis (Saito et al. 1998). However, it is difficult to adhere the tubes to a matrix, and hence surface treatments are used to activate the surface, which can weaken the tubes. The electrical properties of nanotubes vary from metallic to semiconducting depending on their chirality.

Vapor-grown carbon nanofibers do not have such a high aspect ratio as carbon nanotubes, and have more defects. However, they are significantly cheaper and available in much larger quantities. The nanofibers are typically 50–200 nm in diameter and 30–100  $\mu\text{m}$  long (Green et al. 2006; Zhou et al. 2007), as shown in Fig. 2.

Ceramic whiskers have been produced for many years, as reported by Gordon (1978), though their use in epoxies seems to be limited. However, aluminum borate whiskers have been combined with thermoset polymer matrices by Liang and coworkers (Liang and Hu 2004; Tang et al. 2007). Ceramic nanotubes have been produced by coating carbon nanotubes with silicon carbide (Morisada et al. 2007). Silicon carbide nanofibers, which can be about 40 nm in diameter with lengths of up to several hundred microns, have also been produced (Zhu et al. 2002; Bechelany et al. 2007).

**Fig. 2** Scanning electron micrograph of carbon nanofibers in an epoxy matrix, showing fractured surface (Courtesy J. H. Lee)

## 56.2.4 Plate-like Nanoparticles

A range of plate-like nanoparticles have been used with polymer matrices, including layered silicate nanoclays (e.g., montmorillonite), graphite, and  $\alpha$ -zirconium phosphate. Generally, these particles are comprised of stacks of platelets that are intercalated or exfoliated by the polymer during processing. The resulting morphology is typically described as “particulate” (or “conventional”), “intercalated” or “exfoliated,” as identified by wide-angle X-ray scattering (WAXS). These microstructures are shown schematically in Fig. 3 for a nanoclay-modified polymer. In an intercalated microstructure, polymer chains enter the galleries between the platelets and increase the measured spacing (Schadler 2003). For an exfoliated nanocomposite, the platelets are pushed further apart, and the spacing becomes too large to measure using WAXS. Note that an exfoliated structure may be described as “ordered” or “disordered,” as shown in Fig. 3, but the fully disordered exfoliated structure is relatively rare. For a particulate structure, the particles remain unchanged.

Nanoclays (e.g., montmorillonite, hectorite) are layered silicates with a structure of stacked platelets similar to that of mica. The platelet thickness is approximately 1 nm and the lateral dimensions of the plates can vary from 30 nm to tens of microns. Hence, the platelets have a high aspect ratio. The layers have a regular van der Waals gap in-between them, called the “interlayer” or the “gallery” (Alexandre and Dubois 2000). These nanoclays are hydrophilic, and hence are typically surface-treated using long chain alkylammonium compounds to make them organophilic. The stacks of platelets can be readily delaminated by organic molecules to form an intercalated or exfoliated structure.

Natural graphite has also been used. A combination of chemical and thermal treatments can generate exfoliated graphite platelets with a thickness of 20–100 nm. Here, the graphite is intercalated by an acid treatment, followed by exfoliation by a thermal shock at a temperature of around 600 °C. The platelet diameter is in the order of 10  $\mu\text{m}$ , and hence these platelets have a high aspect ratio (Yasmin and Daniel 2004; Yasmin et al. 2006b).

## 56.2.5 Other Nanoparticles

Carbon black is mostly an aciniform (grape-like cluster) particulate, which is produced by the incomplete combustion of oil. The current worldwide production

**Fig. 3** Microstructures of nanoclay-modified polymers

is 8.1 million tonnes per year. It is very common as a pigment in inks and toners, and as a functional filler in tires and rubber products (ICBA 2008).

## 56.3 Manufacturing Using Nanoparticles

### 56.3.1 Dispersion

To obtain the best properties from a nanoparticle-modified polymer, it is considered that the nanoparticles should be well dispersed, and each particle should be properly wetted by the polymer. If agglomerates are formed instead, these can act as defects resulting in a reduction in performance rather than any enhancement. This is a major challenge when preparing adhesive formulations.

Dispersing nanoparticles is difficult due to their high surface area and incompatibility with the matrix polymer. Generally, a surface treatment or compatibilizer is required, and once agglomeration occurs it is very difficult to break up the agglomerates. Hence, particles that are supplied pre-dispersed in a resin (e.g., Nanopox from Nanoresins, or the MX range of core-shell particles from Kaneka) are popular with formulators. However, there is no guarantee that this good initial dispersion will remain after subsequent processing. For example, the addition of a liquid rubber, which phase-separates during curing, to some systems can cause the nanoparticles to agglomerate (Mohammed 2007; Hsieh et al. 2010). Although it is normally assumed that good dispersion is required, small agglomerates do not necessarily adversely affect the performance of such systems.

Assessing the quality of the dispersion of nanoparticles is difficult, as the techniques that can identify particles at the nanoscale such as AFM and TEM involve lengthy specimen preparation. Only a very small volume of the sample can be studied using these techniques, and hence the results may not be representative of the material as a whole. Alternatively, X-ray diffraction can be used, as this technique can analyze a larger volume. However, the data do not characterize how well the particles are dispersed. It is normally suggested that dispersion should be assessed at three size scales – (a) optically, (b) by scanning electron microscopy, and (c) by transmission electron microscopy. If the results from all three techniques indicate a good dispersion of nanoparticles, then it is fairly safe to assume that this is the case. Many authors agree that using optical microscopy is useful to investigate the dispersion of nanoparticles as it highlights the presence of agglomerates (e.g., Hackman and Hollaway 2006; Brooker et al. 2008), although individual nanoparticles will not be visible. Quantitative methods to assess dispersion, using the gray scale of images or by a quadrat method, are being developed (Brooker et al. 2010).

It should be noted that even small volume fractions of nanoparticles involve huge numbers of nanoparticles and very small interparticle distances. Shaffer and Kinloch (2004) point out that one major difficulty with small diameter nanotubes is that they become increasingly difficult to wet. By trivial estimation, even a 1 vol% loading of single-walled nanotubes ensures that all of the polymer molecules are within one

radius of gyration (say 5 nm) of a nanotube. This result implies that complete wetting of high loading fractions of single-walled nanotubes will be difficult, at least by conventional means, and that even more modest concentrations may be brittle and hard to process due to the constraint of the matrix (Shaffer and Kinloch 2004).

The chemical functionalization of the nanoparticles' surface can help improve dispersion, as it can reduce agglomeration, and can also improve the bonding between the particle and the matrix (Gojny et al. 2003; Kathi and Rhee 2008).

### 56.3.2 Mixing

If nanoparticles are supplied well dispersed in a polymer, then simple mixing is often enough to blend the particles into an adhesive formulation (e.g., Kinloch et al. 2005). Low-shear mixing is also sufficient for well-compatibilized systems, as the thermodynamics of these materials can ensure a good dispersion. However, if nanoparticles are supplied as an untreated powder they will generally be agglomerated, and these agglomerates must be broken down during processing. Low-shear mixing alone will not break up these agglomerates. High-power dispersion methods, such as high-shear mixing and sonication, are the easiest methods to improve the dispersion of nanoparticles in polymers (Xie et al. 2005).

In a multicomponent system such as a structural adhesive, the polymer component into which the nanoparticles are introduced does not generally cause a noticeable difference in the final morphology (Hackman and Hollaway 2006; Brooker et al. 2008). However, the morphology may be dependent on the cure time and temperature; plus the temperature, time, and shear rate used for mixing.

For carbon nanotubes, Fiedler et al. (2006) report that the size and shape of the impeller and the mixing speed control the dispersion. Intensive stirring of MWNTs in epoxy resin can achieve a relatively good dispersion. However, reagglomeration occurs due to frictional contacts and elastic interlocking mechanisms (Schmid and Klingenberg 2000). SWNTs have a greater tendency to reagglomerate than MWNTs, and hence higher shear forces are required to achieve a reasonable dispersion.

High-shear mixing can be achieved using a range of techniques. Hackman and Hollaway (2006) compared low-shear mixing to the use of a grinding media mill, filled with 2 mm diameter glass beads. Green et al. (2006) compared low-shear mixing to high-shear mixing generated by extrusion of a nanoparticle-modified epoxy resin through a small orifice. In both cases, the high-shear method gave better dispersion. Glass beads have been shown to break down agglomerated nanoclay particles to form a uniform material. However, although neither work evaluated the dispersion at the nanometer-scale using microscopy, differences could be seen at the microscale (Hackman and Hollaway 2006).

A three-roll mill (or calender) has been used by Yasmin et al. to disperse nanoclay in epoxy (Yasmin et al. 2003; Yasmin et al. 2006a), and by Gojny et al. to disperse nanotubes in epoxy (Gojny et al. 2004). This method is commonly used to disperse microparticles in polymers (Fiedler et al. 2006). As it is not a continuous process, the material was collected and fed back into the mill after each pass. The authors

assumed that the dispersion was achieved (a) by the shear forces generated between the dispersing of the particles as smaller tactoids, and (b) by the combined shear and diffusion processes facilitating the separation and penetration of polymer between the clay platelets (Yasmin et al. 2003; Yasmin et al. 2006a). This process requires a relatively viscous material, and hence is suitable for higher loadings of nanoparticles. According to Fiedler et al. (2006), a major advantage of this method is that it allows the efficient manufacturing of larger quantities of nanocomposites, as the nanoparticle-modified polymer requires only minutes of processing. By comparison, low-shear methods may require processing times of hours.

### 56.3.3 Sonication

Sonication uses an ultrasonic bath or probe to apply sound energy to a liquid that contains particles. Many authors combine sonication and mixing, especially when using probe sonicators as the power is directed into only a small volume, and the low-shear forces do not generally ensure that all of the polymer passes through this volume. The combination of probe sonication with high-speed mixing has been reported to be a relatively successful way to disperse nanoparticles. This technique has been used with nanoclays in epoxy resin (Zunjarrao et al. 2006) and in polyimide (Gintert et al. 2007). It has also been used with carbon nanotubes in epoxy (Sandler et al. 1999).

The very localized introduction of energy from probe sonication leads to a considerable amount of damage, including buckling, bending, dislocations, and rupture of carbon nanotubes (Lu et al. 1996; Fiedler et al. 2006). It will also cause local heating of the sample, and hence if sonication is undertaken with a curing agent or initiator present it may be necessary to cool the sample to prevent premature curing (Lu et al. 1996). The use of an ultrasonic bath reduces the energy density and alleviates some of these problems, but the time taken to achieve a reasonable dispersion is much greater (Brooker et al. 2008).

The processing time can affect the size of nanoclay agglomerates (Lam et al. 2005). However, the d-spacing (the distance between the nanoclay platelets) was unaffected by the sonication time, and hence exfoliation of the nanoclay could not be achieved using sonication. Gintert et al. (2007) also found that sonication was an important step in breaking up nanoclay agglomerates.

### 56.3.4 Alignment

The properties of composites are generally improved by the alignment of the fibers, although this does produce an anisotropic material. It is also possible to align nanoparticles. This is generally achieved by physical means, for example, by application of a force, cutting, extrusion, or drawing (e.g., Ajayan et al. 1994; Baik et al. 2005). Alignment can also be achieved using the application of magnetic or electric fields, with carbon nanotubes (e.g., Chen et al. 2001; Martin et al. 2005),

and with layered silicates (e.g., Koerner et al. 2005). For more information on the alignment of carbon nanotubes, and their dispersion, see the review by Xie et al. (2005).

## 56.4 Properties of Nanoparticle-Modified Polymers

### 56.4.1 Mechanical Properties

The addition of high modulus particles increases the modulus of a polymeric material, independent of the particle size; although the stiffening effect may be higher for particles with larger aspect ratios. There are many theoretical models available to predict the modulus of particle-modified polymers, such as the Halpin-Tsai and Mori-Tanaka models (e.g., Ahmed and Jones 1990). These models have been shown to broadly apply for nanoparticle-modified polymers (e.g., Kinloch and Taylor 2006), see Fig. 4, though more accurate predictions can be obtained by finite element modeling (Sheng et al. 2004). The true aspect ratio of the particles, the degree of their alignment, and some idea of the strength of adhesion between the particle and the polymer matrix, are required for accurate predictions. However, the elastic properties of nanoparticles cannot generally be measured, and hence are almost unknown. This includes nanoclays such as montmorillonite (Vanorio et al. 2003). This absence of modulus data is because the small particle size makes it impossible to perform reliable measurements. Hence, most authors assume that the

**Fig. 4** Relative modulus (composite modulus divided by matrix modulus) of epoxy polymer modified with nanoclay. Experimental data are shown as points, predictions using various theoretical models are shown as lines (Adapted from Kinloch and Taylor 2006)

properties (e.g., modulus, density) of the nanoparticles are equal to those of the bulk material, or of a similar material.

Examples of the stiffening effect that may be obtained using nanoparticles include the addition of 3% carbon nanofibers (CNF) to an amine-cured epoxy polymer (Zhou et al. 2007), which gave a 19% increase in modulus when added. This was accompanied by an increase in the tensile strength and a reduction in the strain to failure. These changes are typical of nanoparticle-modified epoxies. Generally, the stiffness is increased; the strain to failure and the tensile strength may be increased or remain the same. However, when small diameter particles are used, for example, 20 nm diameter silica nanoparticles, then the tensile strength remains unchanged. By comparison, the addition of hard microparticles tends to reduce both the strain to failure and the tensile strength.

**56.4.2 Functional Properties**

The high aspect ratio and low permeability of plate-like nanoparticles should provide good barrier properties when the particles are aligned and incorporated into thin films, by creating a tortuous path for diffusion (Hackman and Hollaway 2006; Sorrentino et al. 2006). Numerical predictions show that the permeability reduction is governed by the product  $a \cdot V_f$ , where  $a$  is the platelet aspect ratio and  $V_f$  is the volume fraction (Gusev and Lusti 2001). Epoxy films that were highly filled with nanoclay have been shown to have low oxygen permeability, up to three orders of magnitude lower than that of the unmodified epoxy (Triantafyllidis et al. 2006), see Table 1. The rate of diffusion of acetone into epoxy is also reduced by the addition of nanoclay (Chen and Curliss 2001), although these data did not reach saturation and so it is not possible to compare the equilibrium uptakes.

The fire resistance of nanoparticle-modified polymers has been studied, but most work has concentrated on thermoplastics. This has generally shown that the addition of nanoclays, and nanotubes, can improve the fire resistance (e.g., Gilman 1999; Gilman et al. 2000b; Beyer 2002). A significant amount of work has been performed using various thermoset polymers modified with nanoclays, including epoxy, vinyl ester, cyanate ester, and polyimide (e.g., Gilman et al. 1999a; Gilman et al. 1999b;

**Table 1** Oxygen permeability data for films of epoxy and nanoclay-modified epoxy (Adapted from Triantafyllidis et al. 2006)

Clay film composition	Clay film thickness (mm)	Epoxy-clay film thickness (mm)	O <sub>2</sub> permeability (cm <sup>3</sup> ml/m <sup>2</sup> day)
Epoxy	–	0.20	98.9
Epoxy-montmorillonite	0.060	0.11	≤0.1
Epoxy-montmorillonite	0.035	0.10	0.97
Epoxy-fluoroectorite	0.065	0.14	1.2

Gilman et al. 2000a). Tests using cone calorimetry showed that the addition of 10% of silicate reduced the peak heat release rate by up to 50%, and increased the mass of char residue formed. However, the onset time was also often reduced, probably due to presence of the surface treatment.

The thermal degradation behavior of nanoclay-modified epoxy has been studied, and is closely linked to the fire performance. Nanoclay has little effect on this behavior, and may even reduce the temperature at which degradation starts due to the relative instability of the surface treatment (Brnardic et al. 2008). The addition of carbon nanofibers to an amine-cured epoxy polymer had no effect on the decomposition temperature of epoxy (Zhou et al. 2007), but single-walled nanotubes have been shown to degrade the thermal stability (Puglia et al. 2003).

The effect on the glass transition temperature,  $T_g$ , of the addition of nanoparticles is dependent on the type of nanoparticles used and the interaction between the particles and the polymer (Becker and Simon 2006). The  $T_g$  can shift to a higher temperature than that of the unmodified polymer (e.g., Messersmith and Giannelis 1994; Kinloch and Taylor 2006; Bugnicourt et al. 2007). This may be due to a high interaction between the particles and the polymer, which may also locally change the properties of the polymer network. For example, the  $T_g$  of a polyurethane (PU) adhesive was increased from 32 °C to 62 °C by the addition of 5% of functionalized nanoclay (Dodiuk et al. 2006). Where polymer chains are intercalated between silicate platelets, then the silicate may constrain the polymer, hence increasing  $T_g$  (Kinloch and Taylor 2006). Bugnicourt et al. (2007) reported that  $T_g$  increased from 161 °C to 180 °C for an amine-cured epoxy modified with silica nanoparticles. They also noted that the poorer the dispersion, the lower the impact of the addition of silica on the magnitude of the  $\tan \delta$  peak and  $T_g$ . However, other tests showed no effect of the addition of silica nanoparticles (Bugnicourt et al. 2007; Johnsen et al. 2007; Hsieh et al. 2010). Reductions in the glass transition temperature have also been reported (e.g., Kornmann 1999). These reductions may be due to the surface treatment degrading during curing (Wang et al. 2000), or by enhanced free volume in the interphase between the particle and the matrix.

Carbon nanotubes have been shown to increase the rate of the curing reaction of epoxies (Yin et al. 1993; Puglia et al. 2003). This effect arises from the surface chemistry of the nanotubes (Shaffer and Sandler 2006). However, barium titanate nanoparticles did not affect the curing behavior of epoxy cured using diamino diphenyl methane (DDM) (Chandradass and Bae 2008).

The use of nanoparticles with a diameter less than that of the wavelength of light allows transparent particle-modified materials to be produced. In practice, the particles do reduce the optical transparency compared to the unmodified matrix due to differences in the respective refractive indices. For example, the light transmittance of epoxy modified with 25 nm diameter silica particles was greater than that for epoxy modified with particles of 540–1,520 nm (Naganuma and Kagawa 2002). However, using the smaller particles does give transmittance of 80–90% of the unmodified matrix value.

It is reported that the addition of nanoclays to epoxy will also reduce the coefficient of thermal expansion (CTE) of the epoxy polymer, as the CTE of the

ceramic particles is less than that of the polymer (Wang et al. 2000). For example, the CTE of epoxy below  $T_g$  can be reduced from 77 to 63  $\mu\text{m}/\text{m}^\circ\text{C}$  by the addition of 3% of nanoclay (Chen and Curliss 2001). However, the addition of nanotubes has been shown to have no significant effect on the CTE (Salinas-Ruiz 2009).

### 56.4.3 Electrical Properties

Alternating current (AC) impedance spectroscopy has been used to measure the conductivity of an amine-cured epoxy modified with multiwalled carbon nanotubes (MWNTs) (Sandler et al. 2003). The conductivity increased as a function of the MWNT weight fraction, see Fig. 5. There was an increase in conductivity of about two orders of magnitude, from  $10^{-9}$  to  $10^{-7}$  S/m, when 0.001 wt% of nanotubes was added. There was a further increase to above  $10^{-3}$  S/m for loading fractions of greater than 0.005 wt%. This increase in conductivity suggests that an infinite network of percolated nanotubes starts forming above 0.001 wt%. The authors also state that comparison with the direct current (DC) conductivity of the composites gave identical results. A similar transition in conductivity occurs for carbon black, but more than 1 wt% of carbon black is required (Sandler et al. 1999; Sandler et al. 2003), see Fig. 5.

**Fig. 5** Conductivity versus filler content for aligned multi-walled carbon nanotubes, entangled nanotubes, and carbon black particles in epoxy (Courtesy M. Shaffer)

The addition of layered silicates to epoxy resin improves the surface discharge endurance of the polymer, considerably increasing the time before electrical breakdown occurs (Montanari et al. 2005). The addition of nonconducting silica or alumina nanoparticles will reduce the conductivity of the polymer (Cao et al. 2004). Layered silicates have been shown to increase the electrical breakdown strength and breakdown time (Imai et al. 2006), see Fig. 6. This indicates that these materials may have potential applications for electrical insulation materials.

The thermal conductivity of epoxy modified with carbon nanotubes has been investigated (Gojny et al. 2006). The authors reported that the thermal conductivity increased slightly with nanotube content, although the changes are very small compared to the changes in electrical conductivity.

#### 56.4.4 Fracture Toughness

It is well established that microparticles can increase the fracture toughness of thermoset polymers in mode I loading (e.g., Moloney et al. 1983; Kinloch and Taylor 2002). Indeed, this is the basis of most structural adhesives, which have a rubber or thermoplastic particulate toughening phase, often combined with co-tougheners. These particles may be preformed, or may be formed by phase-separation of an initially soluble polymer during curing. Inorganic particles such as glass or mica also provide a toughening effect, though the increases in toughness are generally lower than for rubber-toughening. In addition, hybrid formulations that combine rubber and glass particles have been shown to give high toughness.

**Fig. 6** Insulation breakdown time for conventionally filled (50 vol% silica microparticles) epoxy, and this epoxy with added nanoclay under constant AC voltage (10 kV, 1 kHz) (Adapted from Imai et al. 2006)

The addition of nanoclay particles to epoxy has been shown to increase the toughness. The fracture energy of vinyl ester/epoxy systems containing 5 wt% nanoclay was increased more than two times compared to the unmodified polymer (Karger-Kocsis et al. 2003). There was no significant effect of the type of the surface treatment used on the nanoclay. Increasing the amount of nanoclay above 5 wt% reduced both the fracture toughness and fracture energy. Kinloch and Taylor compared the toughening effect due to the addition of layered silicate nanoparticles (nanoclays) with that due to similar microparticles, in this case mica (Kinloch and Taylor 2003, 2006). They reported higher fracture toughness values for the mica microparticles than for the nanoclays, see Fig. 7. They also showed that the fracture toughness was dependent on the weight fraction of nanoclay, with maximum toughness being achieved at between 1 and 5 wt% of nanoclay. The fracture toughness was also dependent on type of nanoclay used, and hence on the surface treatment and the resulting morphology. The addition of layered silicates does not always increase, and may reduce the fracture toughness, for example, with thermoset acrylic systems (Tarrant 2004).

Spherical nanoparticles have also been used to toughen epoxies. Ragosta et al. increased the fracture toughness,  $K_{IC}$ , of tetrafunctional epoxy cured with 4,4-diaminodiphenyl sulfone (DDS) from 0.5 to 1.2 MPa<sup>1/2</sup> using 10 wt% of silica particles (Ragosta et al. 2005). The particles were between 10 and 15 nm in diameter. It has also been shown that the addition of 13 nm diameter alumina particles increased the fracture toughness of epoxy, cured using a cycloaliphatic amine, from 0.5 to 1.2 MPa<sup>1/2</sup> using 11 vol% of alumina (Wetzel et al. 2006). Similarly, the addition of 11 vol% of 300 nm diameter titania particles increased  $K_{IC}$  to 0.85 MPa<sup>1/2</sup>.

**Fig. 7** Fracture toughness of unmodified epoxy, mica microparticle- and nanoclay-modified epoxy versus content of layered silicate. Note “viscosity limit” indicates maximum silicate content before particle-modified resin becomes too viscous to cast (Adapted from Kinloch and Taylor 2006)

The addition of silica nanoparticles increased the fracture toughness of an anhydride-cured epoxy from 0.59 to 1.42 MPam<sup>1/2</sup> when 20 wt% of nanoparticles were added (Kinloch et al. 2005). These toughness values are equivalent to fracture energy,  $G_C$ , values of 100 and 460 J/m<sup>2</sup> respectively, see Fig. 8. In addition, 4 wt% of silica nanoparticles was sufficient to almost triple the fracture energy of the unmodified epoxy, to 290 J/m<sup>2</sup>. The toughening mechanisms involved have been discussed by Johnsen et al. (2007). Zhang et al. (2006) and Rosso et al. (2006) also reported toughness increases due to the addition of similarly sized silica nanoparticles.

The toughening mechanisms of silica nanoparticle-modified epoxy have been identified as plastic shear-yielding, and debonding of the polymer from the nanoparticles, followed by plastic void-growth of the epoxy (Hsieh et al. 2010). The toughening mechanisms of crack pinning, crack deflection, and immobilized polymer around the particles have all been discounted (Johnsen et al. 2007).

Micron-sized rubber particles toughen polymers by cavitating, hence relieving the constraint in the plastic zone at the crack tip. The matrix is then able to deform, absorbing energy by dilation and shear banding, thus giving an increased toughness. However, nanometer-sized rubber particles are thought not to cavitate, because the triaxial stresses required for cavitation are too high. Theoretical models predict that there is a minimum size below which rubber particles will not cavitate (Lazzeri and Bucknall 1993; Dompas and Groeninckx 1994). This diameter is predicted to be approximately 50 nm (Kody and Lesser 1999). This lack of cavitation of small rubber particles has been observed experimentally. For example, no cavitation was observed with carboxyl-terminated butadiene-acrylonitrile (CTBN) rubber particles,

**Fig. 8** Fracture energy versus content of silica nanoparticles in epoxy and rubber-toughened (9% CTBN) epoxy (Adapted from Kinloch et al. 2005)

which were 200 nm in diameter, but cavitation was seen with micron-sized CTBN particles (Chen and Jan 1992).

However, cavitation was observed using 200 nm diameter core-shell latex particles comprised of a methacrylated butadiene-styrene copolymer (MBS) with a poly (methyl methacrylate) (PMMA) shell in a piperidine-cured epoxy polymer (Azimi et al. 1996b). Nano-sized core-shell rubber particles have also been reported to increase toughness (Liang and Pearson 2009). Liang and Pearson showed that the addition of 100 nm core-shell particles increased the fracture toughness of a piperidine-cured epoxy to  $3.1 \text{ MPam}^{1/2}$ . Although no toughness was reported for the unmodified epoxy, similarly cured material has a fracture toughness of between 0.9 and  $1.2 \text{ MPam}^{1/2}$  (Oba 1999; Kawaguchi and Pearson 2003). In earlier work, the toughening effect of 200 nm MBS core-shell particles were compared to 1, 10, and 100  $\mu\text{m}$  diameter CTBN particles (Pearson and Yee 1991). The fracture toughness was very dependent on particle size, and small particles are more efficient in producing a toughening effect than large particles.

The largest increases in toughness have been reported for so-called hybrid materials, which combine rubber and nanoparticle-modification of the epoxy. For example, the addition of silica nanoparticles to a rubber-toughened epoxy, using 9 wt% of CTBN, increased the toughness from 1.11 to  $2.19 \text{ MPam}^{1/2}$  when 15 wt% of nanoparticles were added (Kinloch et al. 2005). These toughness values are equivalent to fracture energy,  $G_C$ , values of 440 and  $1,480 \text{ J/m}^2$ , respectively, see Fig. 8. Synergistic increases in fracture toughness (Liang and Pearson 2009), and in impact strength (Zeng et al. 2007) have also been reported. Synergistic toughening has previously been reported for rubber-toughened epoxy with micron-sized glass beads (e.g., Kinloch et al. 1985; Azimi et al. 1996a). Increases in toughness have also been observed when nanoclay is added to rubber-modified epoxy, but there is not such a strong synergistic effect in this case (Liu et al. 2004).

#### 56.4.5 Fatigue Performance

Nanoparticles have been shown to improve the fatigue performance of thermoset polymers. Wetzel et al. (2006) measured the fatigue crack propagation (FCP) rate,  $da/dN$ , versus the stress-intensity factor range, and showed that this relationship follows the classic Paris-Erdogan law. These fatigue curves are shifted toward higher stress-intensity values as the nanoparticle content rises. At the same time, the gradient decreases. They reported that the gain in FCP resistance of alumina-modified epoxy nanocomposites (10 vol%) is comparable to the reinforcement achieved by rubber particles in epoxy, as was demonstrated using small amounts of rubber (5–10 phr CTBN) (Karger-Kocsis and Friedrich 1992), and is similar to that using 15–20 vol% of glass microspheres (Sautereau et al. 1995). In contrast to such traditional modifiers, the authors point out that the benefits conferred by nanoparticles are neither at the expense of modulus nor of strength.

Silica nanoparticles have been shown to significantly improve the cyclic-fatigue behavior of an anhydride-cured epoxy polymer, increasing the range of applied

stress-intensity factor at threshold,  $\Delta K_{th}$ , see Fig. 9 (Blackman et al. 2007). The nanoparticles also increased the fracture toughness,  $K_{IC}$ . The fatigue data followed the modified Paris law. Similarly, the addition of 200 nm diameter rubber particles increases fracture toughness and improves fatigue resistance (Azimi et al. 1996b). The fatigue data followed the classic Paris-Erdogan law. The use of 200 nm MBS particles in place of 1.5  $\mu m$  CTBN particles resulted in about one order of magnitude improvement in fatigue resistance. A synergistic effect between CTBN rubber particles and silica nanoparticles has also been shown in fatigue, with the maximum increase in the fatigue threshold value being recorded using 9 wt% of rubber and 9 wt% of silica (Sohn Lee 2009).

The addition of carbon nanofibers (CNF) to an amine-cured epoxy polymer significantly increased the number of cycles to failure, as measured using fatigue stress versus number of cycles to failure (S-N) curves (Zhou et al. 2007). The fatigue life went through a maximum at 2 wt% CNF, although only two specimens were used for each combination of stress level and CNF loading.

A reduction in crack growth rate per cycle has also been shown for an epoxy system with the addition of up to 0.5 wt% of carbon nanotubes (Zhang et al. 2007). The authors attributed this effect to pullout of the nanotubes that bridge across the crack opening.

Though there are data available that show how nanoparticles can change the fatigue performance of adhesives, there are no data that quantify the durability (i.e., the resistance to an environment such as water) of these materials when used as adhesives. However, it is likely that nanoparticle-modified adhesives will perform as conventionally filled adhesives.

**Fig. 9** Logarithmic crack growth rate per cycle,  $d a/d N$ , versus logarithmic range of applied stress-intensity factor from cyclic-fatigue tests for unmodified epoxy and silica nanoparticle-modified epoxy (Courtesy J. Sohn Lee)

## 56.4.6 Peel and Lap-Shear Performance

The modification of a polyurethane (PU) adhesive using nanoclays was tested by Dodiuk et al. (2006), using adhesive joints made with aluminum-alloy adherends. The incorporation of functionalized nanoclays into PU improved the lap-shear strength by up to 195%. The functionalized nanoclays also gave higher peel strength than the unmodified PU. Increases of up to 40% were measured, but one of the nanoclays gave almost no change in the peel strength.

The lap-shear strength of carbon-fiber composites bonded using an epoxy adhesive was increased by 45% with the addition of 5% of MWNT (Hsiao et al. 2003). However, the locus of failure was also altered – from interfacial for the control specimens to cohesive for the nanotube-modified materials.

Climbing drum peel and lap-shear tests were performed using aluminum-alloy substrates, with a model rubber-toughened epoxy film adhesive (Gilbert et al. 2003). The adhesive was modified with 5 or 10 wt% of either 50 nm diameter alumina nanoparticles or alumina nanofibers with a diameter of 2–4 nm and an aspect ratio ranging from tens to hundreds. Both of the nano-modifiers increased the peel and shear strength. However, the more successful modification was the addition of 5% of alumina nanoparticles, which increased the peel strength of the adhesive by 50%, and the lap-shear strength by 15%.

The lap-shear and 180° peel test performance of very soft acrylic adhesives modified with nanoclay or silica nanoparticles were improved by the addition of nanoparticles (Patel et al. 2006). The addition of 6 wt% of nanoclay or 50 wt% of silica increased the peel force by about 40%.

Sprenger and coworkers used a room-temperature curing rubber-toughened epoxy adhesive with a  $T_g$  of 70 °C (Kinloch et al. 2003; Sprenger et al. 2003, 2004). The addition of only 4 wt% of 20 nm diameter silica nanoparticles doubled the fracture energy, from 1,200 to 2,300 J/m<sup>2</sup>. The addition of the nanoparticles also increased both the lap-shear and peel strength, as shown in Fig. 10.

## 56.5 Conclusions

Nanoparticle-modified polymers are being extensively researched, and a great deal of work has been done to produce nanoparticles. These nanoparticles are now commercially available in kilogram or tonne quantities, and at reasonable prices (\$10s per kilogram). Hence, nanotechnology and nanoparticles are beginning to be applied in commercial products. It is anticipated that nanoparticles will be increasingly used in structural adhesives. Their application will continue to expand as their availability increases, and hence as their cost decreases.

The dispersion of nanoparticles in polymer matrices can be difficult, and agglomerates can remain even after aggressive processing. These may have a significant detrimental effect on the properties of the material. For this reason, pre-dispersed nanoparticles, available as a masterbatch in a polymer, are attractive. However, these

**Fig. 10** Lap-shear and roller peel strength for hybrid (nanosilica and rubber-modified) epoxy (Adapted from Kinloch et al. 2003)

particles can agglomerate during processing or curing, so there is no guarantee that a good dispersion will be obtained in the final material.

Nanoparticles have been shown to improve the structural and functional properties of thermoset polymers. However, in many cases similar increases can be obtained using micron-sized particles, especially for structural properties. High aspect ratio particles, such as carbon nanotubes or nanoclay, can give significant improvements in functional properties. Examples include electrical percolation at very low particle volume fractions and increases in barrier properties.

It is perhaps the synergistic effect of combining nanoparticles with existing technology based on micron-sized particles that is the most exciting area at present. For example, the fracture toughness and peel performance of adhesive joints can be improved by combining silica nanoparticles and rubber microparticles. Hierarchical materials like these, and patterned arrays of nanoparticles, appear to be the future developments in this field.

**Abstract**

The present chapter describes the adhesive techniques and materials that are widely used in modern clinical dentistry. There are two types of tooth-colored restorative material available to the dentist, the so-called composite resins and the glass-ionomer cements. There are, though, variations on these basic types, as explained in the chapter. In addition, there is the zinc polycarboxylate cement, which was the first adhesive dental restorative material to be developed, and it retains a niche in modern clinical practice.

Composite resins do not themselves possess any adhesive properties, but need to be used in conjunction with separate adhesive substances known as bonding agents. Over recent years, the technology of these materials has developed rapidly and a wide variety of systems are currently available to the clinician. Bonding agents have been characterized by “generation,” and currently seventh generation bonding systems are available. However, a more useful classification is based on the number of steps involved in using them, and this is described in detail.

Bonding agents are applied to the tooth surface following cavity preparation, a process that involves the formation of a layer of deranged dentin known as the “smear layer.” Modern bonding agents may be either “etch-and-rinse,” in which case the smear layer is removed, or “self-etching,” where the smear layer becomes incorporated into the bonding layer. Whichever approach is used, the result is a treated surface to which the composite resin is applied. Testing of such systems is typically in shear mode, and they have been reported to give high shear bond strengths, even though they involve only a very thin layer between a hydrophilic substrate and a hydrophobic repair material.

Glass-ionomers, by contrast, are themselves hydrophilic and inherently adhesive to the tooth surface. It therefore requires only slight pretreatment, typically conditioning with 10% aqueous polyacrylic acid. Glass-ionomers rapidly form durable adhesive bonds to the tooth surface through the development of an ion-exchange layer at the interface. This ability to bond is exploited in both the Atraumatic Restorative Treatment (ART) technique and in bonding of orthodontic brackets, both of which are described in detail in the chapter.

---

## 57.1 Introduction

Dentistry is concerned with the preservation, repair, and replacement of teeth. In its contemporary form, it makes increasing use of adhesive materials and techniques. One example is the placement of adhesive materials to fill fissures of newly erupted teeth as a preventive procedure. Without this treatment, decay-inducing bacteria might otherwise lodge in these fissures, and cause caries to develop (Mount and Hume 2005). Other options in restorative dentistry include repair of teeth damaged by caries or trauma with the tooth-colored materials known as composite resins. Use of these materials involves bonding to the tooth by means of bespoke adhesive systems. Alternatively, teeth damaged by caries can be repaired with the other tooth-colored option, the glass-ionomer cement. These materials are inherently adhesive to both the dentin and enamel of the tooth, which in some applications is an advantage (Mount 2002).

Replacement of missing teeth using bridges typically employs bonding agents and surface pretreatment procedures (Roulet and Vanherle 2004). Tooth-realigning techniques used in the dental specialty known as orthodontics employ brackets and wires to force the teeth into more satisfactory positions. Adhesive materials can be used to hold these brackets in place. Aesthetic procedures, such as the placement of

ceramic veneers to improve the appearance of the incisors, also typically employ adhesives and surface pretreatments (Mount and Hume 2005).

From these comments it is apparent that adhesion and adhesives play important roles in modern dentistry. Current research covers many facets of the adhesion process, including surface pretreatment, formulation of adhesives, durability of bonded structures, and clinical effects of bonding agents and adhesive materials (Roulet and Vanherle 2004; Breschi et al. 2008). The deployment of these substances in the mouth is not entirely straightforward. The mouth is a biological structure, and as such is composed of both hard and soft tissues. The chemicals used as adhesives may have adverse effects, particularly on the soft tissue of the gingiva (gum) and pulp (living cells and blood vessels within the tooth). A theme of the current research is the biocompatibility of adhesive materials in the mouth.

Tooth repairs are required to be capable of surviving for a considerable time, typically of the order of 10–15 years. The long-term effects of foreign materials and their possible degradation products need to be considered in selecting repair materials and planning treatments involving their deployment.

There are many factors driving the changes to increased use of adhesive techniques in dentistry (Roulet and Vanherle 2004). First, there have been many years of research and development activity directed toward the fabrication of esthetic repair materials, both polymer- and ceramic-based. Second, there is an increasing patient demand for esthetic (i.e., tooth-colored) repairs. This is part of a wider trend toward improved dental esthetics that has seen a rise in the developed world of cosmetic dentistry as a branch of the profession and the increasing use of bleaching techniques to make the teeth whiter. This is associated with looking younger and also compensates for the ravages of strongly colored dietary components, such as coffee and red wine.

A third factor contributing to the increase in importance of adhesion in dentistry is that patients are retaining their natural teeth for longer. Whereas earlier generations were prepared to accept some tooth loss and even complete edentulousness as a consequence of ageing, the current generation is less tolerant of these possibilities. There has been a dramatic fall in the incidence of tooth decay in the past 40 years, a phenomenon which is multifactorial, but is closely allied to the increased use of fluoride for preventive purposes. Preventive measures include fluoridation of drinking water, the supply of fluoridated toothpastes, and the application of fluoridated gels by dental professionals (Nicholson and Czarnecka 2008a). As a result, patients retain many of their teeth well into old age, and having done so, are then unwilling to accept radical treatment options, such as extraction or even highly invasive repair with silver-tin amalgam. Increasing levels of affluence, too, make such patients willing to pay for demanding clinical procedures and more expensive materials, which means those based on adhesive techniques and materials.

Finally, the major advances in understanding of bond formation and durability to the tooth surface has enhanced the ability of the scientific community to develop reliable and long-lasting bonding agents. The dental literature reflects this, containing as it does many hundreds, possibly thousands, of scientific articles on the topic of bonding and adhesion. These range from fundamental studies of bonding

mechanisms and surface pretreatments to clinical studies of longevity of repairs and failure mechanisms.

One indication of the importance of this subject is that a specialist journal, the *Journal of Adhesive Dentistry*, was launched in 1999. However this is not the only forum for discussion of research on this topic, and other journals, such as *Journal of Dental Research*, *Dental Materials* and *Journal of Dentistry* also carry numerous research articles every year on adhesive dentistry.

The current chapter aims to cover the subject of adhesive dentistry as comprehensively as possible. Beginning with a consideration of the surfaces to which bonding takes place, it goes on to consider the nature of the main groups of esthetic dental repair materials (the composite resins and the glass-ionomer cements) and how their adhesion is brought about and their durability maximized. There is considerable focus both on fundamental understanding of the mechanism of adhesion and on the clinical outcomes that can be achieved using these materials. Finally, other clinical applications that rely on adhesion are described. These are (i) orthodontic bracket fixation, (ii) fissure sealing, and (iii) the so-called Atraumatic Restorative Treatment technique (ART). The latter is an important development in clinical dentistry, particularly aimed at Third World countries, which is possible only with adhesive materials and which marks an innovative approach within dentistry.

---

## 57.2 Surfaces for Bonding

Unlike adhesive bonding in most areas of technology, in dentistry adhesion involves a living substrate. This is more variable than most surfaces to which adhesive materials are typically applied. To understand the significance of this, the nature of the substrates that are encountered in dentistry must be considered, which means beginning with a consideration of the anatomy of the tooth.

The tooth consists essentially of two types of tissue, the enamel and the dentin. Their compositions are shown in Table 2. From this it can be seen that the mineral phase of the enamel far exceeds that of the dentin, resulting in the enamel being much the harder and more brittle of the two tissues.

Enamel and dentin are joined by a distinctive dentino-enamel junction (DEJ). This zone has important mechanical properties, uniting as it does a thin and highly brittle layer (enamel) with a tougher, more compliant underlying structure (dentin). Among the important properties of the DEJ is that it does not allow cracks to cross from the enamel to the dentin. This feature maintains the integrity of the whole tooth, so that even if small cracks appear in the enamel, they do not propagate through the dentin and damage the whole tooth.

The mineral phase of the tooth is predominantly hydroxyapatite, which is a calcium phosphate mineral of nominal composition  $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$  and has a Ca:P ratio of 1.67:1. Naturally occurring hydroxyapatite, such as that in teeth and also in bones, tends to be a slightly different composition from this idealized formula. It is typically calcium deficient and has a small proportion of its phosphate groups replaced by carbonates (Table 1). This natural mineral, though, is still very

**Table 1** Composition of tooth

	Enamel	Dentin
Inorganic phase (mainly hydroxyapatite)	94–96%	70%
Organic phase (mainly collagen)	4–5%	20%
Water	1%	10%
Ca:P ratio	1.64	1.56

hard and the details of its composition make little or no difference to its mechanical properties.

In order to carry out the various processes involved in dental repair, the tooth generally has to be cut with some sort of instrument. This is usually a rotary bur of the so-called dental drill. The cutting process results in the formation of a layer known as the smear layer on the surface of the tooth (Fig. 1). The smear layer is thin, typically 1–2  $\mu\text{m}$  deep, and is very tenacious. It consists of mineral phase embedded in denatured collagen, and is essentially material with a less ordered structure than uncut enamel or dentin.

The detailed composition, morphology, roughness, and tenacity of the smear layer vary according to the precise details of the cutting process (Ogata et al.

2001). Despite this, the smear layer may be left in place and act as the surface to which bonding is carried out. Dental adhesives need to be able to penetrate this layer, and possibly interact with it, to form a layer capable of being retained for many years. Bond strengths and durability are known to vary according to how this smear layer is created (Koibuchi et al. 2001), and the differences in its properties that result from the different ways it may be formed are responsible for the variations in clinical performance of dental bonding agents.

During the formation of the smear layer, cutting debris is usually forced down into the tubules of the dentin. This debris results in the formation of so-called “smear plugs” and they have the effect of reducing the permeability of the dentin, and also of reducing the total surface area available for bonding (Koibuchi et al. 2001). The reduction in permeability may be an advantage, however, as it stops fluid being forced up the dentinal tubules. This, in turn, protects the bond formed by an adhesive placed onto the cut surface.

The surface treatment that follows cutting may attempt to modify or remove the smear layer, in order to ensure that a uniform and reliable surface is left behind. It may also remove the smear plugs, thus opening the tubules and allowing the bonding agent to penetrate the tooth surface. This may not be desirable, since it may lead to postoperative sensitivity and discomfort in the patient. There is considerable debate amongst dental practitioners as to which is the best way to carry out tooth preparation, and these varying views show that, in the field of adhesive dentistry, maximizing the bond strength is not the only consideration.

---

### 57.3 Surface Pretreatment

The earliest dental restorative materials, gold foil and silver amalgam, have no adhesive properties whatsoever. They needed to be held in place by enlarging the cavity caused by the tooth decay, and forming undercuts. This is still the method used for retaining silver amalgam fillings, gold foil having passed into disuse many years ago. This approach of removing sound, healthy tooth tissue is widely recognized in the dental profession as a major disadvantage of silver amalgams (Mount and Hume 2005).

The first critical step in developing adhesion in dentistry occurred in 1955, when Buonocore reported the acid-etch process for pretreatment of enamel (Buonocore 1955). This employed solutions of phosphoric acid at 37% concentration, and when enamel surfaces were pretreated in this way, microscopic surface irregularities were created, and polymeric filling materials were able to flow into them before hardening. Once these materials had hardened, there was an interlocking effect that strongly united the filling material with the tooth. Shear bond strengths of the order of 20–25 MPa were obtained, which were enough for the resulting bonded filling to withstand the forces of biting and chewing, and to show very good retention rates.

At the time that this work was carried out, the existence of the smear layer was not known. It was obvious, however, that the acid-etch process was critical to successful bonding and that it involved the development of a surface to which bonding could

occur. The concentration of the phosphoric acid was critical, too. The apparently arbitrary concentration of 37% lies halfway between 25%, which was too dilute to be effective, and 50%, which is so concentrated that it removes too much tooth material, and does not result in the formation of a satisfactory interlock bond.

Acid etching owes part of its success to the nature of the enamel. Enamel contains very little protein or water and can therefore be dried without causing the structure to collapse. Clinically, the procedure leads to the observation of a chalky appearance to the enamel, which can be taken as an indication that etching has been successful and the surface is ready to receive the bonding layer.

Bonding to dentin has proved much more challenging. Dentin is wetter than enamel and contains protein in the form of collagen fibers. Acid etching as developed by Buonocore is much less successful when applied to dentin than to enamel, and shear bond strengths are much lower, typically lying in the region 5–10 MPa. This is because etching with 37% phosphoric acid changes the nature of the dentin surface, and it ceases to be a hard, mineralized tissue. Instead, removal of the mineral phase by the acid leaves behind a soft, collagen-rich surface structure, which collapses when dried with air. Unlike etched enamel, the resulting mat of collagen fibers forms only weak bonds with organic monomers, which is why the resulting shear bond strengths are low.

In order to form satisfactory bonds to dentin, it is important to replace the mineral component by monomer (generally termed “resin” by researchers in this field). This resin infiltration needs to take place immediately after removal of the mineral phase, or even possibly at the same time as the mineral phase is being removed, so that the collagen fibers do not collapse. This leads to the formation of an artificial structure consisting of resin-impregnated collagen fibers, which is known as the *hybrid layer* (Nakabayashi et al. 1982; Wang and Spencer 2003). The hybrid layer is strong, and is also sufficiently hydrophobic to allow the polymer-based composite resins to bond to it. Its depth varies with length of the infiltration step, and lies between 2.1 and 4.1  $\mu\text{m}$  (Nakabayashi and Saimi 1996).

In addition to hybrid layer formation, pretreatment of the surface may remove the smear layer and, more important, the smear plugs, thus opening up the tubules of the dentine. Uncured monomer (resin) is then able to flow into these open tubules and form rigid tags on polymerization. This provides an additional mechanism of retention. However, studies have shown that it is the formation of the hybrid layer that makes the biggest contribution to the bond strengths and that even resin systems that are too viscous to flow into the tubules and form resin tags are capable of generating high strength adhesive bonds (Nicholson 2000).

Pretreatment of the cut dentine surface was, for many years, carried out using weak organic acids, such as citric acid or ethylene diamine tetra-acetic acid (EDTA). This was recommended partly on the grounds of the proximity of the pulp. More recently, however, phosphoric acid has been used to etch the surface of dentin, so that similar pretreatments are now recommended for both types of tooth tissue (Nicholson 2000). This was originally called “total etch,” but is now more generally termed “etch-and-rinse” in order to emphasise that the treated surface must be rinsed before placing any further layer on it. In using this approach it is important to ensure

that the dentin is intact, and that there is no exposure of the pulp, and also that very short exposure times are used for phosphoric acid on dentin.

When the etch-and-rinse technique is used, it is important not to dry the tooth surface with air, in order to avoid the collapse of the collagen phase. This was originally known as the “wet” bonding technique, and was developed in the 1990s (Kanca 1996). It was important in simplifying the overall bonding process, and paved the way for the introduction of “etch-and-rinse” bonding agents, now considered one of the two important classes of bonding agent. These are typically based on organic solvents which are hydrophilic enough to interact with a surface containing reasonable amounts of water, such as acetone or ethanol (Tay et al. 1998). They can also dissolve the necessary organic monomers which form the resin layer in the surface of the cut tooth.

The question of how to prepare the tooth surface in order to obtain bonds that are strong and durable remains the subject of research, and there is evidence that the most effective technique varies with the type of bonding agent used. There is also the need to have reliable ways of determining success in bonding (Carvalho et al. 2012). Laboratory data on bond strength gives some information on possible clinical outcomes for bonded restorations, but the correlation is still uncertain. One problem is that laboratory studies typically use non-cariou tooth surfaces, and these differ significantly in their structure and morphology from surfaces affected by caries (Manolea et al. 2016).

Several studies of etching strategies on bond strength and durability have appeared in recent years. Etching remains popular and is also successful with enamel as the substrate using both etch-and-rinse and universal bonding agents (Takamizawa et al. 2016; Antoniazzi et al. 2016). With dentin, recent studies have suggested that dry-bonded etch-and-rinse systems can give strong bonds on both carious and non-cariou dentin, at least over a period of a year *in vitro* (Lenzi et al. 2016). Pre-etching has also been shown to improve the penetration of universal bonding agents into dentin, though this does not lead to improvements in bond strength (Wagner et al. 2014).

These recent laboratory findings have not received clinical endorsement. Generally clinical reports suggest that survival rates for bonded composite restorations are good, as described later in this chapter. However the state of the adhesive bond over time in clinical service is not known. It has been suggested that this subject should be given attention and that teeth repaired with composite resin then extracted for periodontal reasons could be examined carefully to determine the state of the bond, and in this way identify the characteristics of successful bonding agents (Carvalho et al. 2012).

---

## 57.4 Bonding Agents

Bonding agent is the term generally used in the field of adhesive dentistry to describe the substances applied to the surface of the tooth for use as an adhesive. Bonding agents are usually applied to the tooth surface by painting or dabbing them on using a

small brush. Manufacturers have formulated them mainly for application to dentin, and have used a variety of components. Details of formulations are generally not disclosed as they are proprietary, but it is known that the monomer 2-hydroxyethyl methacrylate (HEMA) is widely used in these blended materials. Other monomers known to be used include glutaraldehyde and mono- and dimethacrylates. As we have seen, acetone or ethanol, and also water may be employed as solvents for these systems.

The earliest systems consisted of three components, namely, (1) conditioning agent to fully or partially remove the smear layer, (2) primer for pretreating the dentin surface, and (3) bonding agent that was applied immediately before resin filling. Results with these systems were good, and have not so far been surpassed by any other systems. In clinical use, though, the use of such complicated systems was time consuming and not easy to tolerate by the patient, and so alternatives have been sought.

Modern formulations may combine primer and adhesive components in a single blend, in order to reduce the number of steps involved in the bonding process and to simplify the procedure for clinicians. Despite the widespread use of this approach, some sort of separate acid-etch process is required as the first step of bonding. This may be as a separate etching step, as in the etch-and-rinse approach, or as a combined etching/priming step using self-etching primers.

Etch-and-rinse adhesives are recommended for use with wet-bonding approach, to maintain the integrity of the collagen fibrils. Liquid bonding agent can be rubbed into the dentin surface as an alternative to brushing (Zander-Grande et al. 2011) in order to ensure good infiltration of the bonding agent into the tooth surface and to maintain adequate moisture content.

Self-etching primers are formulated differently from etch-and-rinse systems, and are acidic (Tay and Pashley 2001). They both etch and prime the surface in a single step without the need to rinse away the products of etching. Eliminating the rinse step has the advantage of reducing the technique sensitivity of the bonding process. This is because there is less chance of the clinician making mistakes during what is a very sensitive procedure.

Self-etching formulations are acidic because they contain acid-functional monomers, such as maleic acid. As a result of their acidity, these self-etching primers incorporate the components of the smear layer, a feature that cannot be avoided, as there is no rinse step to wash away the acid treated smear layer. However, this may not be desirable and there is evidence that retention of the smear layer components compromises the bond strength of these primers (Pashley and Carvalho 1997).

The acidity of self-etching primers varies depending on their composition, and these formulations may be classified as either weak or strong (Van Meerbeek et al. 2001). The mild self-etch primers have a pH of around 2, and dissolve the dentine surface only partially. A significant amount of mineral phase remains in the resulting hybrid layer and is bonded by carboxylate or phosphate groups from the acid-functional monomers in the primer formulation. These have been shown to give good clinical outcomes over periods of time of up to eight years (Peumans et al. 2010). By contrast, the strong self-etch primers have a pH as applied of around 1 or

below. This gives them a more aggressive interaction with the smear layer and causes them to generate a bonded surface that closely resembles the surface produced by the etch-and-rinse approach.

As well as etch-and-rinse and self-etch bonding agents, there are some brands available that can be used in either mode and are described as “universal” (Sezinando 2014). The most extensively reported universal bonding agent is Scotchbond™ Universal Adhesive (3 M Oral Care) and this material has been found to give equivalent micro-tensile bond strengths in both etch-and-rinse and self-etch modes (Hanabusa et al. 2012, Munoz et al. 2013). The moisture content of the dentin substrate did not affect bond strengths, probably because the liquid bonding agent itself contains a high proportion of water (D’Hoore et al. 2001). Clinical outcomes with this bonding agent have also been shown to be good (Perdigao et al. 2014).

Within the field of adhesive dentistry, bonding agents have been classified by generation (Dunn 2003). This classification considers that Buonocore’s original approach led to the first generation bonding agent (Buonocore 1955) and that the most recent type is the seventh generation bonding agent. This is a single-layer, one-component self-etching system. More helpfully, bonding agents have recently been classified by number of steps involved (Nicholson and Czarnecka 2016). Since this is based on a fundamental aspect of their use, it is considered more helpful than classification by generations, and is shown in Table 2.

Detailed information on the composition of the various components of bonding agents is not available, due to considerations of commercial confidentiality. However, the various formulations are generally made up of appropriate blends of monomers that vary in how hydrophilic or hydrophobic they are. Resulting films tend to allow some passage of dentinal fluid through them (Tay and Pashley 2003) and there is some evidence that this may assist hydrolytic degradation in service. Unfortunately, little data is available on the long-term clinical durability of these

**Table 2** Classification of modern bonding agents for dentistry (Nicholson and Czarnecka 2016)

Number of steps	Number of bottles	Type	Description	Comments
4	3	Etch-and-rinse	Etch, rinse, apply primer, then bonding agent	Complicated to use but results in the highest reliable bond strengths.
3	2	Etch-and-rinse	Etch, rinse, then apply prime & bond in one step	Agent for priming and bonding is in a single bottle. Gives reasonable bond strengths.
2	2	Self-etch	Apply self-etching primer, then bonding agent	Self-etching primer incorporates smear layer.
1	1	Self-etch	A single formulation comprising blended self-etching primer and bonding agent	Easiest to use. Gives acceptable bond strengths.

bonding agents, and most publications deal with short-term bond strengths, so the extent to which this interaction with dentinal fluid promotes degradation not clear.

Bonding studies have typically reported data for shear bond strengths, though there have also been a number of studies using tensile bond strengths. Values reported vary somewhat, as has been shown, depending on the nature of the particular bonding agent. Reported results typically lie in the range 15–25 MPa for shear bond strengths (Al-Ehaideb and Mohammed 2000; El Kalla and Garcia-Godoy 1998; May et al. 1997), though higher values have been reported. Tensile bond strengths, by contrast, typically lie around 10 MPa (May et al. 1997).

---

## 57.5 Evaluation of Bonding Agents

Clinical trials are the most appropriate tests of the effectiveness of bonding agents. However, they are time consuming and in vitro laboratory tests are more often used instead. Such tests are typically carried out on human teeth that have been extracted for orthodontic reasons or on bovine teeth, and shear bond strength and micro-tensile bond strengths are widely used as indicators of bonding effectiveness.

Results from these experiments need to be evaluated with care. For one thing, given the complex nature of the surface pretreatment processes, bond strength values are not simply material properties. Rather, they reflect a complex interaction between the strength of the composite resin bonded with the bonding agent, the nature of the bonding agent, the stress rate, and the sample size and its overall geometry (De Munk et al. 2005). Despite the need for caution in interpreting these results, useful information can be obtained from this type of test. For example, information on durability and on the effect of thermal cycling is best obtained from such tests.

---

## 57.6 Leakage and Bonding Agents

A clinical issue with bonding agents is the extent to which they have the ability to create a complete seal at the interface with the tooth. This is important to prevent exposure of the dentin to fluids from the mouth. Such exposure may lead to further decay beneath the restoration and may ultimately damage the pulp. Larger voids may allow bacteria to migrate into the space and this may also lead to further decay and associated damage.

The most widely studied of the types of leakage is known as microleakage. It is defined as the clinically undetectable passage of bacteria or fluids between a cavity wall and the restorative material (Kidd 1976). All of the bonding agents currently available for clinical use seem able to prevent this phenomenon and to seal the restorative margins fully.

Microleakage has conventionally been studied in vitro using dye penetration techniques, in which an organic dye dissolved in water is used to highlight the path of any imperfections through the interface between the tooth and the bonding agent/composite resin. This is a broadly satisfactory approach, although there can be

problems with it, as leakage may occur through the dentin rather than through the interface.

Even where there are no gaps capable of admitting a dye solution between the bonding agent and the substrate, some leakage of dentinal fluid has been found to occur (Sano et al. 1995; Tay and Pashley 2003). It is known as nano-leakage and is detectable with  $\text{Ag}^+$  ions in solution, typically as silver nitrate. Silver ions are much smaller than the dye molecules, and they will pass across an interface that is able to exclude dye solutions. Since its discovery as a phenomenon, nano-leakage has been widely studied in bonding agents and shown to take place through regions of enhanced permeability within the matrix of the composite resin.

Any voids associated with nano-leakage are too small to admit bacteria and so it is doubtful if they are in themselves sources of further tooth decay or other immediate clinical problems. However, they may well act as sites of hydrolytic degradation of the bonding agent and may thus grow to the point at which bacteria and their metabolic products may be admitted. This then leads to potential damage to the underlying tooth tissue.

---

## 57.7 Composite Resins

The materials which are retained in place using the bonding agents described in the preceding sections are the dental composite resins. Although all types of aesthetic dental repair materials are composites as defined in materials science, within dentistry the term is restricted to a particular group of materials (Nicholson 2000). These are based on relatively high molar mass monomers, such as bisGMA, an adduct of bisphenol A and glycidyl methacrylate, or urethane dimethacrylate (UDMA). In formulating composite resins for clinical use, these macromonomers may be diluted with other less viscous components, such as ethylene glycol dimethacrylate, and filled with an unreactive filler, such as silica or a barium silicate glass. Stress transfer between matrix and filler is aided by the use of a coupling agent, typically  $\gamma$ -methacroyloxy propyl trimethoxy silane.

Modern composite resins are cured by application of visible light at 470 nm, which activates a photo-sensitive initiator such as camphorquinone. The camphorquinone readily dissociates to form free radicals when exposed to visible light, and these bring about a cure reaction, converting the highly viscous paste to a hard, durable solid material. Typical material properties of these materials are shown in Table 3.

The advantage of composite resins is that they are esthetic (i.e., tooth-colored), and they are also durable. Reports of durability suggest that they are capable of surviving between 7 and 10 years in most patients, though this varies with the general state of oral hygiene of the patient.

Composite resins have an important disadvantage, though, and that is that, because they set by an addition polymerization mechanism, they are prone to shrink on setting. This may cause problems of leakage around the restoration, and also movement of the cusps of the tooth where bonding is particularly strong. These

**Table 3** Properties of composite resins (from McCabe and Walls 2008)

Property	Typical components/values
Main monomer	bisGMA or UDMA
Filler	50–78 wt% glass or quartz

problems are minimized in clinical use by curing the composite resin in increments, gradually building up a full restoration layer by layer.

Within the family of composite resins are the polyacid-modified composite resins, so-called *compomers* (Nicholson 2006). These include components similar to those of glass-ionomer cements, that is, an acid-leachable glass as part of the filler phase, and a small proportion of acid-functional monomer. After setting by addition polymerization, these materials are able to draw in small amounts of moisture in the mouth, and this promotes a secondary acid–base reaction within the matrix. Studies suggest that this is of little practical benefit, though it does help liberate fluoride from the reactive glass filler, and thus allow these materials to release a small amount of fluoride steadily over prolonged periods of time. Like the conventional composite resins, polyacid-modified composites are used in conjunction with bonding agents in order for them to be retained adhesively within the tooth.

### 57.8 Durability of Bonded Composite Resin Restorations

The durability of bonds formed by bonding agents to enamel and dentin is critical to the clinical success of bonded composite restorations. Many studies have concentrated on short-term results only, typically as short as 24 h, and have neglected the fact that these bonds change with time. This is caused by a variety of factors (Breschi et al. 2008).

The first factor to be taken into account in considering bond durability is the ageing of the hybrid layer. This arises for a variety of reasons. There are natural variations in the temperature in the mouth, due to the consumption of hot and cold foods and beverages, and these affect the properties of the bond over time. The bond may also be affected by the consumption of acid foodstuffs, because these affect the hybrid layer by attacking the unprotected collagen fibers chemically. Lastly, the resin itself may undergo degradation *in situ*, resulting in loss of bond strength. Such degradation is typically hydrolytic in character and occurs due to uptake of water by the bonding layer, followed by reaction of the water with ester groups in the resin. Eventually, this leads to loss of portions of bonding agent, and an opening of the bonding layer to further infiltration and hydrolytic degradation.

Since many formulations of bonding agents combine hydrophilic or even ionic monomers with hydrophobic components, cured bonding agents may admit water

fairly easily. Indeed, they may behave as semipermeable membranes, forming distinct water channels within them in response to the ingress of the surrounding saliva. Water movement through bonding agents can be driven by osmotic pressure gradients arising because there are inorganic ions and hydrophilic monomers present, and in extreme cases this may result in the formation of water blisters over the adhesive layer (Breschi et al. 2008).

There is evidence that the new and simpler adhesives are less predictable in their long-term performance than the more established multi-step systems. Various suggestions have been made for improving their performance, of which the most practical appear to be (a) use of a hydrophobic coating and (b) application with extended cure time. This latter step improves the degree of polymerization and reduces the permeability of the bonding layer. It is thus a straightforward way of improving the long-term performance of modern adhesives.

---

## 57.9 Biocompatibility of Bonding Agents

Biocompatibility is defined as “the ability to perform with an appropriate host response in a specific location” (Williams 1987). Its study is complex and beyond the scope of this chapter, but it needs to be considered briefly in the context of the use of bonding agents in clinical dentistry. The tissues involved range in sensitivity from the completely inert (enamel) to the extremely delicate (the pulp), and their response to the range of types of chemical involved in bonding, including acids, monomers, and solvents, varies widely.

An important feature controlling the biocompatibility of bonding agents is the permeability of the dentin and also its thickness. This will determine whether or not monomers diffuse all the way through to the pulp and whether they arrive at sufficiently high concentrations to cause damage.

Of particular concern in these studies has been the presence of 2 hydroxethyl methacrylate (HEMA). This has been shown experimentally to be able to diffuse through the pulp chamber when released from a bonding agent placed beneath a composite resin (Hamid and Hume 1997). Thickness made a difference to the rate of diffusion, but even relatively thick layers of dentin (i.e., in the range 3.4–3.6 mm) were not sufficient to eliminate it completely. Another finding of significance was that diffusion of HEMA was much more rapid in teeth that had been severely affected by caries. In other words, the reason that tooth repair is needed clinically, caries, turns out to be responsible for affecting dentin permeability adversely, and opens the way for potentially harmful monomers to reach the pulp.

HEMA and other monomers used in bonding agents have been shown to be cytotoxic (Hume and Gerzina 1996). They inhibit cell proliferation and decrease mitochondrial activity significantly. The latter means that energy transduction processes in the living cells are affected adversely.

In a fully healthy tooth, pulp fibroblast cells differentiate into odontoblasts, and these cells contribute to the development of the tooth. Low concentrations of bonding agent monomers have been shown to affect this development. A variety

of processes can be affected at levels well below toxic concentration, including expression of collagen 1, osteonectin, and dental sialoprotein. This, in turn, affects the formation of mineral structures within the tooth (Bouillaguet et al. 2000).

Overall, it is clear that dentin bonding agents show significant levels of cytotoxicity to the cells of the pulp. Clinically, though, there has been little concern about this finding and no reported adverse effects in vivo. Reports of sensitivity, discomfort, or even complete death of the pulp have been notably absent from the clinical literature. It seems that biological testing in vitro may have exaggerated the extent to which bonding agents pose a threat.

Release of only small quantities of monomer may mean that only very small amounts reach the pulp itself under clinical conditions. Also, there is fluid circulation within the living pulp, and this may wash away diffusing monomers and potentially reduce the concentrations to below those needed for major cytotoxic damage to occur. Current clinical opinion is strongly supportive of the use of bonding agents in dentistry, despite the volume of data on their possible adverse biological effects.

---

## 57.10 Adhesive Dental Restorative Materials

In this section, the three naturally dental restorative materials will be considered. These are the zinc polycarboxylate cement and the glass-ionomer cements. The latter come in two broad groups, the conventional and the resin-modified glass-ionomers. In all three cases, they are placed as viscous pastes, pressed into place by the dentist to ensure that any surface irregularities are filled, and allowed to cure. They then harden and are finished by shaping them to the structure of the natural tooth with various carving tools. These materials will each be considered in turn.

Zinc polycarboxylate was the first of the adhesive dental restorative materials to be described. It was invented by Smith (1968) who reported that it was fabricated from aqueous polyacrylic acid and deactivated zinc oxide, and that it had excellent adhesion to both dentin and enamel. It was also found to have other desirable properties. For example, it set rapidly with minimal shrinkage, it was bland toward the soft tissues of the mouth, and it was almost completely insoluble in saliva (Smith 1968). Zinc polycarboxylate cement can thus be considered a major development in the field of adhesive dentistry. Typical properties of zinc polycarboxylate cement are shown in Table 4.

Sometime after its introduction to the dental profession, formulations of zinc polycarboxylate were made available in which the finely divided zinc oxide is combined with a dried powder of polyacrylic acid. The mixture is activated by the addition of an appropriate amount of water, and the whole mass sets rapidly to a solid, hard mass that is indistinguishable from formulations prepared from solutions of pre-dissolved polyacrylic acid. Set cements are opaque, due to the presence in them of considerable amounts of unreacted zinc oxide powder, which acts as a reinforcing filler.

Zinc polycarboxylate cements rapidly found use in clinical restorative dentistry. Applications included cavity lining, luting of crowns, and adhesion of orthodontic

t.1	<b>Table 4</b> Properties of zinc polycarboxylate cement	Property	Typical components/values
t.2		Liquid	40–50% polyacrylic acid
t.3		Powder: liquid ratio	2.5–3:1
t.4		Setting time	2.4–4 min
t.5		Compressive strength	80–100 MPa

564 brackets (see Sect. 14). They remain in use for these applications, but have been  
565 displaced to an extent by glass-ionomer cements.

566 The zinc oxide powder for these cements is modified, partly by mixing with small  
567 quantities of magnesium oxide, and partly by heat treatment at temperatures of  
568 between 1100 °C and 1200 °C. This reduces the reactivity toward polyacrylic acid  
569 so that the cement does not set too rapidly. Heat treatment causes a slight yellowing  
570 of the zinc oxide, due to the loss of a very small proportion of the oxygen. The  
571 resulting material is very slightly non-stoichiometric, with a formula corresponding  
572 to  $\text{ZnO}_{(1-x)}$ , where  $x$  is 70 ppm or less (Greenwood and Earnshaw 1984).

573 The bonding strengths of zinc polycarboxylates have been found to be adequate  
574 but not outstanding. Tensile bond strength values of the order of 4–6.5 MPa have  
575 been found for them to enamel in in vitro studies (Brantley and Eliades 2001).  
576 Tensile bond strengths to dentin are lower, suggesting that bonding takes place  
577 primarily to the mineral phase. Actual bond strengths may be higher than these  
578 reported figures, because failure is typically clearly cohesive within the cement,  
579 rather than adhesive in nature.

580 Studies have shown that bond strength varies with thickness of zinc poly-  
581 carboxylate cement. One study showed that the adhesive layer thickness was  
582 maximum at 205  $\mu\text{m}$  (Akinmade and Nicholson 1995) when bonding stainless  
583 steel strips together and determining bond strength in shear. Values ranged from  
584 2.5 to 4 MPa.

585 Zinc polycarboxylate cements not only form adequate bonds to enamel and  
586 dentin, they will also bond to base metals used in dentistry, and also to gold.  
587 However, there is almost no adhesive bond formed on the surface of porcelain  
588 (McCabe and Walls 2008).

589 The next adhesive repair material to become available to the dental profession  
590 was the glass-ionomer cement, which was first described by Wilson and Kent in  
591 1972 (Wilson and Kent 1972). These materials are now used in clinical dentistry  
592 for a variety of aspects of the repair of teeth damaged by dental decay. Depending  
593 on how they are formulated, they may be used as liners and bases or as full  
594 restorations, and they may also be formulated for other clinical uses, as shown in  
595 Table 5. They are esthetic in that they match the natural color of the tooth and,  
596 like the zinc polycarboxylate cement, they are able to bond directly to the surface  
597 of the tooth. They have the additional feature of being able to release small  
598 amounts of fluoride. This is generally considered beneficial preventing further  
599 decay of the repaired tooth, though this point has not been confirmed by clinical  
600 studies.

Glass-ionomers are usually made from polyacrylic acid, although acrylic acid/maleic acid copolymer is used in some brands as an alternative. Typically, an aqueous solution of this polymer is mixed with a special ion-leachable glass of complex composition. The glass is basic, and consists of an alumino-silicate structure augmented with phosphate and also containing fluoride species, such as  $\text{CaF}_2$  or cryolite,  $\text{Na}_3\text{AlF}_6$ . Setting occurs by neutralization, and involves the polymeric acid molecules being cross-linked with multivalent counter-ions ( $\text{Ca}^{2+}$ ,  $\text{Sr}^{2+}$ ,  $\text{Al}^{3+}$ ) after they have been leached from the glass. As indicated, the glasses are complex and often contain two phases, either completely or partially separated. The setting reaction is, therefore, also complicated and involves not only the formation of ionically cross-linked polymer chains but also hydration processes, the details of which are not yet clear. There is also evidence that an inorganic network forming species from the glass, consisting of phosphate moieties, contributes to the strengthening processes that occur in the cement matrix.

Whatever the detail of the setting reactions, they take place fairly rapidly so that typically after about 5 min the cement hardens and can then be finished by the dentist. Subsequently, some slow reactions take place that bring about maturation. This maturation causes gradual increases in translucency and compressive strength and takes place over several weeks following the initial hardening. The final product is a rigid material that has a porcelain-like appearance.

As well as the original glass-ionomer cement described above, there is another variation known as the resin-modified glass-ionomer cement (RMGIC). Like the conventional glass-ionomer, RMGIC contains a basic ion-leachable glass powder, and also a water-soluble polymeric acid. However, this type of material also contains water-soluble organic monomer, usually 2-hydroxyethyl methacrylate (HEMA). An initiator system is also required to bring about additional polymerization of the HEMA (Mitra 1991a).

In most RMGICs the initiator system is photosensitive, and most RMGICs are light cured. Initiators used are sensitive to blue light of wavelength 470 nm, which is the main light emitted by conventional dental curing lamps.

Some brands of RMGIC contain modified polymers. Typically, these are based on poly (acrylic acid) but contain a minority of branches that are terminated in vinyl groups. These undergo copolymerization with the HEMA on irradiation, which means that the final material contains organic as well as ionic cross-links when cured. Typical properties are given in Table 6.

Like conventional glass-ionomers, RMGICs form strong adhesive bonds to enamel and dentine (Mitra 1991b) and also release fluoride. The presence of

**Table 6** Typical properties of resin-modified glass-ionomer cement

Property	Typical components/values
Liquid	40–50% polyacrylic acid, plus 2-hydroxyethyl methacrylate (HEMA)
Powder:liquid ratio	3:1
Setting time	30 s (on application of curing lamp)
Compressive strength	150–180 MPa

HEMA causes the set RMGIC to have some hydrogel character, which means they are capable of swelling in water. In saliva, any such swelling occurs only slightly, if at all, so this does not pose any clinical problems.

RMGICs were originally developed for use as liners and bases in dentistry (Wilson 1990), but have since been formulated for use as complete restoratives. They can also be used for core build-up and for luting, though for the latter application, they are not photocured. Rather, they are cured with a two-part initiator that forms free radicals on mixing, so that they are able to set in the dark. They are widely used, and are reported to be reliable materials capable of giving good results in service. They have been particularly used in pediatric dentistry as alternatives to amalgam.

Based on observations from HEMA-based dental bonding agents, the presence of HEMA has been suggested to compromise the biocompatibility of RMGICs (Nicholson and Czarnecka 2008b). HEMA is released from RMGICs especially in the first 24 h. As already mentioned, it is able to diffuse through the dentin and affect the pulp, to which it has been shown to exhibit cytotoxicity. It may also have systemic effects on dental personnel, including contact dermatitis (Geukins and Goossens 2001) and sensitization (Katsumo et al. 1996). Safety precautions have been recommended for dental personnel using these materials, mainly to ensure good ventilation of the work place and to avoid breathing HEMA vapor from the unset RMGIC.

### 57.11 Bonding of Glass-Ionomer Cements

Glass-ionomers of all types are able to form adhesive bonds to the surface of the tooth. In order to do so under clinical conditions, the newly cut enamel and/or dentin surfaces are generally treated with a dilute solution of polyacrylic acid, typically at 10% concentration. This is a much milder treatment than that used with current bonding agents for composite resins and is more akin to pretreatments used with third generation bonding agents.

Conditioning with polyacrylic acid results in removal of the smear layer and of the smear plugs, and opens up the dentinal tubules (Fig. 2). It does not, however, lead to loss of much, if any, intact tooth mineral from the surface.

The glass-ionomer cement is then applied and allowed to cure. For conventional glass-ionomers, this occurs simply through the acid–base setting reaction already described; for RMGICs, it is generally brought about by exposure to a curing lamp.

**Fig. 2** SEM of dentin conditioned with 10–15 s application of 10% aqueous polyacrylic acid, magnification  $\times 900$  (Mount 1994)

Restorations of RMGIC are often completed in increments, to offset the polymerization shrinkage, as is the case for composite resins.

There have been many published studies of the bond strength of freshly placed glass-ionomers to tooth surfaces. Results obtained are generally relatively low, typically in the range 3–7 MPa when tested in shear. However, this has been shown, in reality, to be a measure of the tensile strength of the glass-ionomer, rather than the shear strength of the bond, as failure tends to be cohesive in nature (Mount 1991). Measured shear bond strengths for RMGICs tend to be slightly higher than for conventional glass-ionomers, a reflection of their higher tensile strengths (Mitra 1991b).

Despite the relatively low shear bond strengths, durability of glass-ionomer cements in clinical service is good. Studies have shown that survival rates may exceed those of bonded composite resins (Burgess et al. 1994), though there are problems about undertaking comparisons with the most recently developed materials and systems, since survival data and information on durability take several years to obtain.

Studies of marginal leakage with glass-ionomers, both conventional and resin modified, have given variable results. It is therefore not possible to draw conclusions about whether conventional or resin-modified glass-ionomers perform better in this

regard. However, it is possible to say that both types may exhibit marginal leakage and that neither is completely reliable in sealing enamel margins. Conversely there have been no satisfactory reports of the development of secondary caries below glass-ionomer restorations, which suggests that even if they leak they are sufficiently anticariogenic to prevent further tooth decay. This anticariogenic character may be attributed to the fluoride release in situ.

Glass-ionomers have been found to show distinct interactions with the tooth surface over the longer term. In an important paper, Ngo et al. (1997) showed that there was a pronounced zone formed at the interface between glass-ionomer cements and the tooth (Fig. 3). This study involved low-temperature Scanning Electron Microscopy examination of freshly extracted teeth that had been filled with a strontium-based conventional glass-ionomer and allowed to mature for 4 days. The interaction zone that formed within this time was not only clearly visible, but shown in subsequent studies to contain both calcium and strontium. Since there was originally no calcium in the cement and little or no strontium in the surface of the dentin, this result can only mean that there has been some sort of chemical reaction between the cement and the dentin to create this structure. Furthermore, it shows that adhesion of glass-ionomer cements involves an ion-exchange process.

Developments in tooth-colored restorative materials have caused some confusion within the dental profession. First, resin-modified glass-ionomers were launched and their composition, in terms of monomer and light-activated initiator, gave them some similarities with composite resins. Soon afterward, the compomers became available. They had a modest but distinct acid-base character which was responsible for maturation reactions within the material. This group of composites thus had some clear glass-ionomer character. The situation was clarified in a paper published in the mid-1990s (McLean et al. 1994), and a system of nomenclature was proposed that has subsequently been widely adopted.

**Fig. 3** Low temperature SEM of interaction zone between glass-ionomer cement (*top*) and dentin (*beneath*), magnification  $\times 4317$  (Ngo et al. 1997)

Recently, this field has been reviewed (Mount et al. 2009) and the conclusion drawn that recent research shows it is the mechanism of bonding that is the most important distinction between the tooth-colored restorative materials. The ion-exchange mechanism can only occur in materials with a substantial acid-base setting mechanism, and this only occurs with glass-ionomer cements. No amount of modification can make systems that are fundamentally hydrophobic, and which set exclusive by polymerization, that is, composite resins, capable of undergoing ion-exchange bonding. These materials will always need bespoke and discrete bonding agents, of the type previously described.

---

## 57.12 ART Technique

The clinical technique known as Atraumatic Restorative Treatment (ART) has been developed since the mid-1980s in response to dental clinical needs in Third World countries. It is an important application of adhesive dental materials, specifically conventional glass-ionomer cements, and would not be possible without this type of adhesive material (Frencken et al. 2004). ART involves the removal of carious tooth tissue with hand instruments rather than conventional dental drills. These hand-held instruments take the form of spoon-shaped excavators, and come in graded sizes.

Following excavation of the soft carious matter, the cavity is cleaned and filled with freshly mixed glass-ionomer cement. Associated pits and fissures within the tooth are filled at the same time. This technique does not require electricity or clean water, so is particularly suitable for settings in the developing world where these facilities are either absent or unreliable.

Adhesive materials are essential for this technique because the tooth can only be excavated to remove soft matter, not drilled to extend the cavities with undercuts. This sort of mechanical retention is required by silver amalgam fillings, and cannot be deployed in regions where the drill cannot be used. The hand-operated excavators used in ART are not capable of removing undamaged enamel or dentin, so cannot be used to prepare undercut cavities.

Clinical reports covering 25 years experience have shown that ART is an effective treatment in a variety of countries of the world (Frencken et al. 2012). Modern conventional glass-ionomer cements for use with this technique have been formulated with optimized particle size and size-distribution glass powders, and they are found to perform very well in patients. Long survival times are being recorded, with almost no problems of debonding in clinical service.

---

## 57.13 Glass-Ionomer Fissure Sealants

Fissure sealing is a preventive technique carried out on newly erupted teeth. Deep fissures in such teeth may act as sites into which plaque and pellicle may become occluded, and it cannot be removed from these sites by brushing. Left undisturbed, this is likely to result in the development of caries.

So-called sealing of these fissures involves minor clinical procedures. First, the plaque and the pellicle are removed using a dental bur, after which the fissure is widened slightly but only within the enamel. To complete the process, some sort of filling material is placed in the newly opened fissure.

For some time, the material of choice was considered to be an unfilled resin, essentially a low viscosity blend of the type of monomers used in conventional composite resins. Such fissure sealants have good retention, which is obviously highly desirable.

However, there is beginning to be a shift in clinical opinion that favors glass-ionomers for this application. Initial results with these materials were not promising, for a variety of reasons. Their early bond strengths are lower than those of resin systems, and they had inferior wear resistance. This meant that they appeared to be lost fairly rapidly. Careful study shows, though, that this does not mean that the treated teeth are no longer protected. Teeth treated in this way do not develop caries and protection may last for at least 6 years (Pardi et al. 2003). This surprising result occurs for two reasons.

First, glass-ionomer fissure sealants release fluoride in amounts that are protective to the surrounding tooth tissue. Second, not all of a glass-ionomer sealant is actually lost. Deep within the fissures, glass-ionomer sealants are retained and not only retained, but also transformed over time. Changes which occur include increasing translucency, improvement in smoothness and in hardness, and elevation in the calcium and phosphate ion concentrations in the surface layer. These alterations take of the order of 2–3 years to develop and seem to be akin to the development of artificial enamel (Van Duinen et al. 2004).

It must be emphasized that this structural change in the glass-ionomer fissure sealant only occurs in the base of the fissures. The rest of the glass-ionomer typically disappears within a few months. The modified glass-ionomer tends to show integration with the adjacent enamel, with excellent sealing. There is no occurrence of caries and every appearance of strong adhesion, though no bond strength data have yet been reported. These findings are similar to those previously discussed for glass-ionomer restorative materials, which also develop strong adhesive bonds with time and show elevated calcium and phosphate levels in the surface following prolonged contact with saliva.

---

## 57.14 Bonding in Orthodontics

Orthodontics is that branch of clinical dentistry concerned with correctly aligning crooked teeth. This is typically carried out during the teenage years, and involves applying brackets to several of the teeth, and connecting them with high-tensile strength wires. Successive visits to the orthodontist are made, and in each the tension in the wires is increased, thus applying a force that causes the tooth to move within the socket and to be retained there permanently. This is due to changes in the shape of the supporting bone around the socket. Brackets are typically retained on the tooth, either mechanically, or by bonding.

The earliest attempts to bond orthodontic brackets used epoxy resins. However, these adhesives were difficult to use, and so this approach did not find much support within the dental profession. In modern orthodontic practice, bonding agents similar to those used in other parts of dentistry are used. This means the deployment of either bonded composite resins or glass-ionomer cements.

Direct bonding of orthodontic brackets uses the acid-etch technique, with phosphoric acid gel to etch the surface and deliver the initial pretreatment (Kitayama et al. 2007). This is followed by the application of bonding agents or of lightly filled or completely unfilled resins to the surface. These form attachments to the surface mechanically by flowing into the irregularities created in the etching step.

A clinical problem with this technique is that brackets bonded by composite resins in this way have a tendency to develop regions of demineralization around them. This leads to the formation of white spots on the tooth surface. Typically where white spot lesions develop, they affect several teeth of a patient.

Another problem is that, when the time comes to remove the brackets, damage may occur to the surface of the tooth. This is because the bond strength generated by this technique is so high that the enamel shears in preference to debonding.

To overcome the problems of “white spot” lesions, and also to exploit the lower inherent bond strength, glass-ionomer cements are increasingly being used for this application. Their ability to release fluoride ensures that there are no sites of demineralization, hence no white spot formation. There is also much less damage when the brackets are removed (Charles 1998).

---

## 57.15 Conclusions

This chapter describes the principal uses of adhesives in clinical dentistry, and covers both the materials and the clinical techniques involved. The subject is of enormous importance in modern dentistry and is connected with the growing interest in the use of tooth-colored repair materials.

The two types of tooth-colored material, namely, the composite resin and the glass-ionomer cement, are described, together with their current variations. Composite resins are bonded with specific bonding agents, and these substances may be used in either etch-and-rinse or self-etch modes. This technology continues to evolve rapidly, and recent advances in the field are covered in detail. Surface pretreatment is critical for the success with bonding and current understanding of this topic is reviewed as well.

Glass-ionomers are naturally adhesive to both dentin and enamel, though some sort of surface pretreatment is necessary prior to their use. Typically this consists of conditioning the freshly cut tooth surface with dilute aqueous polyacrylic acid, followed by rinsing away the products. Glass-ionomers then bond firmly to the tooth, partly through the development of a mechanically strong ion-exchange layer at the interface that develops with time. This bonding ability is exploited in the important technique of ART, created for use in Third World countries to treat the

growing problem of tooth decay. Glass-ionomers are also used as bonding agents for orthodontic brackets.

Zinc polycarboxylate cement, the first adhesive dental restorative material, is also described in this chapter, though it now has only niche applications in dentistry.

**Abstract**

Adhesives are increasingly being used in medicine for repairing cuts and tears in the body as an alternative to mechanical fixation such as sutures. There are very strict regulations controlling the application of adhesives within the body and this means that there are only a limited number of chemistries which are approved for clinical use. The principal internal adhesives in current use are those based on fibrin, gelatin, and poly(ethylene glycol) (PEG) hydrogels and function largely as sealants, though do bond to the tissue surfaces. Cyanoacrylates are approved, mostly only for application to the surface of the skin for wound closure, but are quite widely used in a range of other applications. There are many requirements of an adhesive for internal use and this has led to large number of further systems being proposed. A number of those currently being evaluated for internal

indications are described. Some are based on synthetic chemistry, some from biological sources such as marine creatures, and some are akin to welding or soldering.

Pressure-sensitive adhesives are widely used for securing dressings and devices to the skin surface. Most of these are now based on acrylic or silicone chemistries.

---

## 58.1 Introduction

In simplest terms, the human body is made up of organs and tissues held together in a way which maintains their mechanical integrity and ability to function correctly. However, there are occasions when, due to accident, surgery or wear, some of these tissues or organs fail. In many cases, the body is capable of repairing naturally but sometimes needs assistance with this. Surgery has developed to such an extent that it is frequently possible to refasten or repair the failure such that the tissue can repair itself and regain its normal function, albeit in a scarred state. Initially, these surgical procedures consisted of provision of a mechanical fixation, but more recently a range of adhesive products and techniques have been developed to replace or augment these, analogously to the substitution of adhesives for nails, screws, bolts and rivets in engineering. This chapter aims to summarize the current state of this technology – adhesion and adhesives for repairing the human body. These may be adhesives for repair of internal organs, or for topical application to the skin, alone or on dressings. They are distinguished as adhesives for contact with body tissue, applied for the most part by medical professionals, though with one exception: dentistry is not included. The use of adhesives is well established in dentistry and will not be covered further here as it is the subject of ► [Chap. 57, “Adhesive Dentistry.”](#)

There are a number of other aspects of adhesion in medicine which will only be touched on here. Adhesives are used widely in the manufacture of medical devices. Some of these applications require the adhesive to be in contact with body material, such as recirculating blood, and are therefore subject to some of the strict regulations which are imposed on products with body contact (Tavakoli et al. 2005). Other aspects of adhesion include the aggregation of cells and proteins onto foreign surfaces within the body, forming biofilms, the desired adhesion of cells in culture onto scaffolds for tissue engineering in the regeneration of organs, and the undesirable adhesion, known as “adhesions” between scarred tissues which can produce serious complications after surgery.

---

## 58.2 Mechanical Fastening

Traditionally, repair of damage to the body has been performed by surgeons using mechanical means. The most familiar of these is the suture, a thread of resorbable or non-resorbable polymer, which is stitched through soft tissue using a specially designed needle. Pulling the tissue edges together encourages the formation of a

bond between them as the tissue regrows. When repair is complete, the surgeon may return to remove the sutures or they may degrade and eventually be excreted by the body. Suturing is usually fairly straightforward and medical professionals are trained in its use. It can also be easily removed and reapplied should there be a problem. It has the disadvantage, though, of only holding the tissue at discrete points, leaving less well-secured gaps between these which may be susceptible to leakage (see, e.g., Fig. 1a). More recent developments in soft tissue fixation include metallic staples and barbed polymeric darts, and when fixation is required to hard tissue, there are ranges of interference screws available. Securing pieces of bone mechanically is usually done using plates, held in place with screws, or by the use of long intramedullary nails which can be inserted down the medullary canal in the long bones, and then held fast by transverse screws at the ends. Metallic repair means may be surgically removed after the tissue has healed, but are frequently left in place if they do not cause a problem for the patient.

Externally, the skin may be sutured or bandaged to give support during natural healing. However, crude adhesives, such as tar, have long been used to protect sites of severe damage.

## 58.3 Adhesives Technologies for Internal Applications

### 58.3.1 Overview

From the time of the introduction of the first adhesive used in an internal application, fibrin sealant, some clinicians have been seeking adhesive solutions to problems in the internal repair of the body, aiming to achieve excellent performance without the problems related to the use of the traditional mechanical means of repair such as localized fixation and the need for removal. Chemists and biologists have been keen to support them in this quest and have produced a wide range of different materials

**Fig. 1** Surgical repair of the dura. (a) Mechanical fastening, suturing, does not result in a watertight closure. (b) Adjunctive use of a patch to the closure seals the gap (Images provided courtesy of Tissuemed Ltd.)

with the ability to bond one or more tissue types. Initial experimentation is performed on ex vivo tissue and many materials show some promise in that environment. The ability to bond is, naturally, essential, but is not the only requirement, and many systems which showed initial promise proved not to work when applied in vivo or gave too many undesirable side effects to be permitted for human use. Beyond that, other systems may be successful technically but not be of wide-enough application, or appeal to enough clinical users and purchasers, to be a commercial success and so may be withdrawn from the market. The technical, techno-commercial, and medical literature has many examples of initially promising materials which are not available for clinical use.

This section aims to describe some of the requirements for a tissue adhesive for internal application and then to give further details on the principal materials which are commercially available and clinically used (though not necessarily permitted in all countries). All materials are described generically as chemical species, without brand names and manufacturers' details as these can frequently change and may also differ between countries, potentially leading to confusion. In addition, some of the more promising and distinct developments of potential novel surgical adhesives are described, though usually in less detail. There can be no guarantee that any of these will ever be successful, but it is to be hoped that some will and that further inventors may be inspired to come forward and test new ideas as the subject is still very much alive and there are still many unmet needs for this technology within the clinical community.

### **58.3.2 Requirements of an Adhesive for Internal Use**

The body provides a very distinct environment in which to apply adhesives. There are therefore many special requirements placed on any material considered for this application. Internal use requires stricter provisions than for adhesives which are purely in contact with intact skin. First and foremost they have to be safe. Materials sticking to the body cannot contain chemicals which are toxic to the body or to the cells in their vicinity. In addition, the material must not cause sensitization either for the patient or for the user. Nor must it produce an immune response – rejection – from the body. Safety testing must be comprehensively performed before new chemicals are permitted in these applications.

As with any device or material intended for use in medicine, medical adhesives cannot be sold for clinical use without regulatory clearance from the relevant national authority. This is to ensure, as far as possible, the safety of the product for the designated indication or indications. Different countries impose different requirements on products, which also depend on the nature of the device or material and its intended use. These frequently require extensive testing, both preclinically on animals and clinically in carefully controlled studies on humans, as well as the provision of other safety data. Because of the different regulations, products may be found on sale in one country but restricted in others.

The material must not introduce organisms which might be harmful for the body or for the repair. It must therefore be intrinsically sterile (as produced) or capable of being adequately sterilized. Sterilization is performed by heat (autoclaving), chemical and heat (ethylene oxide), or ionizing radiation (gamma rays), all of which involve the application of much energy. This energy will often be sufficient to initiate chemical reactions, such as the curing of adhesives, so developers of medical adhesives have to include means of ensuring that the adhesives are protected from any possibility of this.

Clearly, a medical adhesive must be capable of reliable secure bonding of the tissue that is to be bonded. Not all tissue is the same. An early misapprehension in the development of medical adhesives was that one adhesive would work everywhere. Subsequent experience has proved that this is not the case. Different formulations have been developed for different tissue types. The moisture content, the fat content, and the protein and polysaccharide content differ, and bone also has mineral content (Duck 1990). It has been found that the strongest bonds occur when there is true chemical bonding to the substrate material (Wilson et al. 2005). Almost universally, the area to be bonded is wet, which is a challenge for many conventional adhesives, and even if it can be temporarily dried at the time of application, the bond will soon be wet again.

The bond must form rapidly as it is unsafe and inefficient for surgery to take longer than strictly necessary. In most cases, a surgeon will opt for a quick action rather than a prolonged surgery. However, it is possible for bonding to occur too rapidly, leading to fixation of an incorrect placement. Related is the concern over adhesive spills or leakage from the joint. It should ideally be possible to see and remove safely any adhesive which gets in the wrong place, though the nature of the adhesive and means of dispensing it should be designed so as to avoid this happening at all. Adhesive products are sometimes colored (usually with a shade of blue), so that they may be distinguished from the surrounding tissue. Figure 5 shows an example of this.

The purpose of most tissue adhesives is to hold the tissue together so that fluids (e.g., blood) do not leak and it is able to heal naturally. Healing may be a slow process, taking several days, so the bond must last as long as the process, ultimately degrading as the tissue is able to regain the necessary strength. Healing, though, will only occur if the adhesive has not formed a barrier to its progress. Several medical adhesives are therefore applied as “patches” or “sleeves,” bridging the gap in tissue, while not penetrating between the tissue surfaces (Fig. 1b). The breakdown products of the adhesive must be safe to the patient and not harmful to the repair process. In general, this requirement is more likely to be met by adhesives of a biological origin, but synthetic and semisynthetic adhesives may also be safe, or the small quantities of material and slow release rate may lead to breakdown products being present in such small concentrations as not to be a problem. In a few cases, it may be necessary for the medical adhesive to provide a permanent fixation, and not to degrade away, if the tissue is not capable of regeneration.

As has already been indicated, packaging and delivery of the adhesive is of key importance. The packaging must keep the material sterile and, for multicomponent

materials, separate. It must be easy to use, and, to remove the possibility of cross-infection by multiple uses, contain the volumes needed to achieve a single repair on one patient, although a second application may be needed in some cases. Application must be foolproof, simple (surgeons' hands may be required to perform many functions), and permit accurate delivery with minimal spillage. Where two components are concerned, the way in which they are mixed, for example, through a mixing nozzle, multi-jet spray, or by sequential delivery, must be reliable and not lead to problems, such as premature setting, clogging the delivery.

### 58.3.3 Categories of Adhesives

Medical adhesives may be categorized in various ways. Clinicians would probably choose listing by the indications for which they may be used. In this chapter, adhesives have been divided into different groups depending on the similarities of the chemistry and technology. There are separate sections below for adhesives which are produced entirely by synthetic chemistry and for those of biological origin. Naturally, there is some crossover where synthetic molecules are used with biological products, and some "biological" materials are being produced by identification of the functional components of a natural product and then reproducing these by a synthetic route. Laser welding and soldering are somewhat different means of producing adhesion between tissues and are covered in a separate section.

### 58.3.4 Synthetic Adhesives

#### Cyanoacrylates

Cyanoacrylates are widely used in a range of engineering applications where instant strong bonding is required when using a minimum of adhesive material. The adhesive only requires a small amount of water on the surfaces in order to set off the polymerization reaction that forms the bond. These features are clearly attractive in a medical context, so it is not surprising that the use of cyanoacrylates in surgery (of small blood vessels) was attempted before 1960. A number of problems were then discovered which have led to only slow adoption over the intervening years, though recently this has gathered pace, particularly after 1998, when the US Food and Drug Administration (FDA) first approved cyanoacrylate products for specific indications, initially external to the body and, more recently, for a few very specific internal applications.

The fundamental structure of a cyanoacrylate is given in Fig. 2. The R group can be one of many different species, though usually alkyl, giving rise to a large family of different molecules with different properties. The adhesive is a low viscosity liquid which cures by anionic polymerization, and the process is exothermic. The reaction can be set off by hydroxyl ions, or similar chemistry, such as hydroxyl or amine groups present in proteins in the tissue surface. Thus, cyanoacrylate is capable of bonding covalently to the tissue surface (Wilson et al. 2005) which contributes, along with its

**Fig. 2** The structure of a cyanoacrylate monomer. R can be selected from many different species; see text for details

ease of penetration into the structure of the surface before curing, to the very strong bonds which it can make to most tissue types (Chivers and Wolowacz 1997). The choice of alkyl group in the molecule is very important. Domestic and industrial “superglues” are usually methyl or ethyl cyanoacrylates. These were initially tried in medical applications and found to be unsatisfactory. The curing reaction was too fast, leading to tissue necrosis due to overheating and the rate of subsequent degradation was also too rapid (Woodward et al. 1965). Larger alkyl groups were found to be more successful and the most commonly used medical cyanoacrylates are currently *n*-butyl-2-cyanoacrylate and octyl-2-cyanoacrylate. In addition to these molecules, formulations include stabilizers to permit sterilization and to reduce the likelihood of polymerization during storage, and thickeners, usually poly(methyl methacrylate) (PMMA) or polymerized cyanoacrylate. The hardness and inflexibility of cured cyanoacrylate can be reduced by the use of other additives. Low curing rates of the octyl- monomer, which otherwise has the advantage of giving a more flexible polymer, can be improved by adding accelerators at the point of delivery.

In the early days of their use, medical cyanoacrylate adhesives received bad publicity due to tissue damage at the site of use. This may have been due to the exothermic curing reaction but may also have been due to the degradation products of the polymer (Leonard et al. 1966). Cyanoacrylates degrade hydrolytically by a reverse Knoevenagel reaction to formaldehyde and alkyl cyanoacetate. Concerns about formaldehyde released into the body have led to many considering it as the major cause of the problem, and several routes have been attempted to reduce the likelihood of its release by altering the chemistry or adding agents to capture it (e.g., Leung and Clark 1994). However, as formaldehyde release is only a potential problem *within* the body, cyanoacrylates have become widely used and approved as a topical means of skin closure in accident and emergency situations, where the adhesive is delivered across the laceration (not in between opposing edges) using careful control of the flow. This process is shown in Fig. 3. The result can be good secure holding of the wound, excellent sealing to provide a barrier to microbial ingress, and also a good cosmesis after the adhesive has sloughed off the surface and the wound is healed (Quinn et al. 1997). Figure 4 shows a comparison of wounds from laparoscopic surgery closed using sutures and using cyanoacrylate. It is only recently that the US FDA has approved this application as a Class III device, for topical use only, initially in 1998 for octyl-2-cyanoacrylate and later (in 2002) for *n*-butyl-2-cyanoacrylate (Mattamal 2005).

Cyanoacrylates have been widely used experimentally in a great number of surgical procedures, particularly in eye and ear surgery, which are largely external to the body

**Fig. 3** Application of a cyanoacrylate adhesive to close a skin wound (Published with permission of MedLogic Global Ltd.)

**Fig. 4** Comparison of wounds post laparoscopic surgery closed (a) using sutures and (b) with cyanoacrylate (Published with permission of MedLogic Global Ltd.)

(Quinn 2005). One internal application has also been approved by the US FDA. This is for a formulation of which the major ingredient is *n*-butyl-2-cyanoacrylate. The application is for neurologic embolization in the skull (Mattamal 2005). A cyanoacrylate adhesive, with a special delivery device, has recently been launched in several countries as a fixation means for polypropylene hernia mesh. It is believed that cyanoacrylate adhesives are used off-label for a range of other internal conditions.

## Modified Gelatin

An early commercial medical adhesive was made from gelatin, resorcinol and formaldehyde and is therefore known as GRF (Braunwald et al. 1966). The gelatin is a bioresorbable polymer which can be cross-linked with formaldehyde, and this may also crosslink to the tissue surfaces. Resorcinol can also be cross-linked by formaldehyde, making a stronger bond. However, on enzymatic degradation, the formaldehyde is released. The issues with formaldehyde which are perceived with cyanoacrylates are therefore also present here, but this has not stopped the material from being widely used, though not in the USA, particularly in aortic dissection repairs and also in liver and kidney surgery. The gelatin-resorcinol mixture is a viscous paste which has to be heated to 45°C before application and then mixed with an aqueous solution of formaldehyde, usually containing some glutaraldehyde as well, as it is delivered to the tissue.

Concerns about the formaldehyde have led to several modifications of this system. In a prominent commercial product, it is replaced by a mixture of glutaraldehyde (pentane-1,5-dial) and glyoxal (ethanedial) (Ennker et al. 1994a, b). This formulation is also used for aortic dissections.

A further alternative is to replace the gelatin with another protein, albumin, and an adhesive sealant is commercially available containing 45% albumin solution which is mixed with 10% glutaraldehyde solution as it is delivered to the repair site. This is successful particularly for hemostasis in cardiac and vascular surgery (Chao and Torchiana 2003).

## Polyurethanes

Polyurethanes are formed from the reaction of diisocyanates and diols to make a prepolymer, usually a paste, which can then further polymerize in moist conditions to give a cross-linked strong material. As the body provides a moist environment for bonding, it is not surprising that many groups have attempted to make polyurethane adhesives for medical applications. Indeed, these were some of the earliest surgical adhesives to be explored and were considered particularly for bonding bone. Obviously, the materials have to be able to degrade to safe products, and therefore lactides and caprolactones have featured in the formulations. However, these have not made a commercial success, because of adverse reactions and because of difficulties in obtaining suitable reaction rates. Most are found to cure too slowly.

Recently, several new urethane systems have been developed with chain extenders derived from lysine or other hydrolyzable, bioresorbable molecules (Gilbert et al. 2008). These are now approved for sale in Europe and the USA for the approximation of tissue layers where subcutaneous dead space exists between the tissue planes in abdominoplasty.

## Synthetic Hydrogels

Much body tissue is effectively a hydrogel. Any adhesive used in the body has to be compatible with the high water content and mechanical properties of tissue, so it is not surprising that hydrogels have been widely used for tissue bonding and

sealing. Many of these are based on poly(ethylene glycol) (PEG), which may be cross-linked by a number of means after derivatization to make these reactive, for example, with tetra-succinimidyl and tetra-thiol residues (Wallace et al. 2001), to give the necessary cohesive strength. Two-component systems have been commercialized for sealant applications, such as for incisions in the dura mater, lungs, and blood vessels (Bennett et al. 2003). The two components, PEG and a cross-linker, trilycine, both with reactive end groups and in separate solutions each with very low viscosity, are delivered together, often by spraying. The reaction is very rapid, producing a film which seals over the defect and bonds mechanically to the tissue surface by penetration of the precursors into its crevices, followed by curing. Figure 5 shows the result of application of such a system during lung surgery. The material breaks down over time in the body and the components are excreted.

Hydrogels may alternatively be cross-linked by derivatization with photocurable monomers. This has the advantage of curing only when the light is shone and the disadvantage of working only in “line of sight” of the light source (Sawhney et al. 1993).

A further series of experimental systems use an aminated star PEG cross-linked with dextran aldehydes. The aldehyde not only cross-links the PEG but also bonds chemically to the tissue surface, so varying the aldehyde content can give a range of bond strengths. It is claimed that this chemistry can thereby be tailored to create adhesives for different tissue types (Artzi et al. 2009).

Several workers have been attempting to mimic the performance of fibrins without the need to use blood-based materials with their attendant risks. These formulations include gelatin cross-linked with a calcium-independent microbial transglutaminase (McDermott et al. 2004) and other gelatin-based materials.

**Fig. 5** Use of a sprayed two-component hydrogel sealant during lung surgery. The sealant (in the lower middle of the picture) contains blue dye to enable the surgeon to see where it is and to judge the thickness of the application (Copyright © 2010 Covidien. ## Other Synthetic Adhesive Materials

Most of the adhesives discussed here for surgical use are delivered in the form of one or more fluids which cure (react) on the tissue surface to produce a bond and also cross-link to develop cohesive strength. An alternative approach is to make a dry film which already has mechanical integrity and which is coated with materials which react on contact with the wet tissue surface to give a strong bond (Thompson 2009). This therefore has some similarities with the wound dressings which are discussed later in this chapter, but there are numerous differences as these commercial “patches” are intended for internal application for sealing leaks of fluid, for example, air leaks in the lungs, blood leaks and cerebrospinal fluid leaks through the dura, but not for holding the tissue in place. An example of its application to seal the dura is shown in Fig. 1b where the sutures holding the tissue together may also be clearly seen through the film. A resorbable biocompatible film of poly(DL-lactide-co-glycolide) is coated with a layer of a terpolymer of polyvinylpyrrolidone (PVP), polyacrylic acid (PAA) and N-hydroxysuccinimide (NHS). This layer becomes rapidly hydrated on making contact with the tissue surface due to the presence of PVP. The PAA gives tack to the film, producing rapid adherence to the tissue, while the NHS is capable of covalent bonding to the tissue surface. A patch like this will degrade in the body over time with the degradation products being excreted, so leaving no residue.

Bone contains inorganic material, mostly calcium-containing minerals such as hydroxyapatite. Bone defects are often surgically filled with cements made of a variety of calcium phosphates which are found to enhance the healing of the bone. The bonding of the filler to the bone is mostly by mechanical interlocking, and therefore not very strong, but it has been found that some magnesium-containing mineral compounds can be used as adhesives, making stronger bonds to help with the initial fixation of the bone. These have been used, for example, in the fixation of bone-tendon grafts for the reconstruction of the anterior cruciate ligament (ACL) (Gulotta et al. 2008).

Glass ionomer cements have been used for some years in dentistry for bonding restorations to teeth. It has been found in certain circumstances that these can also be used for bonding bone, though as the current formulations contain acrylic polymers, these are not resorbable and can only be used in situations where the bond is intended to be permanent and not replaced by regrowth of the tissue. One such commercial application is for repair of the tiny bones in the ear (Tysome and Harcourt 2005).

## 58.3.5 Biological Adhesives

### Fibrin

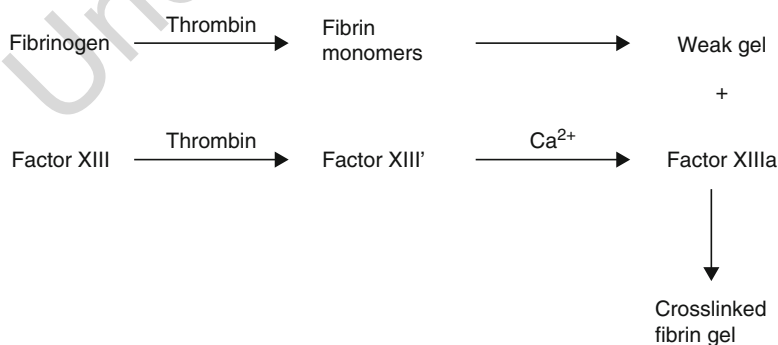

Fibrin adhesives have been used for longer than any other tissue adhesive, being first applied in the mid-twentieth century, although they were not sold commercially until 1978. Frequently referred to as fibrin sealants as their ability to seal leaks is more significant than their mechanical strength, they are widely used in a variety of surgical procedures, and more so in recent years after the approval by the US FDA

of one product in 1998 for certain indications and a second product in 2003 (Spotnitz et al. 2005).

Fibrin adhesives contain several constituents. These are fibrinogen, thrombin, factor XIII and calcium ions (usually as calcium chloride) as well as fibrinolytic inhibitors, such as aprotinin, tranexamic acid, or aminocaproic acid (Sierra 1993). The fibrinogen and factor XIII are typically prepared from human blood sources, usually pooled from carefully screened donors and then treated to inactivate any viruses present (MacPhee 1996) either by cryoprecipitation and freeze drying or by solvent detergent cleaning, heat pasteurization and nanofiltration (Spotnitz et al. 2005). The thrombin and aprotinin are sometimes from human and sometimes from bovine sources. Recombinant processes are being sought for these materials. Some products contain the components as lyophilized powders and solutions that have to be mixed just prior to application, while others are supplied as a liquid to be stored at or below  $-18^{\circ}\text{C}$  and then gently thawed before use. Fibrinogen may also be obtained by extraction from the patient's own blood. This is known as autologous fibrin, and is prepared during surgery by taking blood before the operation and centrifuging it to extract fibrinogen. This is naturally somewhat time consuming but has the advantage of eliminating any chance of virus transmission. The viscosity of the preparation and low strength of the resulting adhesive are limitations of material from this source.

The chemistry of the process of formation of the adhesive material from the ingredients is given in Fig. 6 and resembles the final stages of the coagulation (clotting) of blood. Essentially, the thrombin cleaves fibrinopeptides A and B from the fibrinogen molecule to leave fibrin. This polymerizes to form a soft clot, which is cross-linked by the transglutaminase factor XIIIa, which is produced by the action of thrombin on factor XIII in the presence of calcium ions (Marx 1996; Webster and West 2001). The initial soft clot formation is relatively quick but produces a weak material. The cross-linking is a slower process, taking typically about 2 h, giving rise to a considerable increase in strength by formation of covalent bonds and possibly contributing some bonding to collagen in the tissue surfaces (Marx 1996;

**Fig. 6** Schematic of the formation of fibrin adhesive from its ingredients. This occurs in-situ at the time of use

Donkerwolke et al. 1998). In addition, the cross-linking stabilizes the clot to proteolytic degradation by plasmin. It has been found that different concentrations of the different components can affect the time to cross-link and the strength of the resulting bond (Marx 1996). However, as the materials are of natural origin, it is not always possible to control the ratios precisely.

As a pure biological adhesive resembling blood clots, the fibrin adhesive is able to break down naturally in the body on a timescale resembling that for the tissue to heal (Lontz et al. 1996). Degradation typically occurs in about 2 weeks (Lauto et al. 2008).

Since the bond strength of fibrin adhesives to tissue is not very high (Chivers and Wolowacz 1997), the material is usually used as an adjunct to mechanical fastening such as sutures, hence frequently being referred to as a sealant. It has the advantage of excellent hemostasis and is hence very useful in applications where blood leakage is a problem. In the USA, regulatory approval has been given for several applications where its primary purpose is for hemostasis during surgery on internal organs such as the spleen and liver. It is, however, also used for controlling blood loss during many types of surgery, including orthopedic, and is excellent for sealing blood vessels after suturing and before the blood is readmitted. It may be used for sealing other vessels which do not contain blood, such as lymphatic vessels and the dura containing cerebrospinal fluid, and can be applied to seal an anastomosis (reconnection) of the colon and also air leaks in the lung, although the low strength of fibrin means that special care has to be taken in the latter case when preparing and monitoring the seal. As an adhesive, fibrin has found application in plastic surgery, where it can be used to attach skin grafts to the underlying tissue, though care has to be taken to ensure that it does not act as a barrier to tissue integration under the graft. In these various applications, the bond is most effective if the tissue surfaces are as dry as possible when the fibrin is used, and care must be taken that the bond not be disrupted while cross-linking as pre-cross-linked fibrin can be effective as an antiadhesive (Spotnitz et al. 2005). One of the first applications of fibrin adhesive, one which is still used, is in nerve anastomosis.

An additional application of fibrin is as a delivery means for a variety of pharmaceuticals such as antibiotics, because of its ability to adhere to tissue and so deliver the drug locally, as well as its safe degradation pathways (MacPhee et al. 1996; Webster and West 2001).

### Modified Fibrin

Attempts have been made by several workers to overcome the limitations of fibrin adhesives while maintaining the basic fibrin chemistry. These retain the basic components, unlike those synthetic mimics which have been mentioned above. One way of doing this is to mix fibrillar type I collagen into the fibrinogen/factor XIII solution. When formulated correctly, this enhances the viscosity of the initial solution and therefore its ability to stay at the site where needed, though still permitting easy delivery. In addition, the stiffness and strength of the cross-linked adhesive are enhanced, giving the material greater toughness and ability to withstand loads in use. Effectively it is a fibre-reinforced composite (Sierra 1996). This

technology has been commercialized in a number of formats including: collagen and thrombin to mix with the autologous fibrinogen thus enhancing the otherwise poor properties of autologous fibrin adhesives, collagen fleece coated with lyophilized fibrin adhesive components ready to soak to activate as a patch, and collagen (gelatin) with thrombin which acts as a hemostat with the patient's own blood (Oz et al. 2003).

### Adhesives from Shellfish

The ability of shellfish, such as mussels and barnacles, to stick to underwater structures and remain stuck despite considerable mechanical disturbance, such as due to waves and tides, has long attracted scientists looking for candidate adhesives suitable for medical application where the substrates are wet, the temperature may be up to or over 37 °C, and there is mechanical stress. Since many synthetic adhesives suffer from an inability to stick underwater, an adhesive material which clearly works in wet conditions becomes particularly attractive. Many shellfish-based systems have been assessed, but the most studied has been the byssus, or attachment thread, of several species of mussel, including *Mytilus edulis*. This thread of solidified adhesive ends in an adhesive plaque complex which forms a very strong bond to the substrate surface (Waite 1987; Silverman and Roberto 2007; Forooshani and Lee 2017). Adhesives (known as mussel adhesive proteins or MAPs) can be extracted from the mussels, but it takes a huge number to produce sufficient material for commercial use. Various groups have therefore worked on the identification and synthesis of the essential components of the natural protein in an attempt to be able to produce a MAP without resorting to mussels. It has been found that one of the protein residues essential for bonding (initial chemisorption to the surface and then cross-linking of the adhesive) is 3,4-dihydroxy-L-phenylalanine (DOPA). Any material which resembles MAP will contain this. Genetic engineering may be a route to large-scale production of suitable proteins, but so far this has only succeeded in producing DOPA-containing peptides, not the full sequences of native MAPs. Synthetic analogs are being developed by several groups, for example Yu and Deming 1998 prepared simple copolypeptides of DOPA with L-lysine which, when mixed with certain oxidizing agents, gave good bond strengths to several nonbiological surfaces. An alternative approach has been developed (Lee et al. 2006; Burke et al. 2007), in which the DOPA residues are chemically coupled to PEG molecules and crosslink these rapidly when in the correct oxidation state. The PEG makes up about 80–95% of the formulation which can lead to undesirable side-effects as it swells considerably in an aqueous environment. Further developments include a DOPA-containing block copolymer gel which exhibits a sol-gel transition between room and body temperature and a DOPA-containing monomer (with an acrylate group) which can be photopolymerized (Lee et al. 2006). Recent work has concentrated on putting a wide variety of functional groups onto the catechol to modify the crosslinking and hence control swelling and the mechanical robustness of the structure while altering its ability to bond to surfaces. Different oxidation states of catechol have been found to be needed for bonding to organic tissues from those required when the substrate, such as bone, contains mineral particles (Forooshani and Lee 2017).

## Other Adhesive Technologies

The use of biological molecules has a number of potential advantages in resorption and biocompatibility, though not necessarily in immunogenicity. There is therefore an interest in finding and developing new adhesive systems from biological sources. Many of these are still in the research stage, far from commercialization, and are summarized below to give an idea of the range of ideas being considered.

Attempts are being made to produce proteins (resembling silk and elastin) using recombinant technology from synthetic genes. In this way, specific molecular structures can be constructed to have the desired biological effects, such as good elasticity and bonding to tissue surfaces in the body, while, it is claimed, not having the potentially undesirable side effects which can be shown by wholly natural materials (Cappello 1991).

A number of organisms produce adhesive materials that serve them in a variety of ways, including defense, attack, and to help create protection. As they are naturally produced, they are biocompatible and usually naturally degrade to safe molecules. They are also able to stick in wet environments. Several of these materials have been assessed for use as medical adhesives with promising results.

The sticky secretion from the back of frogs from the genus *Notaden* has been explored by workers in Australia (Graham et al. 2006). This exudate was extracted by stimulating the backs of the frogs and tested in peeling on ex vivo meniscal tissue. Bond strengths exceeded those produced by GRF and fibrin adhesives but not *n*-butyl-2-cyanoacrylate, and it was found that the adhesive functioned primarily as a pressure-sensitive adhesive (PSA) in that the strength was largely unaffected on breaking and reforming the joint.

Shellfish are not the only organisms using adhesives to ensure that they remain in place despite battery from waves and tides. Red and brown algae also produce adhesives, based on polyphenols, which can bond nonspecifically to both hydrophobic and hydrophilic surfaces under water. These have also been investigated, and synthetic analogues have been made which can successfully mimic this performance and are postulated as a soft tissue adhesive (Bitton and Bianco-Peled 2008).

A challenge with any of these is the ability to obtain sufficient for commercial use. These materials are usually made by the organism in very small quantities and harvesting in bulk would be difficult. Preferred approaches are therefore either to identify the essential active molecules and synthesize these (as with mussel adhesion) or to find a way of producing these by using genetic engineering processes.

The mechanism of reversible adhesion used by geckos to walk on walls and ceilings is of interest to several research groups which would like to develop applications using synthetic mimics of this. Unfortunately, gecko adhesion, which is the result of van der Waals interactions between large number of nanoscale pillars and a surface, has been found not to be very effective in the wet, reducing its potential in medical applications. A possible way of overcoming this is being developed in which the nanoscale pillars, made of poly(dimethyl siloxane) (PDMS), are coated with a synthetic mimic of mussel adhesive: poly(dopamine methacrylamide-co-methoxyethyl acrylate) (Lee et al. 2007). The inventors believe that this could have applications as a temporary adhesive for use in the wet in medical settings.

### 58.3.6 Laser Welding and Soldering

The use of light to activate adhesives has been mentioned above offering the advantage that the time of activation is precisely controlled, but the disadvantage of only working in the beam of light. Alternative applications of “light” (including infrared and ultraviolet radiation) have been developed for the clinical bonding of tissue. These are known as welding when light alone is used and soldering when a material is cured with the light (Bass et al. 1996; Lauto et al. 2008).

When tissue is heated, the proteins in it coagulate to form a hard sticky mass. This is similar to the cooking of egg-white. A laser can provide a precise beam of infrared radiation to the edges of two pieces of soft tissue and can weld these together. This is a quick procedure and does not produce the damage that sutures can, but a hazard of this is that the tissue may become too hot and cells could be damaged. This can be reduced by applying a chromophore, which can preferentially absorb the radiation, converting it to heat. For the usual medical infrared laser wavelength of 808 nm, indocyanine green (ICG) is an approved, safe molecule with a maximum absorbance at the same wavelength.

Clinicians have generally found it preferable to apply a solder, a viscous solution of a protein such as albumin or fibronectin (Bass et al. 1996; Chivers 2000; Lauto et al. 2008). When mixed with ICG, this solder is applied over the tissue edges to be bonded and the area is irradiated with an infrared laser beam which is usually pulsed to reduce the net power delivered to the tissue. The enhanced absorption of the ICG enables the solder to reach the coagulation temperature of 65–70 °C well before the tissue has become warm, and the proteins are believed to intermingle with the collagen in the tissue to give a relatively strong repair which can degrade naturally over a clinically acceptable timescale. Concerns over the difficulty of applying a runny liquid and keeping it in place and the possibility of it being diluted by water at the surgical site have led to the development of solid solders, strips and patches of high (>53%) albumin concentration, which can be laid on the tissue surface or placed as a short tube over a cut vessel to be resealed and then irradiated to create the bond. As an alternative to proteins, a similar material has recently been created using chitosan, a polysaccharide (Lauto et al. 2008).

Other, solder-free welding techniques have been reported. One uses Rose Bengal dye activated by laser light at a wavelength of 514 nm, and another a dye made of 1,8 naphthalimide which can be activated by blue light and bonds to tissue seemingly without any heating.

## 58.4 Adhesives for External Application to the Skin

Although cyanoacrylates are now being widely used in the clinic for the closure of skin incisions, as described above, the principal adhesives used on the external surface of the body are pressure-sensitive adhesives. These are the only significant adhesives used on the body in which the application is

frequently not made by a clinician, as they are on first aid dressings and other products for home use.

Pressure-sensitive adhesives (PSAs) have long been used to hold tapes, dressings (Fig. 7), and other devices (e.g., electrodes and ostomy pouches) onto the skin. A further application of PSAs for skin contact is to deliver pharmaceutical agents by a transdermal route. Unlike most other applications of adhesives mentioned here, these are purely for topical use and are normally only in contact with intact skin. This greatly simplifies the regulatory approval process and permits a wide range of materials to be used in comparative safety. There are nevertheless some people who are sensitive to chemicals which may be used in adhesives and care must be taken to watch out for this in clinical practice.

Early PSAs were usually rubber based, containing natural rubber which needs to be modified by the addition of tackifiers, lanolin, and mineral filler to optimize performance. A traditional tackifier is colophony resin (gum rosin), another natural material. A disadvantage of these materials is that they are very poor at handling moisture. These adhesives have to be physically modified, usually by perforation, so that there is not an excessive moisture build-up under a dressing coated with rubber-resin adhesive. Other disadvantages include the lack of resistance to shear, and a tendency to fail in the adhesive mass (cohesive failure), resulting in adhesive

**Fig. 7** High performance wound dressings can be held securely in place on the skin using a pressure sensitive adhesive (Image copyright by Smith & Nephew April 2010)

residues being left on the skin around a dressing while being worn, and after removal. A variety of materials have since been used to make more “skin-friendly” adhesives with better mechanical and moisture-handling capabilities. These include, principally, acrylics and silicones, but there are also poly(vinyl ether)s and poly(vinyl pyrrolidone)s for certain specialist applications (Webster and West 2001). Formulations are continually being developed to attempt to improve these further.

The process of assessing a PSA for use on skin is extremely complex and relies a lot on subjective assessment. Many properties must be considered and have been widely discussed in the literature (Satas and Satas 1989; Chivers 2001). These include the ability to stick securely and yet be easily and safely removed, the ability to stay in place for several days despite the movement of the underlying skin, and the ability to handle moisture and to “breathe” with the skin. Naturally the adhesive is not used alone and must perform successfully when coated on a suitable backing material, usually a film or fabric.

The ability to stick is obvious, as patient health, wound protection and cleanliness can be compromised by a lifting dressing. In contrast, a skin PSA must be able to be removed easily, minimizing discomfort to the patient and risk of damage to skin which may be fragile, as well as ensuring that the adhesive residue is not left on the skin. While it may be thought that the pain experienced when a dressing is removed would be related to the force required to peel the dressing from the skin, it is by no means clear that this is the case. Peeling frequently removes a layer of dead skin cells from the skin surface. It is not known whether this contributes to the discomfort of dressing removal, but it can compromise the ability of the dressing to be repositioned as it can mask the adhesive. Frequent removal of dressings from the same site can cause reddening and even damage to the skin. For that reason, adhesives and systems have been developed which make removal easier (Chivers 2001). Some skin-friendly solvent products are available to help with this, particularly in difficult cases such as ostomy.

Shear of the adhesive is also undesirable as it can lead to dressings sliding from the site of attachment and leaving sticky residues exposed on the skin. These can fasten to clothing or bedding.

As already mentioned, the moisture handling is important, since human skin loses moisture in the form of water vapor at, typically, 200–500 g/m<sup>2</sup>/24 h and inability of any skin covering to cope with this leads to maceration, overhydration, of the skin. In extreme cases the dressing can come off if too wet, which it may also become if immersed in water, since the adhesives cannot stick in very wet conditions. Various ways of handling moisture are available – the formulation of the adhesive can help, but how it is spread on the backing is also important. Gaps may be deliberately produced in the adhesive film – by pattern spreading or perforations.

Developers of new formulations for medical PSAs have a range of in vitro testing methods which they use to help to evaluate these requirements. Ultimately, though, the performance of PSAs on skin is so subtle and subjective that only testing using the correct backing and on humans from the target population will give a true assessment of the acceptability of a new material.

## 58.5 Conclusions

Adhesives technology has two main applications in medicine as considered in this chapter: for internal fixation of tissues usually after surgery, and for use on the skin, primarily to hold dressings in place. There are many differences between the requirements of the technology for these applications.

Internal application is very carefully regulated as there is a need for extreme caution on safety grounds. Adhesives for this have to pass a series of tests before approval, and this may not be universal. Many chemical and biological systems have been tried and several are now in widespread clinical use. The appeal of an adhesive over the current mechanical means of fastening tissue has led many developers to attempt to create new materials from a range of sources. Some of these may be successful, but there is a long way to go in many cases.

Adhesive technology for external application is, by contrast, mature and many successful systems are available as the regulatory requirements are fewer. This has not stopped developers working to improve the existing products, and indeed to modify them for use on further dressing types and for other applications, such as for transdermal drug delivery.

## Abstract

Recycling and environmental aspects of adhesion technology are discussed in this chapter. Adhesively bonded adherends should be often separated before they can be recycled. For this purpose, dismantlable adhesives, which can be separated with stimulations, have been developed recently. There are lots of technical processes to realize such adhesives. For example, softening of adhesive, expansion force due to blowing agents or thermally expandable microcapsules, chemical degradation, electrochemical reaction, and taking advantage of interfacial

phenomena can be applied to dismantlable adhesives. These adhesives have many applications such as temporary joints of work materials, shoe making, integrated circuits (IC) chip fabrication, electronics, housing construction, car fabrication, and so on. The most used trigger to start the separation of these adhesives is heating. Many kinds of methods including infrared, induction, and microwave heating are recently available. In addition, novel dismantlable adhesives, which have anisotropy in strength or are triggered by electric currents, have been presented.

## 59.1 Introduction

Since adhesive bonding has many advantages such as low cost, light weight, easy application, etc., it is increasingly being used by modern industries. Adhesive bonding is more desirable than the other joining methods in terms of energy saving, so that its environmental load is small. However, the consumption of adhesives has been increasing drastically due to the industry globalization and the recent fast-growing of developing countries, and the total environmental load of adhesive bonding is also increasing. To meet environmental issues, the total environmental loads, although they are small, have to be reduced by all possible means.

Adhesive bonding has many aspects related to the environmental issue. One of them is energy consumption in some processes such as production, transportation, application, and curing of adhesives. Another one is recycling of adhesively bonded materials. Strictly speaking, there are other aspects such as recycling of adhesive itself and environmental contamination including vaporized organic chemical compounds (VOC). This chapter treats the recycling issue of adhesively bonded materials. The recycling of the adhesive itself is not dealt with because it is very difficult so far.

Adhesively bonded joints are not easy to separate if they are bonded with strong adhesives or the bonded area is large. Therefore, dismantlability of the joints is not required contrarily to the other joining methods such as mechanical fastening. The fact leads to scarce use of adhesion for substrates that have to be separated. However, a new type of adhesive called a “dismantlable adhesive” has been recently required to meet the demands to separate the adherend for recycling. For instance, a dismantlable design for a product is essential because the materials bonded together become bad wastes difficult to be recycled. However, if the materials can be separated, they become resources. The separation of parts is important even if they are bonded adhesively. Thus, dismantlable adhesives, which can be separated when and as we like, are increasingly required. An advantage of adhesive bonding is the ability to join dissimilar materials. However, it becomes a disadvantage if such materials cannot be recycled. Dismantlable adhesives are also appropriate to solve this problem.

Dismantlable adhesives, however, are thought difficult to realize because a good adhesive has been apprehended as strong and not being able to separate so far. The

effort to realize a good adhesive has been concentrated into this point. The capability to separate when we like is a totally different concept from the past efforts.

As a matter of fact, dismantlable adhesives, if they are weak in strength, have been present since fairly early times. Hot-melt adhesives, for instance, can be separated by heating. However, strong adhesives, especially structural adhesives, present a high technical hurdle to be dismantlable. The trend has been changing for the last decade and many dismantlable adhesives have been proposed as a kind of novel functional adhesives. Although their applications are mainly temporary joints of works or product reworks so far, adherend recycling has become an issue recently. In addition, the adhesives are applied to make separation mechanisms for aircrafts, space crafts, or robots. This chapter deals with dismantlable adhesives, whose development has proceeded very fast recently, and shows the results of recent research and technical trends.

## **59.2 Impact of Adhesion Bonding in the Environmental Issues**

### **59.2.1 Categories of Environmental Issues**

The main environmental issues can be categorized in three following items:

1. Hazardous material emission
2. Greenhouse gas emission
3. Use of finite resources

In this chapter, hazardous material emission is not treated (see ► [Chap. 39, “Environment and Safety”](#)). However, these items are not independent from each other and it is difficult to discuss them separately. Thus, the first item will be shortly referred in this chapter too.

Global warming is the most serious and important issue among environmental issues. There is a lot of theory or controversy on the effect brought by the problem and the time limit that we have for preventing vital results. However, it is certain that the final result is devastating to the global environment unless we can reduce, or sustain in the worst case, greenhouse gas emission. In this case, irreversible warming must occur within some decades. Although it is very rare for adhesives to emit greenhouse gases directly, the gases, mainly carbon dioxide, are possibly emitted during their production, application, curing, or disposal processes.

The third item, use of finite resources, may seem different from environmental issues. However, this should be included in environmental issues because the most important finite resource is fossil fuels such as petrol, and their combustion causes carbon dioxide. In addition, avoiding the use of finite resources without their recycling is indispensable to realize sustainable society. From this viewpoint, this item is also discussed in this chapter.

### 59.2.2 Greenhouse Gas Emission

The main greenhouse gas emitted during the processes of adhesive production, use, and disposal is carbon dioxide. In the production process of adhesives, energy due to fossil fuel may be used and this causes carbon dioxide. Energy should be used in the curing process of adhesives too. Since the raw materials of adhesives are mainly made from petrol, carbon dioxide should also be produced by incineration in the disposal process. In addition, the other greenhouse gases such as hydrocarbons or organic solvents may be emitted to the atmosphere during the production or application process of adhesives. Such greenhouse gases have higher warming effects per unit than carbon dioxide. Therefore, even their total amount of emission is small, attention should be paid.

### 59.2.3 Use of Finite Resources

Some raw materials of adhesives are derived from petrol. Therefore, if petrol resources are depleted, the production of adhesive cannot be maintained. This depletion is an ultimate situation, but even the price rise of petrol can give serious and negative impact to adhesive industries. An alternative option is the use of other fossil carbon resources such as coal. Coal is more abundant than petrol in terms of reserve. However, its carbon dioxide emission per unit is larger than that of petrol. Anyway, true sustainable societies cannot be realized while finite fossil resources such as petrol or coal are widely and often used. Energy consumed in the production process of adhesive and its curing process may be derived from fossil fuels too.

### 59.2.4 Basic Strategies to Meet the Challenge for Environmental Issues

The basic strategies to solve the environmental problems can be categorized as follows:

1. Use of eco-conscious materials
2. Provide reworkability or dismantlability to adhesives
3. Recycling of adhesives itself
4. Optimization of the bonding process
5. Design optimization and lifetime cycle assessment of adhesively bonded joints

In this section, they are explained respectively.

#### Use of Eco-Conscious Materials

Selection of raw materials for adhesives is very important to reduce environmental loads. At first, the raw materials should be environment friendly. Synthetic polymers

have relatively larger energy consumption in this production process than other materials such as fillers, including alumina powders, silica aerogels, calcium carbonate or talc consisting of minerals. Therefore, the composition of an adhesive is influential to the total environmental loads. In addition, if an adhesive is burned in the disposal process of the product bonded with it, carbon dioxide is emitted. As seen above, the presence of fillers can help to reduce the carbon dioxide emission because the portion of polymer in the adhesive decreases.

In order to reduce more effectively the environmental loads, use of recycled materials or carbon-neutral natural materials should be considered. Reclaimed rubbers are often used as the raw material of Pressure Sensitive Adhesive (PSA). Polystyrene foam used as shipping supplies can be solved with solvents and used as a raw material for adhesives. As such, recycled materials can be used to produce adhesives for the purposes of reducing environmental impacts and costs.

Use of carbon-neutral natural materials is another option. Since they absorb carbon dioxide from the air during their growing, the total amount of carbon dioxide in the atmosphere is not changed even if these materials are burned. Historically, natural materials are mainly used as raw materials for adhesives. For instance, glue, lacquer, and casein have been widely used to make adhesives (Fay 2005). They are natural materials and carbon-neutral. The other example of natural material use is the case of PSA. To make PSA, natural rubbers for the main component and rosins for tackifiers, which are derived from plants, are often used. They are also carbon-neutral. Recently, other natural materials have been investigated for raw materials of adhesives. For example, polylactide resin can be applied to the main components of adhesives (Viljanmaa et al. 2002). Lignophenolic resins derived from lumber (Kadota et al. 2004) and chitosan resin from exoskeleton of crustacean are other examples (Yamada et al. 2000; Umemura et al. 2003). Soy beans oils can be epoxidized and used for adhesive main components (Ratna and Banthia 2000). The powder of lumbers such as cork is promising as fillers for adhesives because it can give ductility to the cured bulk of adhesive (Jos and Leite 2007).

### **Reworkability or Dismantlability of Adhesives**

The key word “3R” is often referred when environmental issues are discussed. This word means “reduce,” “reuse,” and “recycle.” In order to reuse or recycle adhesively bonded materials, joint separation is often required. To meet this demand, a new type of adhesive called “dismantlable adhesive,” which can be separated on demand, has been invented.

Defective products due to malfunctioned parts bonded adhesively or to inappropriate adhesion are very bad in terms of environment protection because they become a waste without any use. Therefore, dismantlable adhesive can be used to avoid the situation because bonded parts or inappropriate bonded areas can be separated in order to be repaired. This process is called “reworking” of defect products and involved in the processes of “reducing” wastes and “reusing” other nondefective parts in terms of 3R. This topic will be discussed in more detail in Sect. 2.2.

### **Recycling of the Adhesive Itself**

Actual cases of adhesive recycling are still very rare because the amount of adhesive used in a product is much smaller than that of the adherend materials. In addition, adhesives consist usually of various kinds of materials. On the other hand, removing an adhesive layer from substrate is very difficult. Resolving obtained adhesive wastes by any solvent is also not easy because they are fully cured and cross-linked. However, the needs of sealant recycling are recently becoming important because the total amount of its use is huge. Thus, we should start to consider seriously the method to recycle sealant wastes.

### **Optimization of the Bonding Process**

If the bonding process is not optimized, large environmental loads occur. For instance, although the surfaces of adherends often need pretreatment before bonding, there is room to reduce environmental loads. The use of oil accommodating adhesives is effective for the purpose because degrease and chemical treatments of adherends are not necessary. Otherwise, if solvents are used for degreasing, they are hazardous and their atmospheric release is undesirable. Collection systems of solvent vapor are useful for reducing the atmospheric release. The collected solvent vapor can be used again after condensation or thermally recycled, although carbon dioxide is emitted in this case.

It is also effective to reduce sub materials used in adhesion processes such as wiping cloths, gloves, masking tapes, removing agents, mixing cups, brushes, and static mixing nozzles. Since most of them are disposable, much waste is made unless the bonding process is optimized. In addition, release sheets of PSA become a waste too.

Energy consumption to cure adhesives is also a problem. Capabilities of ambient temperature curing or relatively low temperature curing are desirable to be installed for adhesives. Some acrylic adhesives can be cured quickly at room temperatures and they are strong and tough enough to be used for structural applications. A promising epoxy adhesive for structural use, which is ambient temperature curable and heat resistant due to nano-fillers, has been recently presented (Sprenger et al. 2004).

### **Design Optimization and Life Cycle Assessment of Adhesively Bonded Joints**

Design optimization of adhesively bonded joints can contribute to environmental issues in a broad sense because it reduces the used materials and the weight of the joints. Precise knowledge of adhesives strength, modulus, and stress distribution in joints is helpful for designers, and it leads to rational design of the joints to minimize environmental loads. This point of view is likely to be missed, but very important. Adhesive making companies ought to provide positively the data to design joints appropriately. This is important not only for the optimal design, but also for preventing the duplication of basic tests that may be carried out by the adhesive maker and each user.

The other obligation of adhesive makers is disclosure of information for Life Cycle Assessment (LCA) of adhesively bonded joints. If these data are provided, the users of an adhesive can calculate the environmental impact associated with equivalent energy consumption or equivalent carbon dioxide emission. The later is called “carbon footprint” whose requests by users is recently increasing, and adhesives are not an exception. The users can evaluate the environmental impacts by LCA, and make rational decision to employ adhesive joining or not considering the total tradeoff of the whole life-cycle environmental loads of their products.

### **59.3 Types, Characteristics, and Applications of Dismantlable Adhesives**

The main purpose of dismantlable adhesives is reworking of parts or recycling of materials in a product. Temporary joining of works also needs dismantlable adhesives. Reworking of parts is a process in which defective parts are removed and exchanged by normally functioning parts. If the parts are vitally important, defects of the parts have a huge influence on the product value. If the parts are joined with a dismantlable adhesive, they can be separated and exchanged easily, and that leads to an increased yield ratio of the product. Electronic devices have integrated circuit (IC) chips on their circuit boards bonded with epoxy adhesives called under fillers. Recently, reworkable underfillers, which are softened by heating and can be separated easily, are commercially available. Such reworkable adhesives are very promising because all devices are getting gradually complicated and the probability of error is increasing.

Dismantlable adhesives can be categorized as follows:

1. Thermoplastic adhesives, i.e., hot-melt adhesives
2. Adhesives including blowing agents or expansion agents
3. Adhesives including chemically active materials
4. Adhesives to which an electrochemical reaction on interfaces is applied

#### **59.3.1 Thermoplastic Adhesives and hot-Melt Adhesives**

Thermoplastic adhesives, i.e., hot-melt adhesives can be separated. They are softened by heating. For instance, solid wax has been used for temporary joints of work materials. The work materials are joined and fixed on the bed of a machine tool with the melt solid wax, and separated by heating. The wax is usually used for many materials such as glass, ceramics, and silicones which are nonmagnetic and cannot be fixed with a magnetic chuck. The amount of the wax used is increasing, although it is a relatively old material. In electronics applications, several types of dismantlable adhesives are used for making IC chips. At first, silicone ingots are fixed with an adhesive and cut into wafers with a dicing saw. The adhesive can be

softened by heating. The residue of the adhesive on the wafers can be washed off using a particular solvent or an alkali solution. Next, the wafer is fixed with another type of adhesive which can be separated mechanically using a scraper. The residue of adhesive on the wafer's surface can also be washed off with an alkali solution.

Hot-melt adhesives began to be used for housing applications in order to recycle the materials. Figure 1 shows a bonding method of wall boards or ceiling boards on beams using a hot-melt tape and an induction heating machine. The method is called the "Allover Method" and has been utilized already by Japanese construction companies (Sekine et al. 2009). A key point is that the tape has a conductor layer made of aluminum alloy in it. To bond the boards on the beam, the tape is inserted between them. The process is easy because the tape has a weak tackiness. After that, the layer can be heated using the induction heating machine, and the board and beam are joined together. They can also be separated by heating because it is totally reversible.

Combining thermosetting plastics and thermoplastics, reworkable adhesives having high strength, stability, and good utility, can be realized. Epoxy adhesives, which are thermosetting resins, are used often for electronics packaging. The introduction of a thermoplastic property to the epoxy adhesive leads to a novel function where the adhesive can be cured and melted by heating. This is called "thermally molten epoxy resin" and has become an important object for research recently (Nishida and Hirayama 2006). The resin is used as an under-fill adhesive to bond IC chips on circuit boards. If the IC chips are out of order, they can be removed and replaced by other chips. Such chips are usually bonded with an adhesive and solder, and both of them can be softened by heating. Therefore, the chips can be separated from the boards easily. The process is called "IC chip rework" (Fig. 2) and it is not frequent but occasional.

**59.3.2 Adhesives Including Blowing Agents or Expansion Agents**

Mixture of blowing agents or expansion agents into an adhesive is frequently used as a method to provide dismantlability. For instance, thermally expandable microcapsules (TEMs) are used often, as shown in Fig. 3. The TEMs expand by heating and an internal stress occurs in the matrix resin of the adhesive. The stress causes an

**Fig. 1** Principle of the Allover method using induction heating (IH) and hotmelt adhesives (Sekine et al. 2009)

**Fig. 2** Reworkable underfillers used for integrated circuit (IC) chip bonding

**Fig. 3** Dismantlable adhesive including thermally expandable microcapsules (TEMs)

interfacial separation between the adhesive and the adherend. The type of the matrix resin is important because the internal stress depends on its modulus and strength. Thermoplastic resins are suitable for the adhesive. They can deform much at high temperatures. The expanding force of TEMs induces large deformation in the matrix resin and that leads to interfacial fracture between the adhesive and the adherend (Ishikawa et al. 2005). In addition, the separated surface of the adhesive becomes rough because of the TEMs' expansion, and the roughness becomes a barrier for the adhesive to stick again to the adherend. Therefore, the separated interface cannot be joined again even after the temperature decreases. In the case of a thermoplastic adhesive, the resin is softened over its glass transition temperature, and a similar phenomenon happens also in the case of thermosetting adhesives. Epoxy resins, for example, can be applied as a matrix of a dismantlable system, and they can be used for a wide variety of applications because of the high strength and heat resistance.

As an example of application of this technique, a commercially available tape including TEMs can be shown, which has been used for temporary joints of IC chips die-cutting. The tape has double sided coats of a pressure sensitive adhesive (PSA). The bonding strength and modulus of the PSA are low, so that the tape can expand much with a small amount of TEM inclusion, and the expansion leads to an interfacial separation between the IC chips and the tape. Similar methods are applied to other applications such as adhesives or sealants for housing. A vinyl emulsion adhesive including TEMs is used to join fiber-reinforced plastics (FRP) or decorative steel sheets to plaster boards for fabrication of unit-bath structures in Fig. 4. A silicone sealant including TEMs is used for sealing of kitchen sinks, etc., as shown in Fig. 5. In both the cases above, the joint can be dismantled by heating (Ishikawa et al. 2004).

The technique has been applied to strong adhesives too. A project called "ECODISM," which is the abbreviation of "Ecological and economical development of innovative strategy and process for clean maintenance and dismantling further recycling," was carried out in Europe aiming at the bonding of car structures using dismantlable adhesives or primers (Papon et al. 2008; Alcorta et al. 2004; Bain

**Fig. 4** Wall panels for a unit-bath room consisting of plaster boards and steel plates bonded with a dismantlable adhesive of vinyl emulsion including TEMs (Ishikawa et al. 2004)

**Fig. 5** Bonded and dismantled parts of a kitchen sink bonded with a dismantlable adhesive of silicone resin including TEMs (Ishikawa et al. 2004)

**Fig. 6** Application of a dismantlable adhesive with thermally expandable microcapsules and blowing agents in the car industry, the ECODISM project (Papon et al. 2008)

and Manfre 2000). A urethane adhesive including TEMs and blowing agents (pTSH) was applied to joints between a windscreen and the body structure, as shown in Fig. 6. A rear hatch having polymer-alloy panels and a glass was also fabricated with the dismantlable adhesive. Infrared (IR) lamps were used to heat the structure in order to separate it, and the structure could be dismantled within 150 s.

Epoxy adhesives are also targets for separation using TEMs, although these adhesives are very strong. For instance, a type of TEMs, shown in Fig. 7, is mixed into an epoxy resin to be used as a strong dismantlable adhesive (Nishiyama et al. 2003). The microcapsules have a structure with a core and a shell. The shell consists of polyvinylidene, and the core is filled by isobutene. The average diameter of the TEMs is about 20  $\mu\text{m}$ . The TEMs can expand due to temperature increases because the shell becomes soft and the inner pressure of the TEMs increases. The expansion starting temperature of the TEMs depends on the material characteristics of the shell and the filling hydrocarbon. There are a lot of commercially available grades having different temperatures of expansion beginning and maximum expansion volumes. The TEMs, shown in Fig. 7, have an expansion starting temperature of 80  $^{\circ}\text{C}$  and a maximum expansion volume of 70 times. Therefore, the temperature of dismantlement of an adhesive is selected as a function of the TEMs. Generally speaking, a grade of TEMs having a high expansion starting temperature has a smaller expansion volume than that

**Fig. 7** Structure of thermally expandable microcapsules (TEMs) (Nishiyama et al. 2003)

of low temperature expansion TEMs. Therefore, an increase of the dismantlable temperature of an adhesive may induce a decrease of dismantlability because the expansion volume is vitally important to separate the bonded joints.

As mentioned before, since the stresses caused by the TEMs expansion is the main driving force for joint separation, the expansion characteristics should be known to improve the performance of a dismantlable adhesive. Several experiments have been carried out to investigate the expansion performance of a type of TEM (Nishiyama and Sato 2005). For the purpose, Pressure-Volume-Temperature tests (PVT tests) were conducted using an experimental set up called “PVT measurement equipments.” In these tests, TEMs are contained in a flexible vessel under hydrostatic pressure with silicone oil under different temperature conditions. The hydrostatic pressure is caused using a pump and the temperature increases using a heater. The volume change of the TEMs was measured using a differential transformer. Therefore, the volume change of TEMs under different conditions of pressure and temperature could be measured and the P- V- T relation could be determined by the tests. For instance, the TEM mixed in the epoxy resin can expand 8 times in volume at 100 °C. The pressure,  $P$ , caused by the TEM for a volume expansion of 800% and  $T = 100\text{ }^{\circ}\text{C}$  could be determined as 1–2 MPa. The result is strange because the pressure is much lower than the strength of the epoxy resin. In other words, the pressure is too small to deform the epoxy matrix resin enough for dismantlement. However, the resin becomes soft enough to deform at the temperature of the TEMs expansion. Thus, the combination of the resin softening and the TEM expansion is the key for the adhesive’s large deformation and internal stress occurrence. In order

**Fig. 8** Dismantling experiments to observe the interfacial debonding caused by TEMs in an epoxy adhesive; debonded regions in the joint can be seen as the dark parts in the images at the bottom of the figure, and they are expanding with respect to temperature

to provide dismantlability to an adhesive by mixing TEMs, not only the expansion force of the TEMs is important, but also the low strength and modulus of the matrix resin at high temperatures. A resin, whose  $T_g$  is close to the volume expansion temperature of the TEM, whose modulus and strength decreases drastically around the  $T_g$ , and which is soft enough not to suppress the expansion of the TEM in its rubber plateau, has to be selected as the matrix for a dismantlable adhesive.

Two mechanical models of the interfacial debonding of dismantlable adhesives are proposed in Fig. 8. One of them is the local crack generation model, in which the expansion of a TEM causes a small interfacial crack nearby the contact point between the TEM and the adherend. The crack expands to the neighbor cracks, and the cracks join and lead to the total fracture of the joint. The other model is the global stress

generation model, in which the expansion of TEMs induces volume increase of the adhesive layer, leading to joint fracture due to the global residual stress concentrating around the tip of the adhesive layer or interfacial cracks. An experimental verification of the models has been carried out using a glass joint bonded by an adhesive, including TEMs. In this test, optical and microscopic observation was conducted through the glass adherend. No gas generation was observed. Small circumferential cracks around each TEM were observed as explained by the local crack generation model. However, global cracks occurred at the edges of the joint and propagated inside the joint. This implies that the global stress generation model is also valid. Thus, the results support both models, which happen simultaneously, although the contribution ratio of each effect is still unknown.

### 59.3.3 Adhesives Including Chemically Active Materials

Mixture of chemically active materials is an effective method to dismantle adhesives. For example, expandable graphite and aluminum hydroxide can be used for the purpose. Expandable graphite is a flaky carbon having a layer structure of planar crystals. Chemicals such as acids are intercalated between the crystal layers. The acid is vaporized by heating, and water included in the acid is also vaporized. Therefore, the vaporized acid and the vapor can expand the layer structure as an accordion being pulled, increasing the volume drastically, as shown in Fig. 9. Since the vaporized acid and vapor are hot, they can attack the resin. Aluminum hydroxide consists in a fine powder that is transformed into aluminum oxide and vapor at high temperature. The hot vapor can not only expand the resin, but also attack the resin in the same manner as the expandable graphite does. Water becomes superheated vapor over 100 °C in the atmospheric pressure. The superheated vapor can cause chemical decomposition of the resin. An application of the technique is double-side PSA tapes that include aluminum hydroxide and which used for the joining heat sinks to large-size plasma display panels. They have to be dismantled in their recycling process because they are dissimilar materials. The joint can be separated applying a weak force because the PSA tape can be degraded by heating and the bonding strength decreases very much. Other types of chemicals, oxidizing agents such as ammonium perchlorate, can be used to attack the resin too.

### 59.3.4 Adhesives to Which an Electrochemical Reaction on Interfaces Is Applied

A novel adhesive: Electrelease (EIC Laboratories, MA, USA), which can be separated electrically, is already commercially available (Welsh et al. 2003). The interface between the adhesive and the anodic adherend becomes so weak by applying a DC current that the joint can be broken by hand, as shown in Fig. 10. The adhesive was developed to bond sensors on the wing of aircrafts, and has been tested to be applied to a separation mechanism for space applications. The application of this

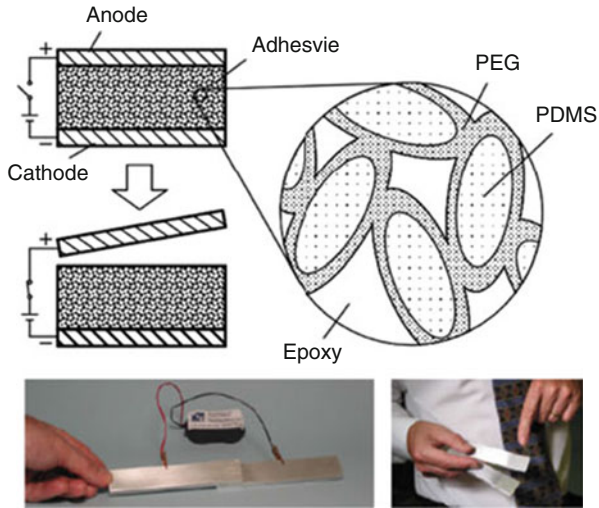

**Fig. 9** Expandable graphite

technique weakens the joint, but not completely. Therefore, some external force has to be applied to separate the joint even after the electric voltage is imposed. For instance, if a weak load is applied continuously using bias springs to the joint, applying only an electric voltage causes the spontaneous separation of the joint. As just described, a one-time separation mechanism triggered electrically can be realized easily using this adhesive as shown, in Fig. 11 (Shiote et al. 2009). The reason why the adhesive can be weakened by electric currents is not completely understood. It is supposed that an electric current transmitted to the adhesive layer causes electrochemical reactions on the surface of the anodic adherend, and this leads to erosion of the metal-oxide layer of the adherend. A similar mechanism of delamination induced by electric currents is known as “cathodic delamination,” in which

**Fig. 10** An electrically dismantlable adhesive (Electrelease<sup>®</sup>, EIC Laboratories) where PEG and PDMS denote polyethyleneglycol and polydimethylsiloxane, respectively (Shiote et al. 2009)

**Fig. 11** One-time separation mechanism using an electrically dismantlable adhesive (Shiote et al. 2009)

alkali materials precipitate at the interface and attack the resin (Horner and Boerio 1990). These delamination mechanisms are quite novel and very promising in terms of expanding the variety of dismantlable adhesives.

### 59.3.5 Miscellaneous Methods

PSAs are promising materials to realize dismantlable joints because separation capabilities are built in already. Recently, strong PSAs have been commercially available, and they have enough strength to be applied for semi-structural uses.

However, it becomes a problem in terms of dismantlability if the strength is too high. To avoid this problem, new types of PSAs, which are strong enough but can be separated easily, have been developed.

Command Tab<sup>®</sup> (3M, MN, U.S.A.) and PowerStrip<sup>®</sup> (TESA, Hamburg, Germany) are examples. Tackiness of PSAs depends on the modulus. If the modulus is out of a particular range known as Chang's "viscoelastic window," the PSA loses the tackiness or the bonding strength (Chang 1991). For instance, the PSA of PowerStrip comprises block-copolymer molecular chains having soft and hard segments, and the modulus depends on the deformation (Krawinkel 2003). If the PSA is pulled enough, the modulus increases and the tackiness decreases. Therefore, the PowerStrip tape can be removed easily, as shown in Fig. 12.

This theory of the viscoelastic window can be applied to other materials. Mixture of cross-linkers is another way by which PSAs can be hardened by heating or UV irradiation and the tackiness decreased. Recently, many kinds of tapes that can be separated by this method are used for dicing of IC chips.

Brittle adhesives have high shear and low peel strength. It is possible to take advantage of this aspect to make a kind of anisotropic adhesive. For example, a temporary joint adhesive, Lock n' Pop<sup>®</sup> (Illinois Tool Works (ITW), WA, U.S.A.) is commercially available. The adhesive is strong enough to fix cardboard boxes due to the high shear strength during their transportation, but is easy to separate by applying vertical forces because of its low peel strength, as shown in Fig. 13.

**Fig. 12** High strength strippable PSA tape (PowerStrip<sup>®</sup>, TESA)

**Fig. 13** Anisotropic strength adhesive for a temporary joint of cardboard boxes (Lock n' Pop<sup>®</sup>, Illinois Tool Works (ITW))

**Fig. 14** A dismantlable adhesive application for shoe industry (Mori and Harano 2009)

### 59.3.6 Recent Advances

The use of adhesives including TEMs has been expanding in many applications. For example, an adhesive has been introduced for shoe fabrication to bond uppers and soles (mid soles and outer soles) as shown in Fig. 14 (Mori and Harano 2009). The adhesive includes TEMs as expansion agents and diethylene glycol or ethylene glycol as heat-generation agents. Since diethylene glycol is a high-dielectric material, the temperature can be risen by microwave irradiation heating. The temperature rise can induce the expansion of TEMs and finally leads to the separation of the uppers and soles. Microwave irradiation has advantages such that low energy loss, and the necessary equipments have become inexpensive recently. For instance, even a home microwave oven can be used to dismantle the shoes. Requirements for adhesives used in sport shoes are many and severe. Bond strength, flexibility, and heat resistance are indispensable. To meet these requirements, a formulation, which includes an urethane resin, 5 wt% of TEMs, and over 20 wt% of high-dielectric materials, is typically used. At the moment, the adhesive is only applied to expensive shoes for top athletes because they want to reuse the uppers when the soles have to be replaced. However, the adhesive is ready to be used in ordinary shoe markets in terms of performance and price. Shoe industries have huge markets in which adhesives have to be used essentially because dissimilar materials are bonded. Since the total mass of production is enormous and has been increasing, the use of recyclable joining techniques is of significance, especially in the future.

The use of TEMs is convenient to provide adhesives with dismantlability, but it is not versatile because of some disadvantages. One of them is the small expansion forces produced by TEMs, by which a weak adhesive can be separated but strong ones such as rubber modified ductile epoxy adhesives cannot be separated because they have high strength and ductility suppressing interfacial fracture even at a higher temperature than its  $T_g$ . To overcome this disadvantage, there are two alternative ways: changing the expansion agents or modifying the matrix resin. As alternative expansion agents, expandable graphite and aluminum hydroxide are promising, as mentioned above. They are not only chemical attack agents, but also expansion agents having larger expansion capabilities than TEMs.

Modification of matrix resins is also important, but this is the next step and it has not been investigated often so far. A strategy is to modify the resin to be softer than the previous ones at high temperature so that the resin can deform due to the TEMs' expansion. A problem is that the heat resistance of the resin might be damaged if the resin's  $T_g$  becomes too low. Thus, a good compromise of heat resistance and dismantlability must be pursued.

Kishi et al. has tried to develop a heat resistant dismantlable adhesive for joining composite materials and metals, and modified the composition of an epoxy adhesive accordingly (Kishi et al. 2006). This research was conducted as part of the national project "R&D of Carbon Fiber-Reinforced Composite Materials to Reduce Automobile Weight" supported by New Energy and Industrial Technology Development Organization (NEDO) in Japan. As mentioned above, the resin should be soft at the temperature of the TEMs' expansion. A problem is that typical heat resistant resins have moduli and strengths enough to suppress the TEMs' expansion even at high temperatures, over their  $T_g$ . In other words, such heat resistant resins are not soft enough for TEMs to expand even at high temperature. Therefore, a kind of resin which has a high  $T_g$  and enough low modulus and strength above the  $T_g$  is necessary for heat resistant dismantlable adhesives. In addition, steep change of the modulus and strength of the resin around the  $T_g$  is also important to increase the maximum allowable temperature of the adhesive, as shown in Fig. 15.

**Fig. 15** An idealistic variation of modulus for dismantlable adhesive's matrix resin

Kishi et al. aimed a target for the adhesive as:

1. The maximum temperature for use is 80 °C. Under this temperature, the resin has a modulus and a strength high enough to bear the applied loads.
2. Over 100 °C, the resin has a steep decrease of the modulus and strength.
3. In the temperature range over 150 °C, in which the resin is in rubbery condition, the resin should have a modulus and strength low enough for TEMs expansion.

For the adhesive, they proposed a formulation, shown in Fig. 16, including diglycidylether of bisphenol A (DGEBA) 828, DGEBA 1001, and glycidylphthalimide (GPI) as the base resins cured with hardeners dicyandiamide (DICY) and 3-(3,4-dichlorophenyl)-1,1-dimethylurea (DCMU) that can increase the Tg of the resin. An important point of the formulation is the inclusion of GPI that has high polarity and can form strong bonds between the main molecular chains. The bonds work as if the cross-linking density of the resin increases at low temperatures. However, the bonds are dissociated at high temperatures, decreasing the substantial cross-linking density. The low modulus at high temperatures and the steep decrease of the modulus around the Tg are due to the destruction of the bonds. Thus, the resin has high modulus and strength in low temperature ranges, high Tg, steep decrease of the modulus, and low modulus over Tg, which are suitable characteristics for heat resistant dismantlable adhesives. For instance, the resin has a modulus higher than 3 GPa in the glass condition range around the ambient temperature. However, the modulus decreases to 2 MPa over 150 °C.

The resin was combined with an expandable graphite and was used to bond metal parts to carbon-fiber-reinforced plastics (CFRP) plate. The joint could be separated within 5 min at 250 °C, as shown in Fig. 17. The adhesive includes 10 wt% of the expandable graphite and it begins to expand around 200 °C, which is much higher than the Tg of the resin. The margin between the expansion temperature of the expandable graphite and the Tg of the resin was decided considering the chemical stability of the expandable graphite at high temperatures. The temperature of 250 °C

**Fig. 16** Components of the heat resistant dismantlable adhesive (Kishi et al. 2006)

**Fig. 17** Specimen of metal parts bonded on a carbon reinforced plastic (CFRP) plate with a heat resistant dismantlable adhesive

in the dismantlable test was decided as a compromise between time and temperature of separation.

### 59.3.7 Future Seeds

One of the promising seeds to realize novel types of dismantlable adhesives is the use of degradable polymers. Polyperoxide-polymers, for instance, can be applied for that purpose because the resin can be cured and re-liquefied reversibly by heating (Matsumoto and Taketani 2006). Adhesives using the resin can be separated and bonded many times. Another kind of polymer having weak points such as Azo groups in the molecular chains is also promising for heat-degradable dismantlable adhesives. A type of rubber such as thermoreversible hydrogen bond cross-linked (THC) rubber, shown in Fig. 18, can be re-liquefied by heating, has been proposed recently (Chino et al. 2002; Chino and Ashiura 2001; Chino 2006). Such rubbers are also applicable for dismantlable adhesives.

Since almost all recent dismantlable adhesives need heating to be separated, heating methods are also important to improve the efficiency of the dismantling process. The necessity of heating will remain even in the future. Heating the whole structure including the adhesively bonded joints is not efficient. Local heating of the joints is more convenient. Induction heating and microwave heating methods are appropriate in terms of efficiency. A new method of microwave heating using nanoferrite particles, shown in Fig. 19, has been proposed and it can be applied for the heating process of joints bonded with dismantlable adhesives (Sauer et al. 2004).

Other stimulations except heating should be investigated in the future. Magnetism, radiation (neutron beams, gamma ray), hydrostatic pressure, compressive stress, UV irradiation, and high voltage discharge are candidates for the stimulation. Dry adhesion, which has been attracting attention recently, is another possibility to provide new ideas for joint dismantlement (Lee et al. 2007). Further investigation and research on interfacial phenomena must be conducted to obtain further

**Fig. 18** Schematic illustration of thermoreversible hydrogen bond cross-linked (THC) rubber principle

**Fig. 19** Microwave heating using nanoferrite as dipole conductors (Sauer et al. 2004)

knowledge because the ultimate dismantlable adhesive must be an adhesive with which its interface can be separated easily and completely with a small amount of energy used for the separation.

---

## 59.4 Conclusion

To promote the use of adhesives, eco-friendly attitudes of both adhesive makers and users are indispensable. Reducing carbon dioxide and energy consumption is the main topics of environmental issues. Recently, alternative options, such as the use of carbon-neutral or recycled materials for making adhesives, can be taken to meet the demands derived from the environmental issues. The optimization of bonding process and joint design is also very important and effective to reduce energy consumption and wastes. Recently, dismantlable adhesives have been available for joining the materials that have to be separated on demand. These adhesives can be applied to adherend recycling or product reworking.

There are many technical seeds for dismantlable adhesives already. Since dismantlable adhesive technology has still some minor problems such as low heat resistance or low durability, they should be solved soon by researchers or industries, and then the use of the adhesives will expand to many applications. Dismantlable adhesive technology has contradictory aspects: good bonding and easy separation. High bonding strength tends to induce difficult separation. Therefore, it is also important to clarify the minimum bond strength necessary for each application instead of pursuing high performance in strength.

adhesion, surface treatment, adhesive and sealant materials, testing of adhesive properties, joint design, durability, manufacture, quality control, applications, and emerging areas. A total of 58 chapters are presented covering all aspects of adhesion and adhesives. In addition to the information contained in each chapter, an extensive list of references is given (approximately 4000 references).

---

## 60.1 Theory of Adhesion

In ► [Chap. 2, “Theories of Fundamental Adhesion”](#) by Packham, the historical development and current status of the four classical theories of adhesion (mechanical theory, adsorption theory, electrostatic theory, and diffusion theory) are reviewed. The role of weak boundary layers is also discussed with emphasis on the importance of careful investigation of the locus of failure of an adhesive bond. Next, Brogly in ► [Chap. 3, “Forces Involved in Adhesion”](#) describes the main forces responsible for adhesion, from strong covalent bonds to weak van der Waals forces, also considering specific interactions such as acid-base or capillary forces. ► [Chapter 4, “Wetting of Solids”](#) by Shanahan and Possart considers thermodynamic aspects of wetting, which involves intimate contact between the two phases and the environment. A short overview of the relevant processes and parameters in the spreading of liquids on substrates is presented in ► [Chap. 5, “Spreading of Liquids on Substrates”](#) by Reiter. In a simplified view, the dynamics of these processes can be understood as being controlled by the balance of driving forces and resistance due to dissipative processes. Finally, in ► [Chap. 6, “Thermodynamics of Adhesion,”](#) Possart and Shanahan show that wetting data may be used to estimate the thermodynamic, or Dupré, energy of adhesion, provided certain assumptions are made and suitable models constructed for, in particular, interfacial tensions.

---

## 60.2 Surface Treatments

The use of surface treatments to optimize adhesion has been well-established. In ► [Chap. 7, “General Introduction to Surface Treatments,”](#) Critchlow considers the main treatment methods for metals and polymers in terms of how such processes are carried out and their influence on surface physical and chemical properties. Consideration has been given to a range of treatments from simple degrease options to the more highly complex multistage processes. Davies, in ► [Chap. 8, “Surface Treatments of Selected Materials,”](#) discusses high-performance surface treatments for several metals and other materials. Surface treatment of aluminum and other metals is used to illustrate how proper surface preparations meet these requirements. ► [Chapter 9, “Surface Characterization and Its Role in Adhesion Science and Technology”](#) by Watts reviews a variety of methods of surface characterization that have been found to be useful in the study of adhesion. The methods considered can conveniently be considered in three groups: surface topography, surface free energy of a material, and surface-specific chemical analysis. Next, Watts in

► [Chap. 10, “Use of Surface Analysis Methods to Probe the Interfacial Chemistry of Adhesion”](#) explores the manner in which the surface analysis methods of X-ray photoelectron spectroscopy (XPS) and time-of-flight secondary ion mass spectrometry (ToF-SIMS) can be used to extract information regarding the interfacial chemistry of adhesion from polymer/metal systems such as adhesive joints. The last chapter of this section, ► [Chap. 11, “Organosilanes: Adhesion Promoters and Primers”](#) by Abel, describes organosilanes from their genesis to their chemistry. The necessary interactions that such molecules have to develop on materials in order to fulfil their main role as adhesion promoters are explained. The use of silanes as primers particularly where the user aims to improve adhesion or protect from corrosion is also considered. Some other organic or nonorganic adhesion promoters are also discussed.

---

## 60.3 Adhesive and Sealant Materials

The first chapter ► [“Classification of Adhesive and Sealant Materials”](#) (Chap. 12) by Sancaktar classifies adhesive and sealant materials. For this purpose, various categories are considered depending on the polymer base, functionality in the polymer “backbone,” physical forms, chemical families, functional types, and methods of application. Next, in ► [Chap. 13, “Composition of Adhesives,”](#) Kim et al. give information about various ingredients that may appear in an adhesive or sealant: primary resins, hardeners, solvents, fillers, plasticizers, reinforcements, and various additives. In the third chapter of this section, Papon (► [Chap. 14, “Adhesive Families”](#)) classifies adhesives and sealants in three broad groups. First, there are adhesives where the polymer is pre-existing (and must be placed beforehand in fluid form: solution, emulsion, or “melt” state). Second there are adhesives where the polymer is formed during the course of a reactive process (polymerization). Third, Papon describes the particular category of pressure-sensitive adhesives where the polymer exhibits viscoelastic properties able to develop adhesion during the bonding step. The basic concepts, formulations, and test methods for pressure-sensitive adhesives are presented in ► [Chap. 15, “Pressure-Sensitive Adhesives \(PSAs\)”](#) by Paul, stressing the importance of interfacial interactions, viscous loss, and extensibility. Selection of the correct adhesive for an application can be a daunting task due to the many types commercially available ranging from different chemistries through different forms to an almost continuum of material properties. Kellar in ► [Chap. 16, “Selection of Adhesives”](#) gives a logical approach to this task and selection criteria.

---

## 60.4 Testing of Adhesive Properties

The first chapter by Dillard ► [“Physical Properties”](#) (Chap. 17) addresses several relevant physical properties of adhesives, including viscosity, density, and stress-strain behavior, quantities that are often thought to be intrinsic properties of a material. The thermal properties of adhesives are described next by Comyn.

Consideration is given to the shelf life, the hardening process, the glass transition temperature, the thermal conductivity and thermal expansion, and the thermal breakdown of adhesives. In ► [Chap. 19, “Failure Strength Tests,”](#) da Silva et al. describe the major failure strength tests used to determine the intrinsic adhesive properties. Tensile, compressive, and shear tests are described with reference to the major international standards. Bulk and in situ (adhesive in a joint) tests are discussed and related. ► [Chap. 20, “Fracture Tests”](#) by Blackman considers first the fracture in a bulk adhesive specimen under mode I, i.e., tensile opening loading conditions. Mode II (in plane shear) and mixed-mode I/II testing of adhesive joints are also considered. There is often the need to measure the resistance to fracture in a joint with flexible substrates. One such test is the peel test, and some variants of the peel test are considered in that chapter. Goglio, in ► [Chap. 21, “Impact Tests,”](#) describes the main tests used to assess the impact strength of adhesives and joints. The main tests used in the experiments are pendulum, falling weight, and Hopkinson bar loading conditions or evolutions of these. The last chapter of this section by Dillard and Yamaguchi deals with ► [Chap. 22, “Special Tests.”](#) This chapter gives a brief description of special mechanical tests for various types of material and sample geometries, such as blister tests, tensile tests and shear tests for sealants/foam adhesives, indentation tests, scratch tests, tack tests, and tests for the evaluation of residual stresses.

---

## 60.5 Joint Design

This section starts with ► [Chap. 23, “Constitutive Adhesive and Sealant Models”](#) by Sancaktar. The chapter includes deformation theories and viscoelasticity with linearity and nonlinearity considerations, rubber elasticity, singularity methods, bulk adhesive as composite material, damage models, the effects of cure and processing conditions on the mechanical behavior, and the concept of the “inter-phase.” ► [Chapter 24, “Analytical Approach”](#) by Tong and Luo presents an analytical approach for determining stress and strength of adhesively bonded joints. Various closed-form solutions for adhesive stresses and edge bending moment for balanced single-lap joints are presented and compared. In ► [Chap. 25, “Numerical Approach: Finite Element Analysis,”](#) Ashcroft provides first a general background to the development and application of the finite element (FE) method. Then he discusses some of the practical aspects of FE modeling and gives applications of the FE method to adhesively bonded joints. FE analysis is currently the only technique that can comprehensively address the challenges of modeling bonded joints under realistic operating conditions. However, a reliable and robust method of using FE analysis to model failure in bonded joints is still to be developed. Öchsner, in ► [Chap. 26, “Special Numerical Techniques to Joint Design,”](#) introduces special numerical techniques to analyze adhesive joints. The first part covers special FE techniques which reduce the size of the computational models. The second part of this chapter introduces alternative approximation methods, the boundary element method and the finite difference method. In ► [Chap. 27, “Design Rules and Methods to Improve Joint Strength,”](#) da Silva et al. describe the main factors influencing joint

strength. Methods are then proposed to improve the joint strength by using fillets, adherend profiling and other geometric solutions, and hybrid joining. Repair designs are also discussed. Finally, configurations are recommended for several types of joint. ► [Chapter 28, “Design with Sealants”](#) by Anderson describes the many factors to go into the design of reliable sealant joints. The various joint types are discussed and illustrated, and their critical dimensions and materials are described. Sato, in ► [Chap. 29, “Design for Impact Loads,”](#) discusses design methods for adhesively bonded joints subjected to impact loading. Methodologies to treat the dynamic responses of structures are shown. Some examples of stress analysis are shown, where closed-form approaches and dynamic FE analyses are explained. The last chapter of this section ► [“Vibration Damping of Adhesively Bonded Joints”](#) (Chap. 30) by Adams et al. discusses the general concept of vibration damping in vibrating structures and how it can be used to limit vibration amplitudes. Simple equations for calculating the damping of a lap joint in tension and bending have been developed. As there is very little experimental data available, the damping of a variety of adhesively bonded single-lap joints has been measured by the authors.

---

## 60.6 Durability

In ► [Chap. 31, “Effect of Water and Mechanical Stress on Durability,”](#) Ashcroft and Comyn discuss the effect that absorbed water has on the strength of adhesively bonded joints. The influence of adherend surface treatment, applied stress, and adhesive type on the environmental degradation of bonded joints is demonstrated. Methods of modeling the environmental degradation of adhesively bonded joints using coupled hygro-mechanical finite element (FE) analysis are then described. Chapter “Radiation and Vacuum” of the first edition has been substituted by ► [“Adhesives in Space Environment”](#) (Chap. 32) by Dagrás et al. In the first part, a description of the different uses and needs related to adhesives on spacecraft is given. Then, the characteristics of space environment are explained. Once in orbit, the adhesive has to withstand constraints as particles radiations, UV, and atomic oxygen that are not present on Earth. Before spacecraft launch, the adhesives have to be validated and tested on ground with conditions as representative as possible of the space environment. Finally, the impact of this space environment on adhesives and the associated degradations are described. ► [Chapter 33, “Fatigue Load Conditions”](#) by Ashcroft discusses some of the main factors when considering fatigue, with particular reference to issues applicable to bonded joint. The main methods of characterizing and predicting the response of bonded joints to fatigue loading are described. Finally, there are sections on the special cases of creep-fatigue and impact fatigue. In ► [Chap. 34, “Creep Load Conditions,”](#) Geiss considers viscoelastic models, superposition principles, experimental testing procedures, and predictive methods. In the last chapter of this section, ► [“Durability of Nonstructural Adhesives”](#) (Chap. 35) by Palmer, methods evaluating durability and test regimes, including exposure to elevated and reduced temperatures, UV radiation, moisture,

181 saline solutions, stress, and fatigue, both individually and combined in cycles are  
182 considered.

---

## 183 **60.7 Manufacture**

184 The first subject in this section is ► [“Storage of Adhesives”](#) (Chap. 36) by  
185 Engeldinger and Lim. A major part of this chapter focuses on the shelf life and  
186 safety aspects. Adhesives are divided into four categories, solvent-based, water-  
187 based, hot-melt, and reactive adhesives. In ► [Chap. 37, “Preparation for Bonding,”](#)  
188 Lutz discusses each item of the process chain: the storage of adhesives, transfer  
189 to the application area, different metering and dispensing technologies, mixing  
190 equipment used, substrate preparation, and quality control. Proposals are made  
191 regarding education of personnel and how to create a safe working environment.  
192 In ► [Chap. 38, “Equipment for Adhesive Bonding,”](#) Peschka describes the equip-  
193 ment required for manual adhesive bonding processes. Automation and robotics are  
194 outlined with a special emphasis on parameters affecting accuracy. Accelerated  
195 curing using such devices as UV radiation and inductive heating is also treated.  
196 The last chapter of this section, ► [“Environment and Safety”](#) (Chap. 39) by van  
197 Halteren, deals with the different aspects of consumer, work, and environmental  
198 protection, including health and safety information, related to the use of adhesives in  
199 industrial and domestic areas.

---

## 200 **60.8 Quality Control**

201 This section starts with ► [Chap. 40, “Quality Control of Raw Materials”](#) by  
202 Wakabayashi. The main components of adhesives are first described, and then  
203 quality control procedures are discussed such as chemistry, impurity content, molec-  
204 ular weight, viscosity, density, and quality control of raw materials in storage. Next,  
205 in ► [Chap. 41, “Processing Quality Control”](#) by Haraga, the processing quality  
206 control of adhesively bonded joints in actual production lines is discussed. Topics  
207 such as control of environmental conditions and materials, inspection of surface  
208 treatment of adherends, adhesive selection for easy process control, and education  
209 and training of operators are treated. In ► [Chap. 42, “Nondestructive Testing”](#) by  
210 Adams, the types of defect encountered in adhesive joints and the nondestructive  
211 testing techniques available to detect them are reviewed. Several techniques are  
212 available for void detection, the most commonly used being ultrasonics and different  
213 types of bond tester. The detection of poor cohesive properties is more difficult but  
214 can be achieved with ultrasonic or dielectric measurements. The last chapter of this  
215 section, ► [“Techniques for Post-fracture Analysis”](#) (Chap. 43), was rewritten by  
216 Créac’hcadec. This chapter presents three types of measurement systems: micros-  
217 copy, compositional analysis, and mechanical observations. A table sums up an  
218 exhaustive list of the major observation devices. Then, the main methods are detailed

with macroscopic and mesoscopic observations, microscopic observation, physico-chemico analysis, and mechanical observations.

## 60.9 Applications

The first application treated is the “Aeronautical Industry” by Hart-Smith. The following topics are treated: basic needs, adhesive characteristics, surface preparation, design of adhesive joints, durability, defects, thermal effects, quality control, composite structures, repairs, and examples of use. ► Chapter 45, “Aerospace Industry” was extensively revised by Pérès and Larnac. The chapter introduces some of the specific bonding-related issues that face those responsible for bonding operations in space applications such as extremely high mechanical loads over a short time, with the launcher and its payloads subjected to gravity magnified by about 20, followed by exposure to extremely high temperatures over a very long period, with the observation and telecom satellites under zero gravity. Dilger and Fraunhofer updated ► Chap. 46, “Automotive Industry.” Typical applications for automobiles are shown. Additionally, suitable adhesive properties and surface treatments are discussed. ► Chapter 47, “Adhesive Bonding for Railway Application” is next treated by Suzuki. It is shown that adhesives are an indispensable joining technology for railway industries. Adhesives are used for the fabrication of almost all rail cars. For example, in the steel main structure of conventional rolling stock, adhesives are applied for bonding decorated aluminum sheets of wall and ceiling to frames, bonding of floor covering to the floor plate, and fixing heat insulating material to the inside of the carriages. ► Chapter 48, “Marine Industry” by Davies describes the use of adhesive bonding to assemble structures in the marine industry. The marine environment is extremely aggressive, and this has resulted in widespread use of fiber-reinforced composite materials. Adhesive bonding is a lightweight and corrosion-resistant means of joining these materials. Three industrial applications are used to illustrate the use of adhesive bonding, small pleasure boats, high-performance racing yachts, and bonded structures in the offshore industry. In the well-revised chapter ► “Civil Construction” (Chap. 49), Böhm et al. describe adhesive bonding applications in the civil construction sector, specific requirements, and adherends. The execution of bonding and properties of adhesive bonded civil constructions are also treated. Jung and Kim, in ► Chap. 50 “Electrical Industry,” explain the mechanisms underlying the electrical conduction in adhesive joints, and the thermal and mechanical parameters that should be measured are introduced. In terms of the evaluation of the reliability of adhesives in electronics, the basic test procedures, including several specific test methods and analysis techniques, are explained. ► Chapter 51, “Shoe Industry” by Martín-Martínez constitutes one of the very few reviews in the existing literature on shoe bonding and gives an updated overview of the upper to sole bonding by means of adhesives. The surface preparation of rubber soles and both the formulations of polyurethane and polychloroprene adhesives are described. The preparation of adhesive joints and adhesion tests are also revised. Another chapter was added to this section on ► “Oil Industry” (Chap. 52) by de Barros et al. due to the increase adhesives application that field,

especially for repairs. The main advantage by using adhesive bonding is to avoid the fire risk concerning the traditional weld process. Adhesives also feature protection against corrosion which is a main concern in offshore installations. This chapter shows that the use of composites has become a real alternative to structural repairs in situ as these materials become more and more reliable.

---

## 60.10 Emerging Areas

► [Chapter 53, “Molecular Dynamics Simulation and Molecular Orbital Method”](#) by Zhao et al., various simulation methods pertaining to adhesion technology are introduced, such as molecular dynamics, quantum mechanics, the molecular orbital method, and the density functional theory. Some examples are proposed investigating adhesion issues using various simulation methods. ► [Chapter 54, “Bioadhesives”](#) was rewritten by Richter. It gives an overview about natural adhesives and biological adhesives leading to bioinspired applications. Biological and microbiological adhesives have an enormous potential for industrial applications. The most prominent ones are constructional, packaging, and medical applications. Gorb, in ► [Chap. 55, “Biological Fibrillar Adhesives: Functional Principles and Biomimetic Applications,”](#) reviews functional principles of biological systems in various animal groups such as insects, spiders, and geckos with an emphasis on insects and discusses their biomimetic potential. Data on ultrastructure and mechanics of materials of adhesive pads, movements during contact formation and breakage, the role of the fluid in the contact between the pad and substrate are presented. ► [Chapter 56, “Adhesives with Nanoparticles”](#) are discussed by Taylor. This chapter outlines the principal types of nanoparticles and the methods that may be used to disperse the particles in a polymer matrix. It discusses how nanoparticles can alter the mechanical properties (stiffness and fracture), electrical properties (conductivity), and the functional properties (permeability, glass transition temperature) of thermoset polymers. In ► [Chap. 57, “Adhesive Dentistry,”](#) Nicholson describes the principal uses of adhesives in clinical dentistry, covering both the materials and the clinical techniques involved. The two types of tooth-colored material, namely, the composite resin and the glass-ionomer cement, are described, together with their current variations. Surface pretreatment is critical for the success of these systems, and the current state of the understanding of this aspect of the subject is described. ► [Chapter 58, “Adhesion in Medicine”](#) is covered by Chivers. Adhesives technology has two main applications in medicine as considered in this chapter, for internal fixation of tissues usually after surgery and for use on the skin, primarily to hold dressings in place. The last chapter by Sato concerns ► [“Recycling and Environmental Aspects”](#) (Chap. 59). Adhesively bonded adherends should be often separated before they can be recycled. For this purpose, dismantlable adhesives, which can be separated with stimulations (softening of adhesive, expansion force due to blowing agents or thermally expandable microcapsules, chemical degradation, and electrochemical reaction), have been developed recently. These adhesives can be applied to adherend recycling or product reworking.

## 60.11 Conclusions

The preparation of this second edition has been an interesting experience for the editors. The review process gave a deeper insight into the various aspects of adhesion from basics to applications. Authors come from every background (chemistry, physics, mechanics) and work in either academia or industry, proving that adhesion is a truly multidisciplinary and widely applied subject. The editors would like to thank the authors for their patience with the preparation of this handbook. Finally, the editors especially thank Dr. Christoph Baumann, Ms. Tina Shelton, and Ms. Monika Garg, Springer editors, who helped enormously toward the success of this handbook.
