## Second Edition Preface

50

51 The first edition of *Handbook of Adhesion Technology* has been very well accepted  
52 by the adhesion community with over 25,000 downloads per year. This was the main  
53 motivation for the preparation of this 2nd edition. Also, there has been a general  
54 increase of the scientific and industrial community in this technology, which justifies  
55 an update. There are more papers published every year, there are new journals related  
56 to the field, there are more national and international conferences, and there are more  
57 applications. A revolution is currently taking place in the transport industry where  
58 fuel is being replaced by electric power. This change means that lighter structures  
59 need to be manufactured with the use of light materials and more efficient joining  
60 methods such as adhesive bonding. But, the use of adhesive bonding is not limited to  
61 the transport industry, and there are several other applications described in this  
62 handbook such as the use of adhesives in medicine.

63 This 2nd edition of *Handbook of Adhesion Technology* is a complete revision of  
64 the 1st edition with an update of the methods that have been investigated recently,  
65 which are now fully accepted by the adhesion community. Themes that are now  
66 included in more detail include, for example, hybrid adhesives used for automotive  
67 applications, ecofriendly surface treatments, damage mechanics, joint durability  
68 prediction, functionally graded joints, adhesive selection for space applications,  
69 and, lastly, trends in bioadhesion. There is also a new chapter related to the  
70 application of adhesives in the oil industry. Besides these content changes, there  
71 has been a complete revision of all chapters in terms of text, figures, tables, and  
72 references for a more didactic character of this reference book.

73 The editors would like to thank the authors for their patience with the preparation  
74 of this handbook. Finally, the editors especially thank Dr. Christoph Baumann,  
75 Ms. Tina Shelton, and Ms. Monika Garg, Springer editors, who helped enormously  
76 toward the success of this handbook.

Uncorrected Proof

Adhesives have been used for thousands of years, but until 100 years ago, the vast majority was from natural products such as bones, skins, fish, milk, and plants. Since about 1900, adhesives based on synthetic polymers have been introduced, and today, there are many industrial uses of adhesives and sealants. It is difficult to imagine a product—in the home, in industry, in transportation, or anywhere else for that matter—that does not use adhesives or sealants in some manner.

Adhesion technology is nowadays a common approach to many joining situations. There are many books and several international journals dealing with this subject. However, when the end-user needs to apply this technology, he does not have the time or the resources to thoroughly study the various technologies related to adhesives and sealants. It is not practical to go through volumes of text and product information looking for the specific methods or processes to apply. However, such information should be close-by if the need arises. The *Handbook of Adhesion Technology* is intended to fill a gap between the necessarily simplified treatment of the student textbook and the full and thorough treatment of the research monograph and review article. The subject is treated very comprehensively and with the most up to date information so that the end-user has in a single book a proper guidance and fundamental knowledge required for many adhesive bonding or sealing applications.

The *Handbook of Adhesion Technology* is intended to be a book of reference in the field of adhesion. Essential information is provided for all those concerned with the adhesion phenomenon. Adhesion is a phenomenon of interest in diverse scientific disciplines and of importance in a wide range of technologies. Therefore, this handbook includes the background science (physics, chemistry, and materials science), engineering aspects of adhesion, and industry specific applications. It is arranged in a user-friendly format with ten main sections: theory of adhesion, surface treatments, adhesive and sealant materials, testing of adhesive properties, joint design, durability, manufacture, quality control, applications, and emerging areas. The sections contain each about five chapters written by internationally renowned authors who are authorities in their fields.

This Handbook is intended to be a reference for people needing a quick, but authoritative, description of topics in the field of adhesion and the use of adhesives and sealants. It is intended for scientists and engineers of many different backgrounds who need to have an understanding of various aspects of adhesion

technology. These will include those working in research or design, as well as others involved with marketing services. It is expected to be a valuable resource for both undergraduate and research students.

The editors would like to thank the authors for their patience with the preparation of this Handbook. Finally, the editors especially thank Christoph Baumann and Tina Shelton, Springer editors, who helped enormously toward the success of this Handbook.

## About the Editors

**Lucas F. M. da Silva** is currently Associate Professor with Aggregation at the Department of Mechanical Engineering of the Faculty of Engineering of the University of Porto and Director of the Integrated Master in Mechanical Engineering. He obtained his Ph.D. in bonding of composites from the University of Bristol (UK) in 2004. He leads the Adhesives Group, composed of post-docs, Ph.D. students, and M.Sc. students. He has published 206 ISI papers (174 as author and 32 as editor) and 23 books (9 as author and 14 as editor) mainly on adhesive joint mechanics. His papers were cited 4690 times and correspond to an h-index of 37 (SCOPUS, 06/02/2018).

One of his papers obtained the SAGE Best Paper Award 2010 and Donald Julius Groen Prize 2010 (both awards given by the Institution of Mechanical Engineers). He received in 2013 and 2018 the Award of Scientific Excellence by the Faculty of Engineering of the University of Porto.

He is editor-in-chief of *The Journal of Adhesion*, *Proceedings of the Institution of Mechanical Engineers, Part L: Journal of Materials: Design and Applications*, and *University of Porto Journal of Engineering*. He is also co-editor of two Springer book series (*Advanced Structured Materials* and *Springer Briefs in Engineering: Computational Mechanics*). He is member of the editorial board of *International Journal of Adhesion and Adhesives* and *Journal of Adhesion Science and Technology*. He is reviewer of 60 ISI journals.

He organizes international conferences on adhesive bonding (*Structural Adhesive Bonding* every odd year and *Industrial Applications of Adhesive Bonding* every even year) and materials (*Materials Design and*

Applications every even year), and founded the Portuguese Adhesion Society that belongs to European Adhesion Societies Group (EURADH).

He has seven pending patents. He developed a software for designing adhesive joints available online (*jointdesigner*). He is consultant of several international companies (e.g., Alstom, Nagase Chemtex, John Deere).

**Andreas Öchsner** is Full Professor for lightweight design and structural simulation at the Esslingen University of Applied Sciences, Germany. Having obtained a Diploma Degree (Dipl.-Ing.) in Aeronautical Engineering at the University of Stuttgart (1997), Germany, he spent the time from 1997 to 2003 at the University of Erlangen-Nuremberg as a research and teaching assistant to obtain his Doctor of Engineering Sciences (Dr.-Ing.). From 2003 to 2006, he worked as Assistant Professor in the Department of Mechanical Engineering and Head of the Cellular Metals Group affiliated with the University of Aveiro, Portugal. He spent 7 years (2007–2013) as a Full Professor at the Department of Applied Mechanics, Technical University of Malaysia, where he was also Head of the Advanced Materials and Structure Lab. From 2014 to 2017, he was a Full Professor at the School of Engineering, Griffith University, Australia, and Leader of the Mechanical Engineering Program (Head of Discipline and Program Director). His research interests are related to experimental and computational mechanics, cellular metals and thin structures and interphases. He has published over 450 scientific publications, comprising 13 research monographs, 23 book chapters, and four teaching books on finite element methods. He obtained more than 3000 citations in Google Scholar. He is the general Chairman of 12 international conferences on computational and experimental engineering (ACE-X series) and 14 international conferences in the area of heat and mass transfer (DSL series). His editorial work comprises posts as editor-in-chief of the international journal *Continuum Mechanics and Thermodynamics* (Springer), editor-in-chief of the Springer book series on Advanced Structured Materials, and editor of *SpringerBriefs in Applied Sciences and Technology: Computational Mechanics*.

His research activities were recognized in 2010 by the award of a higher doctorate degree (D.Sc.) by the University of Newcastle, Australia.

**Robert D. Adams** got his first degree, in Mechanical Engineering, from Imperial College, London, in 1962, and his Ph.D. from Cambridge University in 1967 and an Sc.D. in 2017. He was awarded a D.Sc. (Eng) from London University in 1986. Most of his academic career (1967–2005) was at Bristol University where he was made Full Professor in 1986. He was Head of the Department of Mechanical Engineering from 1994 to 1998 and Graduate Dean from 1998 to 2004. In 1991, he was awarded the Visiting Foreign Franqui Chair and Medal at the Free University of Brussels (VUB). He is now an Emeritus Professor of Applied Mechanics at the University of Bristol and a Visiting Professor at the Universities of Oxford and Oxford Brookes. He has published and edited several books and published about 200 papers in international refereed journals.

In 2011, he was awarded the R.L. Patrick Fellowship of the US Adhesion Society. He is active in organizing conferences and publishing and was a founder member of EURADH and WCARP, the main European and World series on Adhesion. He has been joint editor-in-chief of the *International Journal of Adhesion and Adhesives* since 1999. His main research area is on adhesively bonded joints, and he pioneered the application of finite element analysis for determining the stresses, strains, and strength of such joints. In addition to his adhesives research, he has also worked extensively on vibration properties in composites and developed low-velocity impact tests for nondestructively testing composites and sandwich structures.

## Abstract

This introductory chapter gives a brief description of adhesive bonding and adhesion-related phenomena. The major definitions of the terms associated to this technology such as adhesion, cohesion, adhesives, sealants, and adherends are given so that there is uniformity of language throughout the handbook. The reasons that drove the editors to prepare and revise this book are explained. Finally, the organization of the book is described.

## 1.1 Background

Adhesives have been used for thousands of years, but until 100 years ago, the vast majority was from natural products such as bones, skins, fish, milk, and plants. Since about 1900, adhesives based on synthetic polymers have been introduced, and today, there are many industrial uses of adhesives and sealants. It is difficult to imagine a product – in the home, in industry, in transportation, or anywhere else for that matter – that does not use adhesives or sealants in some manner.

It is possible to distinguish three stages in the formation of a bonded joint. Initially, the adhesive must be in the solid state so that it can spread easily on the surface and wet properly the adherends to be bonded so that an intimate molecular contact is created between the adhesive and the surface. Secondly, in order for the adhesive to support the loads that it will encounter in service, the liquid adhesive must harden. Often, the adhesive is initially in the form of a monomer and polymerizes into a polymer with a high molecular weight. Pressure-sensitive adhesives are an exception in that they do not harden but remain permanently sticky. Finally, it is necessary to understand that the capacity of the joints to carry the load and the durability of the joint are affected by various factors such as the joint design, the way the loads are applied, and the environment that the joint will be subjected to. Thus, to obtain good results with adhesive bonding technology, it is necessary to have knowledge in various sciences including surface chemistry, chemistry and physics of polymers, materials engineering, mechanical engineering, etc. (Petric 2000).

Adhesively bonded joints are an increasing alternative to mechanical joints in engineering applications and provide many advantages over conventional mechanical fasteners. They provide a more uniform stress distribution along the bonded area which enables to have a higher stiffness and load transmission, reducing the weight and thus the cost. Figure 1 shows how the stress distribution in a bonded joint can give a higher stiffness and more uniform stress distribution in relation to a riveted joint. Due to the polymeric nature of the adhesive, adhesive joints provide good damping properties which also enable to have high fatigue strength. Adhesives can bond dissimilar materials with different coefficients of thermal expansion because the adhesive flexibility can compensate the difference. They bond thin plates very efficiently being one of the major applications of structural adhesives. Adhesives have a strength well below that of metals; however, when used to bond thin plates with a large bearing area, the strength of the adhesive is sufficient for structural applications. The adhesive application can be very efficient because it is easy to create an automatic process. The joint design is very flexible and new concepts and materials can be introduced. A good example is the sandwich structures where the core is made of honeycomb and the skin of a composite. They enable to have very smooth surface finishes because they avoid the use of holes for rivets or bolts or welding marks. They create an intimate contact between the bonded surfaces which is good in structural terms and also for corrosion resistance.

**Fig. 1** Improved stiffness (left) and stress distribution (right) of adhesively bonded joints in relation to riveted joints

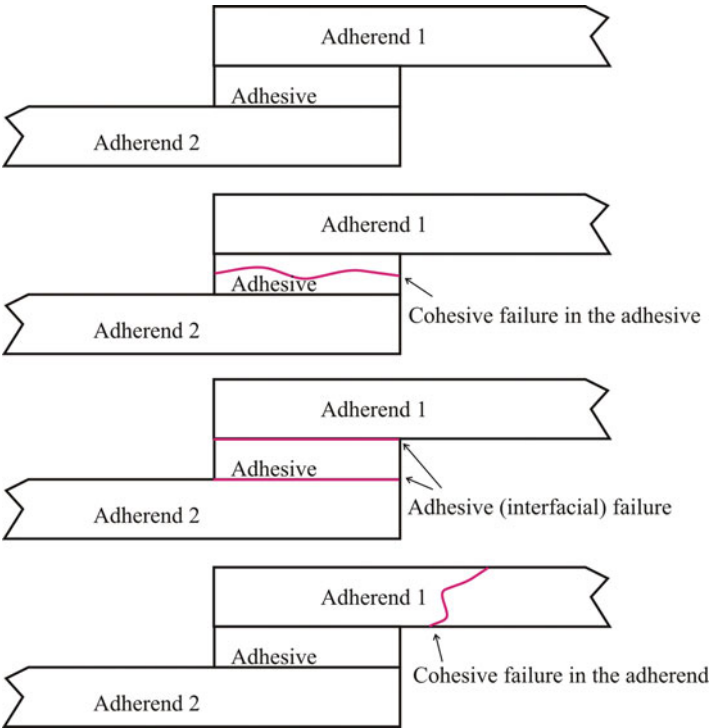

Adhesive bonding is also associated to some disadvantages that leave room for more technological research and development. It is necessary to reduce the peel and cleavage stresses because they concentrate the load in a small area giving poor joint strength. They have limited resistance to extreme temperature and humidity conditions due to the polymeric nature of the adhesive. The bonding is usually not instantaneous which requires the use of tools to maintain the substrates in position. In addition, the hardening needs temperature for many adhesives. This is a big economical disadvantage. To have a good interfacial strength and a durable joint, a careful surface preparation is necessary such as solvent cleaning, mechanical abrasion, or chemical treatments. The quality control is more difficult than mechanical fasteners because it is not possible to dismantle an adhesive bond. However, a series of nondestructive techniques are now available. The joint design tends to be complex in many cases. There are no simple rules such as in the case of bolts, rivets, or welding, and design engineers still do not trust this technique, especially when it comes to long-term strength.

Applications related to adhesive bonding are today very diverse and can be found in virtually all types of industry. The aeronautical industry is one of the precursors of this technology and increasingly uses adhesives as more composites are introduced in airplanes. The rail and automotive industry is also turning to adhesives to produce lighter vehicles. Civil construction, shoes, and electronics are other examples. Emerging fields such as biology and medicine are also using developing processes based on cell adhesion and protein adhesion on surfaces which are important issues in, for example, biocompatibility of materials for prosthetics, artificial organs, and surgical glues.

This handbook is focused on adhesion science and technology. The topics of particular interest are surface preparation, joint configuration, adhesive properties, environmental conditions, analytical and finite element analyses of joints, and test methods.

## 1.2 Definitions

Adhesives have been used for many centuries. However, this method of joining only evolved significantly in the last 70 years. The main reason is because adhesives used in advanced technological applications are based on synthetic polymers whose development only occurred in the middle of the 1940s. The synthetic polymers possess properties that enable them to adhere easily the most materials and a strength capable to transmit considerable loads. According to Kinloch (1987), an adhesive may be defined as a material which when applied to surfaces of materials can join them together and resist separation. However, there are other substances which are outside this definition but which show the phenomenon of adhesion; these include paints and printing inks. A structural adhesive is an adhesive that can resist substantial loads and that is responsible for the strength and stiffness of the structure (Adams et al. 1997). The shear strength can vary from 5 MPa for a polyurethane to 50 MPa for an epoxy. Sealants are also an important part of this handbook and work under the same principles of adhesives. However, in this case the objective is to bond two surfaces, filling the gap between them and forming a barrier or protective layer. The materials to be bonded are called substrates. However, after bonding, the term generally used is adherend. Both adhesives and sealants work by adhesion phenomena. Adhesion is the attraction between two substances resulting from intermolecular forces that establish between them. This concept is different from that of cohesion which only involves intermolecular forces inside one substance. The intermolecular forces that exist in adhesion and cohesion are mainly van der Waals-type forces. Mechanical, electrical, and diffusion phenomena may also occur at the adhesion level (Possart 2005). Figure 2 illustrates the difference between adhesion and cohesion. Materials bonded with adhesives or sealants break by adhesion, cohesion, or a combination of the two. The region between the adhesive and the adherend is referred as the interphase. The interphase has chemical and physical characteristics different from those of the bulk adhesive or adherend. The nature of the interphase is a critical factor in the determination of the mechanical properties of the adhesive bond. The interface, different from the interphase, is a plane of contact between the surface and the two materials. It is within the interphase. It is useful to define and measure the surface energy. The interface is also designated by boundary layer. In the interphase, there might be several interfaces between different materials localized between the adhesive (or sealant) and the adherend. A primer is a substance which is often applied on the substrate to improve adhesion or protect the surfaces until the adhesive or sealant application. The joint is the whole part formed by the adherends, the adhesive or sealant, the primer (if present), and the interphases and interfaces associated to it, as shown in Fig. 3.

**Fig. 2** Examples of cohesive and adhesive failures

**Fig. 3** Adhesive joint

### 1.3 Motivation

The adhesion technology is nowadays a common approach to many joining situations. There are many books such as those of Kinloch (1987), Dostal (1990), Adams et al. (1997), Petrie (2000), Packham (2005), Adams (2005), Possart (2005), Lacombe (2006), Tong and Steven (1999), Ebnesajjad (2008), da Silva and Öchsner

(2008), da Silva et al. (2011, 2012), and da Silva and Sato (2013), and several international journals (*International Journal of Adhesion and Adhesives*, *The Journal of Adhesion*, *Journal of Adhesion Science and Technology*, *Applied Adhesion Science*, and *Reviews of Adhesion and Adhesives*) dealing with this subject. However, when the end user needs to apply this technology, he does not have the time or the resources to thoroughly study the various technologies related to adhesives and sealants. It is not practical to go through volumes of text and product information looking for the specific methods or processes to apply. However, such information should be close by if the need arises. The *Handbook of Adhesion Technology* (second edition) is intended to fill a gap between the necessarily simplified treatment of the student textbook and the full and thorough treatment of the research monograph and review article. The subject is treated very comprehensively and with the most up-to-date information so that the end user has in a single book a proper guidance and fundamental knowledge required for many adhesive bonding or sealing applications.

This book is intended to be a reference for people needing a quick, but authoritative, description of topics in the field of adhesion and the use of adhesives and sealants. It is intended for scientists and engineers of many different backgrounds who need to have an understanding of various aspects of adhesion technology. These will include those working in research or design, as well as others involved with marketing services. It is expected to be a valuable resource for both undergraduate and research students. The first edition of 2011 is already 6 years old, and the editors felt the necessity to update the whole book and include new material. The fact that the book has been of great interest to the adhesion community was also an important motivation for a complete review.

---

## 1.4 Organization of the Handbook

The *Handbook of Adhesion Technology*, second edition, is intended to be a book of reference in the field of adhesion. Essential information is provided for all those concerned with the adhesion phenomenon. Adhesion is a phenomenon of interest in diverse scientific disciplines and of importance in a wide range of technologies. Therefore, this handbook includes the background science (physics, chemistry, and materials science), engineering aspects of adhesion, and industry-specific applications. It is arranged in a user-friendly format with ten main sections: theory of adhesion, surface treatments, adhesive and sealant materials, testing of adhesive properties, joint design, durability, manufacture, quality control, applications, and emerging areas. The sections contain each about five chapters written by internationally renowned authors who are authorities in their fields. The last chapter gives a brief summary of each chapter with information about the main changes in relation to the first edition. Every chapter has been arranged so that it can be studied independently as well as in conjunction with the others. For those who are interested in in-depth information, numerous sources have been listed at the end of each chapter. The references listed serve as both bibliography and additional reading sources.

## Abstract

The historical development and current status of the four classical theories of adhesion are first reviewed. The *adsorption theory* emphasizes the point that once adhesive and substrate come into contact forces of attraction will act between them. As long as the extent of wetting is good, these forces, whether primary bonds, such as covalent, or secondary van der Waals forces, are generally considered sufficient to give a high bond strength. Primary bonding may be necessary to achieve bond durability in a hostile environment.

The *mechanical theory* focuses on interlocking between adhesive and a rough substrate surface. Again good wetting is required, or surface roughening is likely to lead to poor bond strength. It has been shown to apply to some surfaces rough on a macroscale as well as to microfibrinous and microporous surfaces, such as anodized aluminum. The enhanced adhesion is associated with increasing plastic energy dissipation during fracture in the bulk adhesive.

The *electrostatic theory* points to electrical phenomena such as sparking, which may be observed during the destruction of an adhesive bond, and consider the transfer of electrostatic charge between the adhesive and substrate. It regards the adhesive-substrate system as analogous to a parallel plate condenser. Estimates of the energy associated with this process are generally small compared with adhesion fracture energies, and the theory is much less vigorously supported than was the case some 50 years ago.

The *diffusion theory* has attracted increasing interest since the development of reptation theory of polymer chain dynamics. It provides a model for polymer-to-polymer adhesion, and gives an explanation of the time and molecular weight dependence of adhesion to polymers of various compatibilities.

The role of *weak boundary layers* is discussed with emphasis on the importance of careful investigation of the locus of failure of an adhesive bond.

In conclusion it is argued that the classical theories are best regarded as emphasizing a different aspect of a more comprehensive model which, in principle, relates molecular dispositions in the region of the interface to macroscopic properties of an adhesive joint.

## 2.1 Introduction

### 2.1.1 Practical and Fundamental Adhesion

The phenomenon of adhesion has been of interest for tens of thousands of years. Our remote ancestors were concerned to stick pigments to walls for cave painting and flint and bone to wood for tools and weapons (Pascoe 2005; Wadley et al. 2009).

Aristotle remarked on the gecko's ability to adhere to vertical surfaces; both Galileo and Newton were fascinated by the high forces of adhesion that could be observed in certain surfaces in intimate contact.

As Newton realized, there are two different types of question to be asked about the phenomenon of adhesion. The *first* type asks about the forces and so on which have to be applied to *separate* the bonded components; the *second* concerns what holds the components together in the first place. These two types of question respectively concern *practical* and *fundamental* adhesion. Some authors have written as if they thought that fundamental and practical adhesion were the same. This tendency was more prevalent in the past, but is still occasionally encountered.

Practical adhesion, then, is concerned with the magnitude of mechanical force or the quantity of energy which has to be applied to break an adhesive bond. It is relevant whether an adhesively bonded component breaks under load in service, or in some test machine in the laboratory. Practical adhesion is clearly of enormous importance and is considered in detail in this *Handbook* in ► Chaps. 20, "Fracture Tests," ► 21, "Impact Tests," ► 22, "Special Tests," and ► 23, "Constitutive Adhesive and Sealant Models." This chapter is concerned with fundamental adhesion. It is concerned with forces and mechanisms on, or approaching, the molecular scale, which are involved in holding together the different components of an adhesive bond. Newton recognized that the forces concerned in fundamental adhesion could be very large and challenged "experimental philosophy" to discover what they were! (Newton 1730).

Serious scientific concern with fundamental adhesion is usually dated back to the classic work of McBain and Hopkins in the 1920s, and to the various theories were advanced during the middle part of the last century. There was a strong tendency during much of this period to regard different theories as rival explanations of the same phenomena, rather than as complementary aspects of a broader rationalization. Much of the literature of the time, and even some of the literature today, reflects this approach, and therefore it is appropriate, if somewhat anachronistic, in this chapter first to consider different theories individually. A synthesis will be given in the conclusions.

It is obvious that adhesion at the fundamental level is a prerequisite for the existence of practical adhesion. What is the relationship between fundamental and practical adhesion? The answer to this question is by no means simple; indeed some authorities in the past have considered that there was no relation between the two. It is not appropriate here to attempt a detailed answer, but a simple, indeed simplified, account will be presented now.

Practical adhesion is generally assessed in the laboratory by loading an adhesive joint and observing the force required to produce failure, cf. ► Chaps. 20, "Fracture Tests," ► 21, "Impact Tests," and ► 22, "Special Tests." In some tests, the numerical value representing practical adhesion is a fracture energy (per unit area); in other tests, a fracture stress. Let us consider each in turn.

### 2.1.2 Fracture Energy

When an adhesive joint fails energy will have to be supplied to break the bonds where the joint fails, creating two new surfaces. These bonds broken may be,

according to circumstances, primary or secondary bonds. This energy required to form new surfaces is surface energy. If the failure is at the interface between phases 1 and 2, the appropriate surface energy term is the work of adhesion,  $W_A$ ,

$$W_A = \gamma_1 + \gamma_2 - \gamma_{12} \quad (1)$$

where  $\gamma_1$  and  $\gamma_2$  are the surface energies of materials 1 and 2 respectively in contact with air, and  $\gamma_{12}$  is the interfacial energy between phases 1 and 2.

An adhesive joint often fails cohesively within one component, rather than at the interface. Under these circumstances, the corresponding term will be the work of cohesion,  $W_C$ , given (for failure in phase 1) by

$$W_C = 2\gamma_1 \quad (2)$$

The work of adhesion and work of cohesion have been defined and discussed more fully in ► [Chap. 5, “Spreading of Liquids on Substrates.”](#)

In practice the magnitude of the fracture energy,  $G$ , is (almost) always considerably greater than that of the surface energy term  $W_A$  or  $W_C$  (now written as  $G_0$ ), given by Eqs. 1 or 2.  $G_0$  may be some average of  $W_A$  or  $W_C$ , depending on the locus of failure. These Eqs. 1 and 2, are thermodynamic equations; however, fracture of an adhesive bond will rarely, if ever, be reversible as thermodynamics require. Moreover, during the fracture process other energy absorbing processes occur, for example, plastic and viscoelastic deformation. Thus

$$G = G_0 + \psi \quad (3)$$

where  $\psi$  represents these other energy absorbing processes.

From a simple standpoint, Eq. 3 can be taken as representing the relationship between practical adhesion (represented by the measured  $G$ ) and fundamental adhesion associated with molecular forces at the interface,  $G_0$ . To repeat, usually  $\psi$  is very much larger than  $G_0$ , and so practical fracture energies for adhesive joints are almost always orders of magnitude greater than work of adhesion or work of cohesion.

It might be thought from this that the surface energy term  $G_0$  was not important as its magnitude was small. However  $G_0$  and  $\psi$  are coupled: as  $G_0$  increases  $\psi$  gets larger as well. Put simply, a very weak interface (low  $G_0$ ) would not be able to transmit a high stress needed to produce high  $\psi$ , say by plastic deformation. In some mechanically simple adhesive bonds, the loss term is directly proportional to the surface energy term. If  $G_0$  is doubled,  $\psi$  also is doubled, so the overall fracture energy,  $G$ , becomes twice as large.

### 2.1.3 Fracture Stress

Where the measure of practical adhesion is a fracture stress, similar considerations apply. A simple treatment of the physics of fracture (Griffith-Irwin theory, v. Good 1972) shows that the fracture stress  $\sigma_f$  also depends on the fracture energy  $G$ :

$$\sigma_f = k(EG/l)^{\frac{1}{2}} \quad (4)$$

where  $k$  is a constant,  $l$  is the length of the critical crack which leads to fracture, and  $E$  is the effective modulus. When this equation was first put forward, it was considered that the term  $G$  was the surface energy, but it was soon recognized that this led to strength predictions which were much too low. It was realized that  $G$  represented the sum of all the energy absorbing processes involved in the fracture, i.e., once again Eq. 3 applied. Practical adhesion (now represented by  $\sigma_f$ ) is related to fundamental adhesion through Eqs. 3 and 4.

## 2.1.4 Structure of This Chapter

Contemporary discussion of the fundamentals of adhesion generally reflects the historical development of the subject. For convenience, this approach will be adopted here. Early work in the 1920s discussed two kinds of adhesion. Where surfaces were smooth what would now be described as *Adsorption Theory* applied, with rough or porous surfaces *Mechanical Theory*. The next two Sects. 2 and 3, of this chapter discuss these in turn.

These theories were challenged by work originating in the Soviet Union. The *Electrostatic Theory*, considered in Sect. 4, laying emphasis on the transfer of charge across an interface, was put forward by Deryagin in the 1940s. A different challenge came from a different Soviet school which insisted on the fundamental importance of diffusion across an interface. The *Diffusion Theory* is the subject of Sect. 5.

The *weak-boundary-layer theory* is essentially a theory of fracture, rather than of fundamental adhesion. However it is frequently discussed along with these other theories, so consideration is given to it here in Sect. 6.

A great deal has been discovered about the mechanisms of adhesion since the middle years of the last century when the “classic” theories of adhesion were first proposed. The concluding section of the chapter will reassess them in the light of present understanding and question whether emphasis on one theory at the expense of another is still a useful way of rationalizing the results of experimental research in adhesion.

## 2.2 Adsorption Theory

### 2.2.1 Contact and Bond Formation

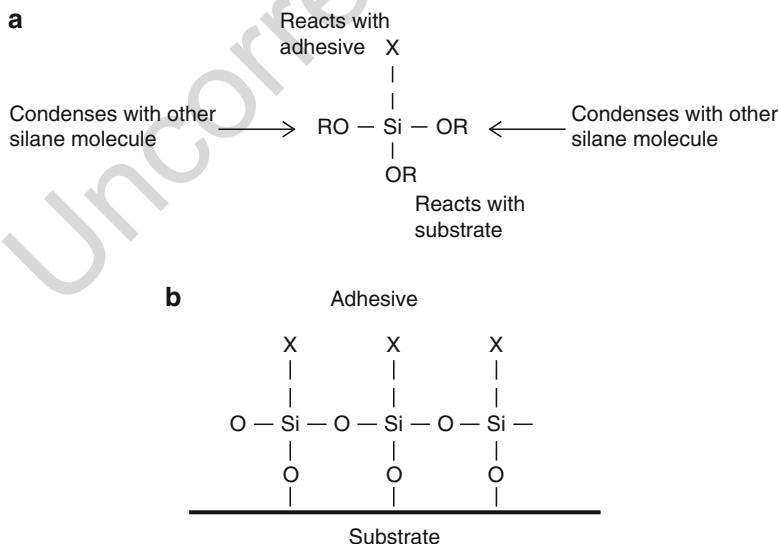

It is clear that the adhesive and substrate must come into contact for the possibility of the formation of an adhesive bond to exist. By far, the most common situation is one where a liquid adhesive comes into contact with a solid substrate. (That obviously means close contact on a molecular scale.) Factors that affect the extent of wetting and spreading of a liquid drop on a solid surface are, therefore, of primary

importance in any consideration of theories of adhesion. It is appropriate, then, that two other chapters in this handbook are devoted to these considerations.

As these other chapters show, there is a well-developed thermodynamic theory of wetting and spreading. This relates surface energies and surface tensions to contact angles and extent of wetting. Where the relevant surface energies and contact angles are known, or can be deduced, the extent of contact between a specific adhesive and substrate at equilibrium can be predicted. *The essential idea of the adsorption theory of adhesion is that whenever there is contact between two materials at a molecular level, there will be adhesion.*

When two materials come into contact, there will be forces of attraction between them. What those forces will be will depend on the chemical nature of the surfaces of the materials concerned. If this is known, it may be possible to postulate, or even to prove experimentally, the formation of a specific type of bond. Thus, metallic bonds may be involved in contact between a metallic solder and substrate metal (Some authors discuss secondary bonding in adhesion under the heading "Adsorption Theory," and treat primary bonding under a different heading, e.g., "Chemical Adhesion.").

Strong evidence for the presence of covalent bonds has been found, e.g., from some studies of the action of organosilane adhesion promoters used in bonding epoxies and other adhesives to metal and glass surfaces. It has long been suggested that the effectiveness of silanes was, in part, associated with covalent bond formation between the silane and a metal or glass surface, as indicated schematically in Fig. 1. Secondary ion mass spectroscopy (SIMS), which enables molecular fragments from

**Fig. 1** Typical structure (a) and postulated mode of action (b) for a silane adhesion promoter

**Fig. 2** Interaction between PMMA and surfaces of differing acidic and basic nature (After Leadley and Watts (1997)). <sup>a</sup>Indicating hydrolysis of the ester and adsorption through the carboxylate anion

an interface to be examined, has produced evidence of the presence of such silicon-oxygen-metal covalent bonds.

Using high-resolution X-ray photoelectron spectroscopy (XPS), small changes can sometimes be detected in the molecular bonding of a chemical group at the interface. Leadley and Watts (1997) used the technique to examine the interface between polymethylmethacrylate (PMMA) and oxidized surfaces of metals or silicon. They found evidence for hydrogen bonding, ionic bonding, and ion-dipole interactions, depending on the strength of the acid or basic nature of the mineral surface (Fig. 2). All three are examples of electron donor-acceptor (i.e., Lewis acid-base) interactions.

A broadly similar conclusion was reached by a different route by Schneider et al. (2002). Maleic anhydride is used as a curing agent for some types of epoxy resin. The authors studied its interaction with a model system consisting of a thin aluminum layer deposited on a silicon wafer. The aluminum was allowed to oxidize and was then equilibrated with a laboratory atmosphere, before a monolayer of maleic anhydride was deposited from solution in acetone. Reflection-absorption intra-red spectroscopy indicated that the anhydride was hydrolyzed to the acid and adsorbed onto the oxidized aluminum surface. As a result of comparing the observed absorption frequencies with those calculated by quantum mechanical modeling for various plausible structures, the authors argued for the presence of three different adsorption structures (Fig. 3) in the ratio 6:1:1 for Fig. 3a-c. The dominant structure involved a carboxylate ion adsorbed on two neighboring aluminum ions. Figure 3b shows similar carboxylate ion adsorption with additional hydrogen bond adsorption involving the second carboxylic acid group of the maleic acid molecule. The third structure, Fig. 3c, involves interaction between the carbonyl oxygen and aluminum in the substrate surface. All three structures again involve electron donor-acceptor (i.e., Lewis acid-base) interactions.

Weak, secondary forces, resulting from molecular dipoles, also act between materials. They are often classified according to the nature of the interacting dipoles. Keesom orientation forces act between permanent dipoles, London dispersion forces

**Fig. 3** Adsorption of maleic acid on model-oxidized aluminum surface (After Schneider et al. (2002))

**Table 1** Classification of secondary forces

			Dipolar interaction
<b>Van der Waals</b>	London	Dispersion	Transient/transient
	Debye	Induction	Permanent/induced
	Keesom	Orientation	Permanent/permanent

**Table 2** Alternative classification of secondary forces (N.B. some authors, especially in earlier literature, have used t upon specifi to include hydrogen bonding and other electron donorersion forces are universal. They only require

			Dipolar interaction
<b>Van der Waals</b>	London	Dispersion	Transient/transient
<b>Polar forces</b>	Debye	Induction	Permanent/induced
	Keesom	Orientation	Permanent/permanent

between transient dipoles, and Debye induction forces between a permanent and an induced dipole, see Tables 1 and 2. These are collectively known as van der Waals forces (but note alternative usage of this term, Table 2) and occur widely between materials. They are much less dependent upon specific chemical structure than primary bonds. Indeed, dispersion forces are universal. They only require the presence of a nucleus and of extranuclear electrons, so they act between all atomic and molecular species.

Thus, whenever there is contact between two materials at a molecular level, there will be adhesion. Physical adsorption or chemical adsorption (chemisorption) will occur. Specific types of bonding may be present, but there will always, at least, be London dispersion forces. That is the essential idea of the adsorption theory of adhesion.

### 2.2.2 Strength of the Adhesive Bond

Elementary chemistry books give bond dissociation energies for bonds of different types. Primary bonds are typically of the order of hundreds of kilojoules per mole, van der Waals bonds tens of kilojoules per mole. It is natural then that many have supposed that an adhesive bond involving primary bonds at the interface will be stronger than one relying simply on van der Waals interactions. However, Eq. 3 above implies that the situation is not so simple. The “strength of an adhesive bond” (practical adhesion) depends not just on the interfacial forces (reflected in  $G_0$ ) but also on other energy terms ( $\psi$ ), and these latter are usually much greater in magnitude.

It is possible to calculate the energy of interaction between model molecules, representing adhesives, and model surfaces. When the results of such calculations are compared with corresponding practically measured adhesion, the predicted strength is found to be much higher than the measured strength. Even when dispersion forces are the only interactions considered, the calculated value is generally an order of magnitude higher than the measured strength. This has led to the conclusion that dispersion forces alone are more than sufficient to account for practical strengths of adhesive bonds. The question to be answered when considering the strength of adhesive bonds is not “why are they so strong?” but “why are they not stronger?” Of course, an analogous question occurs when considering the strength of materials in general, and much of the science of materials is devoted to answering it!

### 2.2.3 Environmental Stability

The discussion so far points to the critical importance of wetting in the formation of an adhesive bond. Once wetting occurs, there are adhesive–substrate interactions – adsorption of some sort has occurred, and dispersion forces alone will be sufficient to give a strong bond.

In a practical context, van der Waals adsorption may not form the basis for a satisfactory adhesive bond. The bond may not be stable in the service environment. This can be seen from a discussion of the work of adhesion considered above.

If the work of adhesion (as defined in Eq. 1) is positive, the adhesive will make contact with the adhesive and adsorption will take place. However, in the presence of a medium  $m$ , Eq. 1 has to be modified, and the work of adhesion now becomes

$$W_{A/m} = \gamma_{1m} + \gamma_{2m} - \gamma_{12} \quad (5)$$

where  $\gamma_{1m}$  is the surface energy of material 1 in the presence of the medium  $m$ . If  $\gamma_{1m}$  and/or  $\gamma_{2m}$  are sufficiently low, the work of adhesion (Eq. 5) may now become negative, and the bond fails.

A widely encountered “medium” is water, either liquid or vapor, and this is strongly adsorbed onto many high-energy surfaces, lowering their surface energy.

There are many examples of adhesive bonds that fail in a humid environment because the adhesive is displaced by this mechanism from the substrate.

Thus dispersion force adsorption may be sufficient, in principle, to provide good fundamental adhesion. In practice, it is often necessary to produce stronger bonds that are less susceptible to attack by medium  $m$ , e.g., less susceptible to hydrolysis. Silane adhesion promoters, discussed above, increase the hydrolytic stability of interfaces between adhesives and glass or metals through covalent bond formation.

#### 2.2.4 Kinetic Effects

At the start of Sect. 2, it was pointed out that thermodynamic theories of wetting (cf. ► Chap. 6, “Thermodynamics of Adhesion”) enable a prediction to be made of the extent of contact between a liquid adhesive and a given substrate, provided information relating to interfacial energies and contact angles was available. Obviously a thermodynamic theory predicts the equilibrium state, and in practice, it is important to consider whether equilibrium will be attained.

Typically, adhesives are liquids that solidify following application to the substrate. There is no reason to suppose that equilibrium wetting will always be achieved before they set. Whether equilibrium will be attained will depend on the relation between such factors as the forces causing the adhesive to spread and the rate of increase in viscosity with time. Moreover, the surface energy of the solidified adhesive will differ from that of the liquid, changing the equilibrium conditions. Such considerations are relevant to the application of the adsorption theory of adhesion.

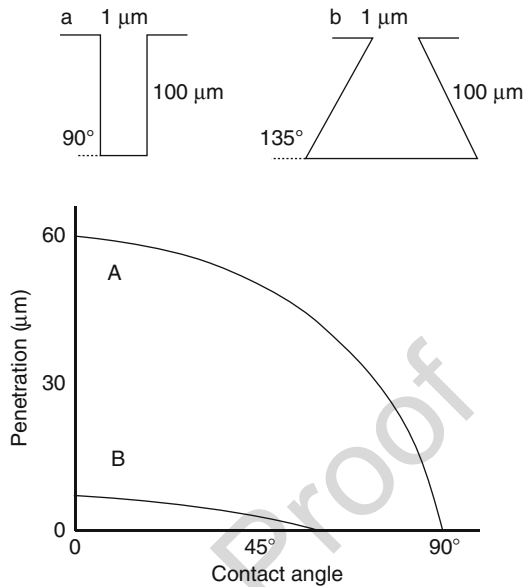

#### 2.2.5 Rough Surfaces

Rough surfaces are central to the concept of the mechanical theory of adhesion, discussed in Sect. 3. However, practical surfaces are always rough to some degree, and the discussion of the adsorption theory so far has tacitly assumed that the surface to be bonded was smooth.

If this roughness is not very great, its effect on wetting will be small, but some of the surfaces used in adhesion technology are extremely rough on a macro or microscale. Significant roughness can seriously reduce the extent of wetting achieved at equilibrium. If wetting is reduced, adsorption, and as a consequence fundamental adhesion, will be reduced also. The extent of this effect depends on the roughness features. It is possible, with plausible assumptions about surface tension and contact angle, to calculate equilibrium contact with model rough surfaces. Figure 4 shows some results after the classic work of de Bruyne (1956). Obviously a reentrant (“ink bottle”) pore is particularly difficult to wet.

The calculations on which Fig. 4 is based assume that equilibrium will be established. Considerations of the rate of setting of the adhesive and of its effect on viscosity and contact angle are relevant here. Depending on these factors, contact

**Fig. 4** Equilibrium penetration of a liquid into cylindrical and g will be small, but some de Bruyne (1956)

between an adhesive and a particular rough surface may be further inhibited by kinetic effects (Packham 2002).

### 2.3 Mechanical Theory

#### 2.3.1 Macro and Microroughness

Many of the features of the adsorption theory of adhesion, just discussed, can be traced back to McBain and Hopkins' classical work in the 1920s, where they are referred to it as "specific adhesion" (McBain and Hopkins 1925; Packham 1998, 2002, 2003). They also described "mechanical adhesion" to porous substrates, such as wood, unglazed porcelain, pumice, and charcoal. They regarded it as obvious "that a good joint must result whenever a strong continuous film of partly embedded adhesive is formed in situ." This is, in essence, the mechanical theory of adhesion.

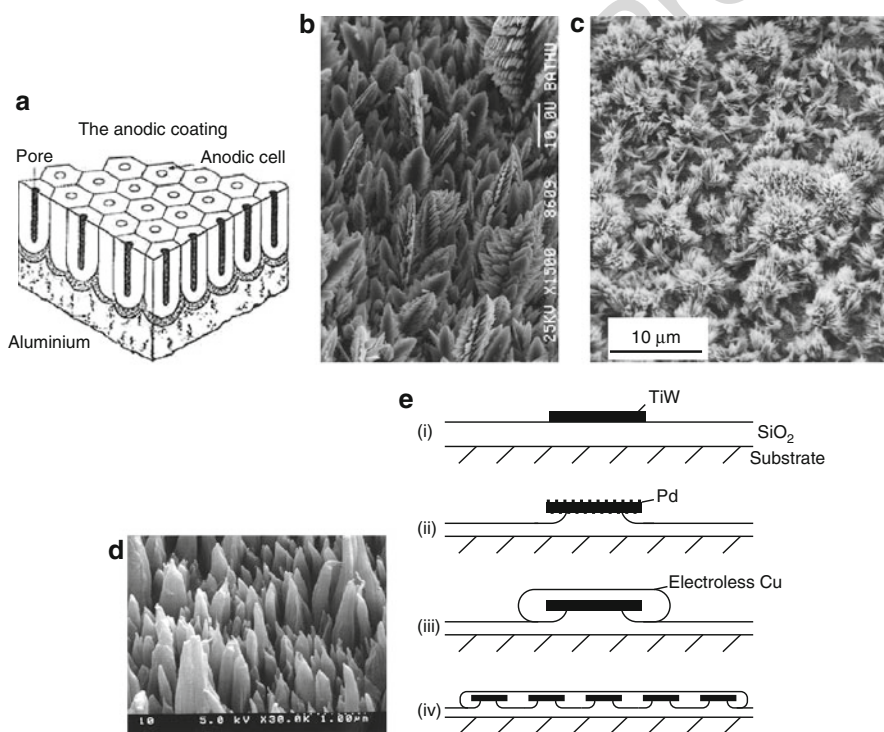

Clearly, this mechanical adhesion relies on contact between adhesive and substrate, and therefore adsorption forces, described in Sect. 2, will act between the two materials.

Despite the "obvious" nature of the mechanical theory of adhesion, by the 1950s, the validity of the mechanism was largely denied by scientists working on adhesion. This denial was based on the results of studies in which adhesion to similar surfaces with different degrees of roughness was reported. These generally showed an inverse relationship between roughness and practical adhesion.

These results, no doubt, bore witness to the difficulty of obtaining good wetting of a rough surface by a viscous adhesive, cf. Fig. 4. Thus, many joints to rough surfaces

have voids at the interface and asperities will act as points of stress concentration, which can lower the practical adhesion with a brittle adhesive. However, there are now many examples in the literature where good wetting is obtained with rough surfaces, and, indeed, stress concentrations can even enhance practical adhesion with a ductile adhesive, but initiating local plastic deformation, which increases the energy dissipated during failure –  $\psi$  in Eq. 3.

Many successful prebonding treatments produce rough, microfibrinous, or microporous surfaces. Some of these are shown in Fig. 5. The integrity of a sizable proportion of the world's civil aviation fleet relies on adhesive bonding to anodized aluminum (Fig. 5a). A black, microfibrinous oxide coating on copper is often used as a pretreatment for bonding in electronic applications (Fig. 5c). PTFE is notoriously difficult to bond. Figure 5d shows the surface resulting from a successful bonding pretreatment involving irradiation by argon ions. Figure 5e shows an example, on a somewhat coarser scale, where the poor adhesion of copper to silica has been

**Fig. 5** Some rough surfaces resulting from pretreatment prior to adhesive bonding: (a) porous anodic oxide on aluminum (schematic); (b) dendrites of zinc electrodeposited onto a zinc surface; (c) black CuO layer produced on copper; (d) PTFE irradiated by argon ions (After Koh et al. 1997); (e) adhesion of copper to silica using a mechanical key (van der Putten 1993). (i) TiW islands deposited; (ii) Pd activator adsorbed and HF etching; (iii) electroless Cu deposited; (iv) Cu electrodeposited

overcome by anchoring the copper to the silica surface using titanium tungstide “keys.”

Control experiments have shown scientifically that very rough surfaces, such as those illustrated in Fig. 5, give high adhesion under circumstances where adhesion to a corresponding smooth surface is low. So it could reasonably be said that the mechanical theory of adhesion applies in these cases. Of course, this does not necessarily mean that the high adhesion is the only technological reason for using the pretreatment. For example, the anodization of aluminum enhances durability of an adhesive bond in humid environments: in the aviation context, this is more important than the actual level of practical adhesion achieved.

### 2.3.2 Mechanism of Adhesion to Rough Surfaces

On the phenomenological level, it is clear that there are many rough surfaces known to adhesion science and technology where the surface roughness plays an essential role in adhesion: the mechanical theory of adhesion applies. Rather than simply ascribing adhesion to “mechanical effects,” it is useful to explore *why* roughness can lead to good adhesion.

Consider again Eq. 3. The surface energy term  $G_0$  is, from the standard definition of surface energy, the excess energy in the surface of the material, over that in the bulk material. In a simple way, this excess energy can be thought of as the energy necessary to break those bonds needed to produce the surface. Compare the bulk atom (B) in Fig. 6, with an atom S on a plane surface. In this schematic two-dimensional diagram, where the material is represented as a close-packed array of spherical atoms, B is bonded to six nearest neighbors, but S is only bonded to four. By extension of this argument, it can be seen that an atom (A) on an asperity will have a still higher surface energy. Thus, a rough surface, especially a very rough surface such as those illustrated in Fig. 5b–d, will have a higher surface energy than a corresponding smooth surface.

Returning to Eq. 3, it must be remembered that the fracture energy  $G$  is fracture energy *per unit area*. Obviously,  $G_0$  and  $\psi$  are also energies per unit area. The area relevant here is the formal (ideal) area, i.e., the macroscopic area of the interface, assuming that there was no roughness. For a rough surface, the “true” area will be greater and the surface energy term ( $G_0$ ) will consequently be higher. For moderate increases in surface roughness, a proportional increase in adhesion (practical adhesion) has been demonstrated (Gent and Lai 1995).

For very rough microporous and microfibrinous surfaces, the effective increase in area becomes enormous:  $G_0$  can be raised to a very high value indeed. Many engineering surfaces are fractal in nature: for such surfaces, the “area” is, in principle, indefinitely large. The practical adhesion to such surfaces does not become indefinitely large, because a joint with a strong interfacial region will fail cohesively in some other region where  $G_0$  is locally smaller.

The results presented in Table 3 show this effect in practice. Much higher fracture energies are found for adhesive bonds made to microfibrinous surfaces than to

**Fig. 6** Local environment of an atom in the bulk of a material (*B*), on a plane surface (*S*), and on an asperity on a rough surface (*A*) (Schematic representation)

**Table 3** Adhesion of low density polyethylene (*LDPE*) to copper and of epoxy resin to electro-formed zinc, assessed, respectively, by peel and single edge notched (*SEN*) tests (Evans and Packham 1979; Hine et al. 1984)

Polymer	Substrate	Test	Fracture energy <sup>a</sup> J/m <sup>2</sup>	Fracture surface
LDPE	Copper (polished)	180° peel	210 ± 60	Close to substrate
LDPE	Copper (microfibrous <sup>b</sup> )	180° peel	1,620 ± 140	Plastic deformation of PE
Epoxy (unmodified)	Zinc (flat)	SEN	105 ± 30	Apparently adhesive
Epoxy (unmodified)	Zinc (dendritic <sup>c</sup> )	SEN	670 ± 290	Cohesive above dendrite tips
Epoxy (toughened <sup>d</sup> )	Zinc (flat)	SEN	700 ± 200	Adhesive with residual polymer areas
Epoxy (toughened <sup>d</sup> )	Zinc (dendritic <sup>c</sup> )	SEN	2,548 ± 515	Cohesive

<sup>a</sup>95% confidence limits given  
<sup>b</sup>cf. Fig. 5c  
<sup>c</sup>cf. Fig. 5b  
<sup>d</sup>15% CTBN rubber toughening agent incorporated

**Fig. 7** Adhesion of polyethylene to copper. Substrate surface after peeling from (a) polished copper and (b) copper with a microfibrinous oxide surface

corresponding smooth surfaces. For the smooth surfaces, stresses are concentrated at the interface, and failure occurs at or close to the interface with little plastic energy dissipation (Fig. 7a); for the microfibrinous surfaces, the stresses are concentrated at the fiber or dendrite tips causing yielding, which moves into the polymer, giving cohesive failure and higher fracture energy associated with the plastic deformation involved (Fig. 7b). It is interesting to note that, even with the brittle unmodified epoxy resin, cohesive failure occurs showing signs of plastic deformation associated with the dendrite tips (Fig. 8).

Thus, the basic ideas, related by McBain and Hopkins in the 1920s, underlying both the adsorption and mechanical theories of adhesion still provide useful models for rationalizing observations in adhesion science. Two further adhesion theories, the electrostatic and diffusion theories, emerged from the Soviet Union in the middle of the twentieth century. We now turn to consider them, and how they are regarded today.

## 2.4 Electrostatic Theory

### 2.4.1 Early Formulation

The electrostatic theory was put forward in the 1940s by Deryagin (alternative transliteration Derjaguin) and colleagues in the Soviet Union (Deryagin and Krotova 1948). The interface is seen as analogous to the plates of an electrical condenser across which charge transfer occurs. A physical model was introduced representing the electric double layer as a three-dimensional region at the polymer–solid contact (Deryagin et al. 1973).

**Fig. 8** Zinc with a dendritic surface bonded with unmodified epoxy resin: fracture surface showing plastic deformation of the epoxy just above the dendrite tips (Hine et al. 1984)

The basis of the theory is that free charges exist to some extent in any condensed material, even in the best dielectrics, and there will always be an electrochemical potential difference across the interface between two materials in contact, e.g., adhesive and substrate. Free electronic or ionic charge carriers will tend to move across the contact interface, and an electric double layer is established. This mechanism is considered quite distinct from any charge transfer, which may be associated with bonding at the interface, as discussed in Sect. 1.1.

Electrical phenomena (e.g., sparking) can often be demonstrated to accompany the destruction of an adhesive bond. The work of separation of the plates of a condenser depends upon rate of separation and ambient gas pressure. Measured peel energy certainly depends on rate of separation, and some published results indicate a dependence upon gas pressure. Deryagin argued that this supported the electrostatic theory of adhesion. He published results showing good correlation between measured peel energy and condenser discharge energy, but the details of his argument have been the subject of adverse criticism, see, e.g., Wake (1982) and Kinloch (1987).

More recently, Possart has used potential contrast scanning electron microscopy to study electric double layer formation associated with the interface between a thin layer of solvent-cast low-density polyethylene and aluminum (Possart 1988). While arguing that the electrical discharge energy of the double layer makes a contribution to the fracture energy, this study accepts that many other energy mechanisms also contribute. The work spent in mechanical testing surmounts the electrostatic interaction energy in the double layer by several orders of magnitude. The work of peeling was measured to be  $1 \text{ J/m}^2$ . The specific electrostatic work of separation was calculated as  $247 \text{ J/m}^2$ .

There was a period in the mid-years of the last century when its supporters presented the electrostatic theory as a comprehensive theory of adhesion, replacing the adsorption theory. Many critics of the theory pointed out examples where a change of filler or of polymer might lead to the absence of electrical phenomena,

despite there being similar levels of measured adhesion: most cases of conventional adhesion, it was argued, could be explained without recourse to the electrostatic theory. By the 1970s, Deryagin himself was prepared to accept that “an adhesive bond is always caused by either the forces of chemical bonding or by so-called van der Waals forces.” (Deryagin et al. 1978). The present writer’s perception is that the widely held view is that electrostatic contributions in conventional adhesion are likely to be small; this view, however, is not universally accepted.

## 2.4.2 Particle Adhesion

Although the detailed mechanism is distinct from that just discussed, it is relevant to note that electrostatic forces are still considered to be of relevance in adhesion of small particles. An advantage of this sort of adhesion is that it may be possible to manipulate the charged particles by external electric fields. Electrostatic precipitation is a well-established industrial technique. It is used to remove dust particles from a gas flow, e.g., from flue gases in a power station. Electrically charged dust particles are attracted to an electrode surface and are thus removed from the gas stream. In a similar way, the application of a strong field across the open base of a silo can be used to prevent the egress of charged dust particles.

The modern photocopier relies for its function on both electrostatic and van der Waals forces. Charged toner particles initially adhere to charged regions on a moving photoconductor belt and are subsequently transferred by electrostatic forces to a paper sheet on which they are fused (Kendall 2001).

## 2.5 Diffusion Theory

### 2.5.1 Origins: Voyutskii and Colleagues

The second adhesion theory to emerge from the Soviet Union in the mid-years of the twentieth century was the diffusion theory. The basic principles were set out by S.S. Voyutskii and his colleagues. Their compatriot, R.M. Vasenin, contributed to its quantitative development using Fickian diffusion theory (Voyutskii 1963; Wake 1982).

Much of Voyutskii’s original work was done on the self-adhesion (called autohesion) of unvulcanized rubbers. It was subsequently extended to polymer adhesion, more generally. The theory postulates that the molecules of the two parts of the specimen interdiffuse, so that the interface becomes diffuse and eventually disappears. For polymers in contact, Voyutskii studied the effects on adhesion of such variables as time, temperature, contact pressure, molecular weight, polarity, and crosslinking. He argued that the results proved that the adhesion was associated with the interdiffusion of polymer chains.

Voyutskii’s 1963 book, *Autohesion and Adhesion of High Polymers*, is the locus classicus for the exposition of his ideas in English. Here he takes a robust,

comprehensive view of the scope of the diffusion theory arguing that it is superior both to adsorption theory and electrostatic theory. He even argues for its application to the adhesion of polymers to metals.

As already indicated, the mid-decades of the twentieth century were the time when many authorities in the field of adhesion took an exclusive approach to theories of adhesion: if one theory was correct, another must be incorrect. In contrast, it is now much more widely recognized that different theories may have different areas of applicability, or even be better regarded as emphasizing a particular feature of a broader, overarching understanding.

Consistent with the spirit of the 1950s and 1960s, the diffusion theory generally got an unsympathetic reaction among supporters of the adsorption theory, i.e., mainly workers in the West. But attitudes changed, and by 1970, the position could probably be summarized by saying that diffusion was generally accepted as a mechanism for adhesion between samples of the same polymer (autohesion) or between very similar polymers (Wake 1982), but it was not more broadly accepted, even for polymer–polymer adhesion.

The reluctance to accept the applicability of diffusion theory to adhesion between chemically different polymers was because mutual solubility (emphasized by Voyutskii) was regarded as an essential feature of the mechanism, and most polymer pairs were known to be incompatible.

## 2.5.2 Polymer–Polymer Compatibility

It is often important to know whether two phases are mutually soluble, i.e., will mix on the molecular level to form a true solution. The question of mutual solubility – compatibility – can be approached in terms of thermodynamic criteria. The two phases will be compatible if the Gibbs free energy for mixing is negative. The Gibbs free energy of mixing  $\Delta G_m$  is related to the enthalpy (heat) of mixing  $\Delta H_m$  and entropy of mixing  $\Delta S_m$  by the usual second Law equation:

$$\Delta G_m = \Delta H_m - T\Delta S_m \quad (6)$$

where  $T$  is the absolute temperature. As mixing always increases disorder,  $\Delta S_m$  is positive, it follows that the  $-T\Delta S_m$  term is always negative, and therefore favors mixing. However, where polymers are involved, the long chain molecules mean that the entropy gain is much smaller than when compounds with small molecules are mixed. The  $-T\Delta S_m$  term, although negative, tends to be small in magnitude.

One approach to the discussion of compatibility in polymer systems is the Flory-Huggins theory (Berg 2002). This considers the number of ways in which chain segments of the polymers may be distributed among identical unit cells in a hypothetical lattice. The theory gives an expression for the free energy of mixing of polymers 1 and 2 (volume fractions  $\phi_1$  and  $\phi_2$ , degrees of polymerization  $x_1$  and  $x_2$ ) in terms of the Flory-Huggins interaction parameter,  $\chi$ . It may be written as:

$$\Delta G_{\text{mix}} = kT[\chi\phi_1\phi_2 + (\phi_1/x_1)\ln\phi_1 + (\phi_2/x_2)\ln\phi_2] \quad (7)$$

$$\frac{\Delta G_{\text{mix}}}{kT} = \underbrace{\chi\phi_1\phi_2}_{\text{enthalpy}} + \underbrace{(\phi_1/x_1)\ln\phi_1 + (\phi_2/x_2)\ln\phi_2}_{\text{configurational entropy}} \quad (8)$$

where  $k$  is Boltzmann's constant and  $T$  absolute temperature. In this particular form of the equation, the free energy change is expressed per total number of polymer chain segments. The interaction parameter,  $\chi$ , is a dimensionless temperature-dependent parameter.

The last two terms in Eqs. 7 and 8, involving  $\ln \phi$ , represent the configurational entropy of mixing. This is negative and so favors the formation of a solution, but, as explained, it is small in magnitude because of the limited potential gain in entropy in mixing long chain molecules. The first term, involving  $\chi$ , was originally conceived as expressing the enthalpy of mixing and is usually positive, meaning that for most polymer–polymer combinations  $\Delta G_{\text{mix}}$  overall is positive, and so the mixture is heterogeneous. Even polymers as similar as polyethylene and polypropylene are incompatible: the value of  $\chi$  at 140 °C has been calculated to be 0.011.

Such thermodynamic treatments point to the incompatibility of most polymer/polymer combinations, and practical studies with polymer blends lead to the same conclusion. Mutual solubility, regarded as an essential feature of the diffusion theory, would rarely be achieved, restricting the applicability of the theory to autohesion, and perhaps to adhesion between polymers of closely similar chemical structure.

## Developments in Molecular Dynamics

Following the work on molecular dynamics by de Gennes (1998) and by Doi and Edwards (1986) leading to the development of reptation theory, a much more detailed description of the motion of polymer chains can now be given (Wool 1995, 2002, 2005). Consider two samples of an amorphous polymer brought into contact above the glass transition temperatures. The conformations of the chains at the interface will tend to relax. Five different mechanisms of relaxation can be identified, corresponding to five different time scales. In order of increasing relaxation time, they are: (1) short-range Fickian diffusion of individual chain segments, (2) Rouse relaxation between chain entanglements, (3) Rouse relaxation of the whole chain, (4) reptation diffusion, and (5) Fickian long-range diffusion.

It is the reptation region (4) of diffusion of chain segments to a depth of the order of the radius of gyration that is considered to be the most important in discussing the development of strength of interfaces. This is illustrated for the autohesion of polystyrene at 118 °C by the data of Table 4 (Wool 2005). It can be seen that reptation leads to considerable interpenetration of the chains and, as discussed below, to significant strength.

The reptation model envisages the polymer chain to be enclosed within an initial tube out of which it gradually escapes by wriggling in a snake-like manner (“reptating”: *reptare* to creep). The reptation relaxation time  $T_r$  corresponds to the time when about 70% of the chain has escaped from the initial tube. During this time,

**Table 4** Chain relaxation and diffusion mechanisms: relaxation time ( $\tau$ ) and molecular weight ( $M$ ) relationships.  $M_c$  is molecular weight between chain entanglements,  $\tau_c$  is the Rouse relaxation time between chain entanglements,  $\tau_{RO}$  is the Rouse relaxation time of the whole chain,  $T_r$  is the reptation relaxation time

Mechanism	Relation between relaxation time and molecular weight	Relaxation time <sup>a</sup>	Average diffusion distance <sup>a</sup> at $\tau$
Rouse relaxation between chain entanglements	$\tau_c \sim M_c^2$	10 s	30 Å
Rouse relaxation of the whole chain	$\tau_{RO} \sim M^2$	21 min	60 Å
Reptation	$T_r \sim M^3$	1,860 min	110 Å

Numerical data<sup>a</sup> refer specifically to polystyrene ( $M = 245,000$ ) welded to itself at 118 °C

the interfacial thickness increases with time  $t$ , in proportion to  $t^{1/4}$ , in contrast with the  $t^{1/2}$  relationship for Fickian diffusion. The relaxation time  $T_r$  is proportional to the cube of molecular weight.

**2.5.3 Interfacial Strength and Interdiffusion**

The fracture strength of a polymer depends on molecular weight, the chain length, and in a similar way, the fracture of a polymer–polymer adhesive bond depends on the length of the chain, which has diffused across the interface.

Figure 9 shows the molecular weight dependence of the fracture energy for polystyrene. It can serve as a focus for consideration of the mechanisms involved in polymer–polymer adhesion. Two characteristic molecular weights are involved in this discussion:  $M_c$  and  $M^*$ .  $M_c$  is the average molecular weight between chain entanglements, the critical entanglement molecular weight. It represents the onset of the well-known zero shear viscosity law

$$\eta \sim M^{3.4} \tag{9}$$

and the molecular weight at which the dynamics change from Rouse to reptation. In contrast,  $M^*$  is the value above which the molecules are too long for chain disentanglement (or pullout) to occur. They are related approximately by:

$$M^* \approx 8M_c \tag{10}$$

*Low molecular weight* When  $M < M_c$  (region A, Fig. 9) only short lengths of polymer chain are involved in the fracture process, which occurs by chain pullout. The fracture energy is low, up to about 1 J/m<sup>2</sup>.

Fracture behavior in this region can be treated using the “nail solution” where the weak interface is modeled as if the two sides were nailed together with  $\Sigma$  nails per unit area, each of length  $L$ . The analysis shows that the fracture energy associated

**Fig. 9** Fracture energy versus molecular weight for polystyrene in the virgin state (After Wool 2005).  $M_c$  is the average molecular weight between chain entanglements;  $M^*$  is the average molecular weight above which the molecules are too long for chain disentanglement (or pull-out) to occur

589 with chain pullout,  $G$ , increases with  $L^2$  and with  $\Sigma$ . To this “friction” term must be  
 590 added a surface energy term, so that

$$G_{1c} \sim 2S\gamma + kL^2\Sigma \quad (11)$$

591 where  $S$  depends on surface roughness ( $S = 1$  for a perfectly flat fracture surface) and  
 592  $k$  is a constant related to the “friction” involved in chain pullout. The term “friction,”  
 593 of course, refers to inter- and intramolecular attractions, such as van der Waals  
 594 forces.

595 *Intermediate molecular weight* When  $M_c < M < M^*$  (region B, Fig. 9), the chains  
 596 are long enough for entanglement to occur and the fracture energy rises progres-  
 597 sively. Fracture in this region occurs by disentanglement and chain pullout: bond  
 598 rupture is not considered to be significant.

599 Fracture in this region can be treated by the vector percolation theory, which  
 600 models the polymer as a three-dimensional network, the links of which are progres-  
 601 sively broken (here by chain disentanglement) until a critical value, the percolation  
 602 threshold, is reached, and the whole net fractures (Wool 2005).

603 *High-molecular weight* Here,  $M > M^*$  (region C, Fig. 9) and the dominant fracture  
 604 mechanism becomes bond rupture. Vector percolation theory predicts extensive  
 605 bond rupture throughout a significant volume of the polymer before failure occurs.  
 606 With glassy polymers, this is often associated with crazing. The fracture energy is  
 607 high tending to a limit, according to the Flory equation for molecular weight  
 608 dependence:

$$G_{1c}/G_{1c}^* = [1 - M_c/M] \quad (12)$$

609 where  $G_{1c}^*$  represents the fracture energy at high molecular weight.

To summarize, for autohesion (polymer–polymer welding), there will be rapid (Rouse) interdiffusion, which occurs to distances comparable to the radius of gyration of the entanglement molecular weight,  $M_e$ , say 3 nm (Table 4). The interface is very weak and could be described in terms of the nail solution, with chain pullout being the dominant fracture mechanism.

As welding proceeds, chains diffuse by reptation diffusion, and the failure mechanism then involves chain disentanglement and, with more extensive diffusion at longer times, bond rupture dominates. When bond rupture begins to dominate, the weld will appear fully healed, even in the absence of full interpenetration. There is a rate effect here. At high test rates, chains may not have time to disentangle and may rupture instead. This will give a high fracture toughness,  $G_{1c}$ , but at much lower deformation rates, weld weakness may be apparent. Wool (2002) cites, as an example, welding of a particular polystyrene at 125 °C, where essentially full (short time) weld strength would be obtained in 156 min, but the fatigue strength would be about one-fifth of its virgin value. For complete welding, a reptation time of 435 min, the relaxation time for reptation, would be needed. The importance of this observation for the molding of thermoplastics is obvious.

#### 2.5.4 Interfaces Between Incompatible Polymers

Despite macroscopic thermodynamic incompatibility, Sect. 5.2, an atomically sharp interface between two such polymers will not be stable. Although there is an enthalpy debt to be paid if a chain of polymer 1 starts to diffuse into polymer 2, there is an entropy gain. Helfand and Tagami (1972, Helfand 1992) introduced a model, which considered the probability that a chain of polymer 1 has diffused a given distance into polymer 2 when the interactions are characterized by the parameter  $\chi$ . They predicted that at equilibrium, the “thickness,”  $d_\infty$ , of the interface would depend upon the interaction parameter and the mean statistical segment length,  $b$ , as follows

$$d_\infty = 2b/(6\chi)^{\frac{1}{2}} \quad (13)$$

Thus, despite the argument in Sect. 5.2, some interdiffusion can be expected between formally incompatible polymers. The extent will depend on the extent of incompatibility, e.g., on the value of the interaction parameter: the smaller the  $\chi$ , the greater the possibility of interdiffusion.

Different mechanisms were discussed above (Sect. 5.3) in the context of autohesion. Depending on the extent of interdiffusion, fracture may occur at low energy by chain pullout or by chain disentanglement with bond rupture accompanied by crazing giving the highest fracture energies corresponding to the greatest extent of interdiffusion. In principle, the same considerations should apply to adhesion between different polymers.

The toughness of an interface will be expected to be related to the depth of interpenetration of the chains. Wool (1995) has argued that the fracture energy,  $G$ , for

**Fig. 10** Fracture energy  $G_{Ic}$  of bonds between a range of immiscible polymers as a function of number of entanglements (After Wool 2005)

chain pullout, is proportional to the square of the interface thickness, which, via Eq. 6, gives

$$G \propto d_{\infty}^2 \propto 1/\chi \quad (14)$$

cf. Eq. 13 above.

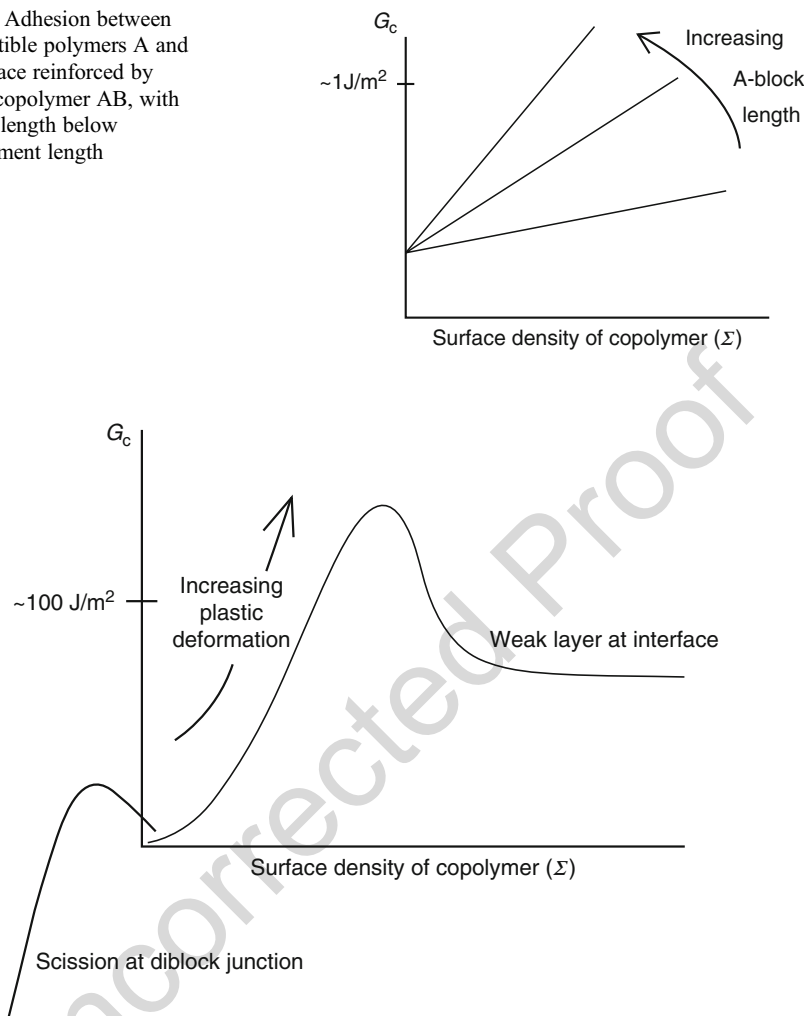

For higher fracture energies, a linear relationship with the number of chain entanglements,  $N_{ent}$ , has been found for a range of polymer pairs, Fig. 10.

### 2.5.5 Copolymer Compatibilizers

Much higher adhesion may be obtained between incompatible polymers through the use of copolymer compatibilizers. If an AB diblock copolymer is introduced at the interface between two incompatible polymers A and B, the interface may be toughened by diffusion of the copolymer ends into the respective homopolymer. Much ingenuity has been employed in developing this type of compatibilizer.

A range of fracture toughness values ( $G_c$ ) may be obtained. The general principles are similar to those discussed in Sect. 5.3. For diblock copolymers, both surface density ( $\Sigma$ ) and degree of polymerization ( $N$ ) of the blocks are important. For example, if the degree of polymerization of the A block were shorter than the entanglement length, but that of the B block longer, interdiffusion could occur at the interface, but the bond would be weak with chain pullout of the A part of the copolymer from polymer A. Typical results are illustrated schematically in Fig. 11 (cf. Creton et al. 1994a): strength of the bond increases both with surface density of copolymer and with segment chain length (here segment A). However, as all the lengths of segment A are below the entanglement length, the fracture energy corresponds to chain pullout and is low.

**Fig. 11** Adhesion between incompatible polymers A and B. Interface reinforced by diblock copolymer AB, with A-block length below entanglement length

**Fig. 12** Adhesion between incompatible polymers A and B. Interface reinforced by long chain length diblock copolymer

With greater degrees of polymerization, chain entanglement can take place, Fig. 12. At low surface density ( $\Sigma$ ), chain scission will occur close to the junction of the diblock, with each fragment remaining on the “correct” side of the interface. The fracture energy is low. As the copolymer surface density increases, fracture energy rises steeply with plastic deformation, e.g., crazing, occurring in the polymer followed by chain scission or pullout. If an increase in copolymer surface density continues, eventually the surface becomes saturated and a weak layer forms at the interface with fracture energy falling toward a limiting value (cf. Creton et al. 1994b).

**Fig. 13** Schematic representation of a random copolymer at the interface between two incompatible homopolymers. Incompatibility increases in the order (a), (b), and (c)

Toughening of a polymer–polymer interface with random copolymers can sometimes be more effective than with diblocks, provided the polymers are not too incompatible. This is of industrial, as well as of scientific, interest as random copolymers are usually cheaper to produce.

Each molecule in diblock copolymers will form a single, strong chemical linkage across the interface. However if the incompatibility between the homopolymers is not too large, a molecule of a random copolymer will form coils wandering many times across interface, forming many “stiches.” At larger incompatibilities, the random copolymer will no longer describe coils, but the homopolymers will still be linked by “loops.” If the incompatibility is too large, the copolymer will simply form collapsed globules at the interface, a weak boundary layer giving no enhancement of adhesion, cf. Fig. 13.

As with block copolymers, the important parameters are the surface density and length of the copolymer chains. Toughening of the interface may occur as a result of pullout or scission of the connector chains, or of fibril or craze formation in the matrix. This last mechanism gives the highest fracture toughness,  $G$ , and tends to occur at high surface density of chains.

Needless to say, implicit in the general discussion of Sects. 5.4 and 5.5 is that the time and temperature of contact are such that the degree of interdiffusion discussed can occur. The lowering of temperature, and the shortening times will lead to kinetic inhibition.

### 2.5.6 Diffusion Theory: Conclusion

The ideas advanced by Voyutskii and his colleagues over half a century ago have now been developed far beyond what was possible at the time. It is now possible to relate with some clarity the circumstances where interdiffusion plays a significant part in adhesion, and plausible molecular models have been developed, which go a long way to describe it, relating joint strength to interfacial structure. These scientific developments have important technological implications for the development of new multicomponent polymer materials and for the recycling of mixed plastics waste.

## 2.6 Weak-Boundary-Layer Theory

### 2.6.1 Practical Adhesion

This article is concerned with *theories of fundamental adhesion*, i.e., with theories concerned with the reasons for two materials holding together in an adhesive bond, however weak. In contrast, a weak boundary is a cohesively weak layer in the interfacial region (some authors use the term “interphase”) of an adhesive joint, which may cause the joint itself to be weak, i.e., to fail at a low stress or with low fracture energy. So the question of weak boundary layers occurs when the level of practical adhesion is under consideration, and may form part of an answer to a question such as “why did this joint fail at such and such a stress?”

However, 50 years ago, when there was considerably less basic understanding, and more confusion, in the study of adhesion than there is now, “weak boundary layer theory” would often be discussed alongside theories such as the adsorption theory and the electrostatic theory. The tendency to group theories of adhesion in this way has persisted, and so it may now be useful to discuss the significance of weak boundary layers.

#### Need for Pretreatment

At one level, the existence of weak boundary layers and their deleterious effect on adhesion is obvious. Surface pretreatments, prior to adhesive bonding, are almost always a prerequisite for success. That is, because almost all surfaces will be contaminated to some degree from the environment to which they have been exposed. Generally speaking, extensive cleaning under conditions of ultrahigh vacuum is required to remove such contamination and to maintain a molecularly “clean” surface. Good adhesion is aided by high-substrate surface energy, partly to aid wetting (see ► Chap. 4, “Wetting of Solids,” ► 5, “Spreading of Liquids on Substrates,” and ► 6, “Thermodynamics of Adhesion”) and partly to increase fracture energy  $G$ , see Eqs. 1 and 3. The universal tendency for high-energy states to move toward lower-energy states is manifested here by adsorption onto a high-energy substrate surface of extraneous material. This can come from other solids or liquids with which the surface has been in contact, as well as from the atmosphere. Thus the surface of a metal, which, outside the realms of surface science might be described as “clean,” will be covered by complex layer including an oxide, probably partly hydrated, perhaps carbonated, adsorbed water, residual lubricant, and processing aids. Such a layer, in molecular terms, will be thick. It is unlikely to have good wetting properties and is likely to be cohesively weak. Unless removed by pretreatment, it is likely to form a weak boundary layer and to give poor practical adhesion. A successful pretreatment is very unlikely to produce a molecularly “clean” surface, but the surface produced will not suffer from the same cohesive weakness and lyophobicity of the original. Polymers are also likely to require pretreatment, because their surfaces usually carry complex layers, chemically different from the bulk material. The formation of these layers is now considered.

## 2.6.2 Polymer Surfaces

Few, if any, polymers in commercial practice are used without the incorporation of a range of additives. These may include antioxidants, processing aids, perhaps plasticizers and lubricants. Elastomers are likely to be based on even more extensive formulations including a complex vulcanization mixture.

In Sect. 5.2, the question of polymer–polymer compatibility was considered, and it was argued that the majority of binary polymer blends will be two phased because the component polymers are incompatible, the free energy of mixing,  $\Delta G_m$ , will be positive. Essentially, the same argument applies when polymer additive solutions are considered. The physical chemistry is similar: the entropy term will be small compared with that for a low-molecular-weight solvent–solute combination, and the enthalpy term is likely to be positive (cf. Eqs. 6–8). Most polymer-additive systems are thermodynamically unstable: the additive will tend to migrate out of the polymer. Loss of plasticizer from PVC (polyvinyl chloride) is a widely experienced phenomenon. The mode of action of antistatic agents depends on their progressive migration to the polymer surface.

Most adhesives are polymeric and set during the bonding process by loss of solvent, by solidifying from the melt, or by some form of cross-linking or polymerization reaction. In all of these solidification processes, there is the potential for low-molecular-weight additives to migrate to the substrate–adhesive interface and to form a weak boundary layer. Moreover, almost all polymers have a distribution of molecular weights, and there will be a similar tendency for low-molecular-weight fractions of the polymer itself to be rejected to the interface during solidification, especially during cooling from the melt.

## 2.6.3 Formation of Weak Layers During Bonding

The need for pretreatment to remove weak surface layers is widely understood. More subtly, other weak layers can form during the bonding process by the migration of low-molecular-weight species to the interface: sometimes these can lead to poor joint performance.

Many examples in the literature show that these effects occur. Classic experiments include removing low-molecular-weight fractions from a polymer, and observing increased adhesion, and complementarily, adding low-molecular-weight fractions, and observing a reduction in adhesion (Bikerman 1961). In Sect. 5.5, examples were given of weak boundary layers formed by copolymer compatibilizers.

## 2.6.4 The Legacy of Bikerman

Much of the early work on weak boundary layers was done by Bikerman and his colleagues in the 1950s and 1960s. His frequent observation of cohesive failure close

to the interface, combined with direct demonstration of a weak boundary layer mechanism in specific examples, led him to take up an extreme position (Bikerman 1961). This insisted on (1) the widespread occurrence of weak boundary layers, (2) the impossibility of adhesive (i.e., interfacial) failure, and (3) the practical strength of an adhesive bond depended on the rheology of the joint, not upon the forces at the interface.

Although Bikerman's position would not be supported today, it stimulated developments in the understanding of theories of adhesion, which can, to some extent, be regarded as his legacy. The potential for the formation of weak boundary layers (1) is well established, and much of the technique of adhesive bond preparation is designed to avoid them.

*Locus of failure* Where weak boundary layers exert an effect on adhesion behavior, failure typically occurs within the weak layer, close to the adhesive–substrate interface. The boundary layer will often be very thin, in macroscopic terms, and there are large numbers of examples where workers have reported the adhesive (i.e., interfacial) failure of a joint, when in fact it could be shown that failure was cohesive within a boundary layer. Bikerman's insistence (2) that adhesive failure could not occur had the beneficial effect of concentrating attention on the locus of failure. Careful examination of locus of failure is an important technique – still sometimes neglected – in the study of adhesive bonds. Modern methods of surface analysis are appropriate here. They have established that, although adhesive failure may be rare, it does occur sometimes.

In considering locus of failure, it must be emphasized that observation of cohesive failure close to the adhesive–substrate interface does not, itself, prove the presence of a weak boundary layer. The idea that an adhesive joint “fails at its weakest link” is naïve. The locus of failure of a joint depends in a complex way on the chemical and physical properties of the materials in the joint, and on the way the stress is applied to them. Cohesive failure close to an interface is entirely possible in the complete absence of weak interfacial layers (Good 1972). Dillard has demonstrated how failure can change between cohesive, interfacial, and oscillating for exactly the same joint, depending on how the stress is applied (Chen and Dillard 2002).

*Practical bond strength* Bikerman was right (3) in insisting on the importance of joint rheology in determining the practical strength of an adhesive bond. It was an important point to make at the time. However, he was wrong to say that interfacial forces were irrelevant. The connection between the two, expressed in a simple form in Eq. 3, is discussed in detail elsewhere in this handbook (► Chap. 3, “Forces Involved in Adhesion”).

---

## 2.7 Conclusions

A theory in science is a model that aims to order the experimental results in a field and, for a fruitful theory, to suggest new experiments and their outcome. We do not look to theories for immutable truths: we expect them in time to be modified and discarded (Popper 1959; Khun 1970).

In the light of our present understanding of adhesion, what can be said about the “classical” adhesion theories? On one level, it could be said that the adsorption, mechanical, and diffusion theories (and some would add electrostatic theory) maintain their importance undiminished. It is still acknowledged that adsorption plays a vital role, that there are examples where diffusion is crucial and so forth. However, the classic theories originated at a time when there were few, if any, experimental techniques available to study surfaces and interfaces at the nanometer level. We now benefit from several decades of results from scanning probe technologies and surface analysis and theoretical advances in contact mechanics and molecular chain dynamics. We have direct evidence for the presence of particular groups on a surface, for the effects of variations of topography and chemical nature over small distances on a surface. Consequently, in many cases, we have a much clearer understanding of what is happening in the interfacial region, and of how it affects adhesion.

One consequence of this understanding is that we can often make plausible suggestions about adhesion mechanisms without having to hide behind broad-brush statements about “mechanical effects” or “chemical activation.” We should also recognize now that the mechanisms characteristic of classical theories are not completely distinct. This is our contemporary answer, no doubt provisional, to Newton’s challenge (Sect. 1.1).

A good example of such an approach to theories of adhesion is provided by a recent extensive review of fracture and adhesion of soft materials by Creton and Ciccotti (2016). Nowhere in their review of adhesion mechanisms do Creton and Ciccotti find it necessary to refer to “classical” theories of adhesion, adsorption, mechanical, and so on. However, they discuss the use and range of validity of equations for fracture energy applicable to some of the soft materials which is their concern. These include equations which are much more specific versions of the general Eqs. 3 and 4 above.

It is recognized that the practical surfaces used in adhesion are always to a degree rough: the only question is “how rough?” As the roughness of a surface changes, so must the chemical environment of its surface atoms and molecules. Thus, changing the roughness changes the local chemistry, which will affect the adsorption properties of the surface. The scale of roughness of surfaces encountered in adhesive joints varies from the macroscopic through to the nano- and molecular scale, from the classic realm of the mechanical theory to that of the diffusion theory. The energy expended in peeling strands of rubbery polymer from a macroporous surface has been successfully analyzed in essentially the same way as the pullout of individual polymer chains by the “nail” model in diffusion theory (Sect. 5.3) (Gent and Lin 1990). In principle, the range of types of forces that may act between adsorbate and adsorbed molecule on a nominally flat surface are the same as those that may act between diffusing molecules.

Moreover, the way in which adhesion is enhanced is essentially the same whether we think in terms of adsorption, diffusion, or roughening. These provide mechanisms whereby the energy dissipation ( $\psi$  in Eq. 3) is enhanced. Whether the focus is on enhanced chemical interaction, surface roughening, or interdigitation of polymer chains, a common consequence is increased plastic or viscoelastic losses and crazing.

Each of the classical theories is best regarded as emphasizing a different aspect of a more comprehensive model, which, in principle, relates molecular dispositions in the region of the interface to macroscopic properties of an adhesive joint. It would be a mistake today to lay too much emphasis on the distinction between classical theories, although this has been valuable at various times during the last 80 years in stimulating the development of new concepts and in suggesting fruitful experiments.

## Abstract

The establishment of interfacial bonds through forces at the interface causes materials to attract one another. Therefore adhesion between materials and adhesive in assemblies are intimately related to the interatomic and intermolecular interactions at the interface of the two considered surfaces. Describing the mechanism responsible for adhesion in simple terms is difficult due to the complexity and evolving understanding of the subject. Nevertheless, when considering adhesion phenomena it is important to consider both the bulk and surface

mechanical properties of the materials in contact and the type of interfacial forces established at the interface. High adhesion can only be obtained if the interface can sustain sufficient stress to induce dissipative forms of deformation, such as flow, yield, or crazing, in the polymer. Under most circumstances such dissipative processes can only be obtained when the interface is coupled with sufficient density of bonds. This chapter focuses on the description of the main forces responsible for adhesion, from strong covalent bonds to weak van der Waals forces, also considering some more specific interactions such as acid-base (like hydrogen bonding) or capillary forces (that could, as an example, influence adhesion of nanoparticles). The second part of this chapter concerns recent developments in experimental scanning probe techniques that may give access to direct adhesion forces determination at the nanoscale. A case study is presented.

### 3.1 Introduction

The term of adhesion between two objects appears confusing or ambiguous, because generally it is employed to describe: first, the formation of the interface between a pair of materials, i.e., the establishment of interfacial bonds through forces at the interface which cause materials to attract one another and second, the breaking stress or energy required to break the assembly. One can easily understand that both interfacial forces and mechanical properties of adherends in the vicinity of the interface and in the bulk contribute to the global mechanical response of the assembly. Such a fundamental issue reflects a paradox that has stimulated intensive research for decades: if adhesion is only a matter of thermodynamics, the work needed for separation would be close to the surface energies of the adherends, which are typically  $10^{-2}$ – $10^{-1}$  J/m<sup>2</sup>. Practical work of separation can be  $10$ – $10^6$  greater! On the other hand, separation has often been viewed as involving processes at the molecular level. The force needed for separation should then be as large as  $10^8$  N/m<sup>2</sup>– $10^9$  N/m<sup>2</sup>. Therefore the first part of this chapter relates more precisely to the question: what, precisely, is the role of interfacial forces in determining the mechanical strength of bonded structures such as adhesive joints, composites, coatings, etc.? In other words, do interfacial forces determine, by their “weakness” or “strength,” the “weakness” or “strength” of joint systems? A related question is: how to access adhesion forces at a local scale? In recent years, atomic force microscopy (AFM) has become a powerful tool, sensitive enough, to detect small surface forces and to study adhesion at the nanoscale. Adhesion forces and surface mechanical properties of surfaces can be achieved with such a nanometer probe even if quantitative results need important calibration procedures. The purpose and scope of the second part of this chapter is to give highlight to the experimental methods that enables one to measure adhesion forces on the basis of AFM force-distance experiments. Relationships are proposed that give a complete understanding on how capillary and van der Waals forces contribute to adhesion forces at a local scale.

## 3.2 Physical Forces and Chemical Interactions: Basic Terms and Knowledge

### 3.2.1 van der Waals Forces

The first forces subject to discussion are long-range van der Waals forces that include dispersion and polarization forces that arise from dipole moments induced in atoms and molecules by the electric fields of nearby charges and permanent dipoles.

#### Dispersion, Orientation, and Induction Forces

Dispersion forces (London 1937) represent the most important contribution to van der Waals forces between atoms and molecules. They are always present, act between all atoms and molecules (including totally neutral ones), and generally exceed the dipole-dependent induction and orientation forces except for small highly polar molecules (Israelachvili 1991). Even if they are of weak intensity, the perturbation responsible for dispersion forces is the existence of a finite dipole moment (given by the fluctuation of instantaneous positions of the electrons relative to the nuclear protons) that will generate an electric field that polarizes any nearby neutral atom, inducing a dipole moment in it. The same is for the second interacting atom. As a consequence, the resulting instantaneous dipole-dipole interaction gives rise to an instantaneous attractive force, called dispersion force. London has established using quantum mechanical perturbation theory the famous expression for the dispersion interaction energy ( $E_{\text{Disp.}}$ ) between two atoms or molecules (Eqs. 1 and 2) as follows:

$$E_{\text{Disp.}} = -C_{\text{Disp.}}/r^6$$

$$= (-3h\nu_1\nu_2\alpha_1\alpha_2)/\left[2(4\pi\epsilon_0)^2(\nu_1 + \nu_2)r^6\right] \approx (-\alpha_1\alpha_2)/r^6 \quad (1)$$

where  $r$  is the separation distance and  $C_{\text{Disp.}}$  is a constant proportional to the product of the polarizabilities ( $\alpha$ ) of the considered atoms or molecules,  $h$  is Planck's constant,  $\nu$  is electronic absorption frequency, and  $\epsilon_0$  is the dielectric permittivity in vacuum. The main features of dispersion forces may be summarized as follows (Israelachvili 1991):

- Dispersion forces are long-range forces and can be effective from large distances ( $>10$  nm) down to interatomic distances;
- Dispersion forces may be repulsive or attractive. Expression of the dispersion force does not follow a simple power law;
- Dispersion forces can also align or orient molecules, though this effect is usually weak;
- Dispersion interaction between two bodies is affected by the presence of other bodies nearby (nonadditivity interaction).

For larger molecules, with diameters greater than about 0.5 nm, the London equation can no longer be used. As molecules grow in size, their center-to-center

distance ceases to have any significance as regards the strength of cohesive energy. Likewise, the London equation cannot be applied to asymmetric (nonspherical) molecules such as polymers. Under such conditions, the exact dispersion interaction is difficult to compute. It is important then to consider that London theory must be modified and a complete description can be found in Spruch (1986) to account for the interaction between molecules at large distances ( $>10$  nm). A retardation effect occurs because a finite time is required for an electromagnetic wave to be propagated through the medium the atoms or molecules are situated in. As a consequence, the dispersion energy drops-off with distance ( $E_{\text{Disp.}}$  vary with  $1/r^7$  rather than  $1/r^6$ ) when the retardation effect comes into play. In the limit of very large separations, retarded dispersion interaction is given by the Casimir – Polder equation (Casimir and Polder 1948):

$$E_{\text{Disp.}} = (-23hc\alpha_1\alpha_2)/(8\pi^2r^7) \approx (-\alpha_1\alpha_2)/r^7 \quad (2)$$

where  $c$  is the speed of light in vacuum. Besides the most basic and predominant nonpolar interactions (dispersion forces), there are polarization or polar interactions between molecules of counter bodies, such as dipole-dipole interactions (Keesom 1922) and dipole-induced dipole interactions (Debye 1921). The essential difference between dispersion and polarization forces is that, while the former involve simultaneous excitation of both molecules, those for the latter involve only a passive partner. The Keesom orientation interaction energy between two molecules with permanent dipoles is temperature dependent and proportional to the dipole moments as follows:

$$E_{\text{Orient.}} = -C_{\text{Orient.}}/r^6 = -(\mu_1^2\mu_2^2)/(3kT(4\pi\epsilon_0)^2r^6) \approx -(\mu_1^2\mu_2^2)/r^6 \quad (3)$$

where  $r$  is the separation distance, and  $C_{\text{Orient.}}$  is a constant proportional to the temperature ( $T$ ), Boltzmann constant ( $k$ ), and the square product of the dipole moments ( $\mu$ ) of the considered molecules.

Debye argued that if the attraction energy was simply due to a Keesom effect then the interaction energy should be drastically reduced at high temperatures. Since experimental results were contrary to the prediction, he concluded that an additional attractive effect should be involved. He showed that an additional polar interaction should be induced between a permanent dipole and an induced dipole. The Debye induction interaction energy between two molecules with permanent dipoles is proportional to the square of the dipole moments and to the polarizabilities as follows:

$$\begin{aligned} E_{\text{Induct.}}(r) &= -C_{\text{Induct.}}/r^6 = -(\alpha_1\mu_1^2 + \alpha_2\mu_1^2)/[(4\pi\epsilon_0)^2r^6] \\ &\approx -(\alpha_1\mu_2^2 + \alpha_2\mu_1^2)/r^6 \end{aligned} \quad (4)$$

where  $r$  is the separation distance, and  $C_{\text{Induct.}}$  is a constant proportional to the sum of the square dipole moments ( $\mu^2$ ) times the polarizabilities ( $\alpha$ ) of the considered

molecules. If one of the interacting molecules has no permanent dipole (say the second), the term  $(\alpha_1\mu_2^2 + \alpha_2\mu_1^2)$  is reduced to  $(\alpha_2\mu_1^2)$ .

Finally the total van der Waals free energy of interaction has the following form:

$$E_{wdw}(r) = -C_{wdw}/r^6 = -[C_{\text{Disp.}} + C_{\text{Orient.}} + C_{\text{Induct.}}]/r^6 \quad (5)$$

An interesting property of van der Waals interactions must be considered that is the general dominance of dispersion forces in Eq. 5 except for highly polar molecules (i.e., water). Nevertheless rigorous computation of van der Waals force remains difficult.

### van der Waals Forces Between Macroscopic Bodies

To calculate the contribution of van der Waals forces in the interaction energy between macroscopic bodies one may sum the energies of all the atoms in one body with all the atoms in the other and thus obtain the “two-body” interaction energy. The resulting interaction laws are given in terms of a characteristic constant, namely, Hamaker constant (Hamaker 1937). The Hamaker constant is defined as:

$$A = \pi^2 C_{vdw} \rho_1 \rho_2 \text{ and } C_{vdw} \approx \alpha_1 \alpha_2 \quad (6)$$

where  $C_{wdw}$  is the coefficient in the atom-atom pair van der Waals interaction energy, and  $\rho_1$  and  $\rho_2$  are the numbers of atoms per unit of volume in the considered macroscopic bodies. Typical values for the Hamaker constants of condensed phases (liquid or solid) are about  $10^{-19}$  J for interactions in vacuum or air. Computation of Hamaker constants for polymers and various other materials could be found in Hough and White (1980). The nonretarded van der Waals interaction free energy between bodies of different geometries on the basis of pairwise additivity is given in Fig. 1. Direct applications are possible considering experiments such as surface force measurements with surface force apparatus (SFA) or adhesion force measurements with atomic force microscope (AFM).

**Fig. 1** van der Waals free energy of interaction between interacting bodies ((a) atom – plane, (b) sphere – plane, and (c) plane – plane)

### 3.2.2 Acid-Base Interactions

#### The Original Lewis Definition

The Lewis definition of acid-base interactions are now over a half century old. Nevertheless they are always useful and have broadened their meaning and applications, covering concepts such as bond-formation, central atom-ligand interactions, electrophilic-nucleophilic reagents, cationoid-anionoid reagents, charge transfer complex formation, donor-acceptor reactions, etc. In 1923, Lewis reviewed and extensively elaborated the theory of the electron-pair bond (Lewis 1923). He states that a basic substance is one which has a lone pair of electrons which may be used to complete valence shell of another atom (the acid) and that an acid substance is one which can employ a lone pair from another molecule (the base) in completing the valence shell of one of its own atoms. Hence, the shared electron-pair bond model explains the existence of both nonpolar bond and polar link from the same premises. As the electrochemical natures of two atoms sharing an electron pair began to differ more and more, the pair should become more and more unequally shared, eventually becoming the sole property of the more electronegative atom and resulting in the formation of ions. Ionic and nonpolar bonds appear as logical extremes of a continuum of intermediate bond type. Differences in the continuum are only attributable to variations in the electron-pair donation, i.e., in the way in which the charges are localized within the molecule. As a consequence the distinctions between salts, acids, and bases; coordination compounds; and organic compounds are not of fundamental nature.

#### Molecular Orbital (MO) Approach of Acid-Base Reactions

Translated into the idiom of molecular orbital theory (Mulliken and Pearson 1969), the acid-base definitions should be read as follows:

- A base is a species which employs a doubly occupied orbital in initiating a reaction.
- An acid is a species which employs an empty orbital in initiating a reaction.

The donor orbital is usually the highest occupied molecular orbital HOMO, and the acceptor orbital is usually the lowest unoccupied molecular orbital or LUMO. Thus it is important to understand that considering the interaction between two species, the acid is always defined relatively to the base and the base relatively to the acid. The molecular orbital definitions have a number of important consequences:

First, it is not necessary that the donor and acceptor orbitals be localizable on a single atom or between two atoms, as implied by Lewis dot structures. That is, the orbitals may be multicentered even in a relatively localized representation. Thus donor-acceptor interactions involving delocalized electron systems ( $\pi$ -ring) (Hawthorne and Dunks 1972) are naturally assumed by the definitions. The same is for numerous organic or polymer molecules involving delocalized electrons. Second, the HOMO or donor orbital on a base is likely to be either bonding or nonbonding in character, the latter always being the case for monoatomic species. The LUMO or acceptor orbital of an acid is likely to be either antibonding or

nonbonding in character, the latter always being the case for monoatomic species. Third, all degrees of electron donation are possible, ranging from zero to the complete transfer of one or more electrons from the donor to the acceptor. This continuity can be represented (Eq. 7) by wave functions (Klopman 1974) where the degree of donation increases as  $(a/b)^2$  does ( $a$  and  $b$  are weighting coefficients).

$$\psi_{AB} = a\psi_A + b\psi_B \tag{7}$$

where  $\psi_{AB}$  is the wave function of the acid-base one-to-one adduct,  $\psi_A$  is the ground state wave function of the acid, and  $\psi_B$  the ground state wave function of the base.

Table 1 reports the possible adducts classified in terms of the bonding properties of the donor and acceptor orbitals of the acid and base. Complete description of the mechanisms involved during the following adducts formation can be found in Jensen’s complete review (Jensen 1979).

Even if the nature of an acid or a base is highly relative, a brief classification based on bonds properties and orbital symmetry can be proposed (where  $n$  represents the nonbonding orbital,  $\sigma$  represents the sigma orbital, and  $\pi$  the pi orbital.  $\sigma$  and  $\pi$  orbitals are also called bonding or antibonding orbitals if they address to a base or an acid, respectively).

- $n$  donor: Lewis bases, complex and simple anions, carbanions, amines, oxides, sulfurs, phosphines, sulfoxides, ketones, ethers, alcohols, etc.
- $\pi$  donor: Unsaturated and aromatic hydrocarbons having electron donor substituents, etc.
- $\sigma$  donor: Saturated hydrocarbons, CO, single links like C-C, C-H, polar links like NaCl, BaO, silanes, etc.
- $n$  acceptor: Lewis acids, simple cations, etc.
- $\pi$  acceptor:  $N_2$ ,  $SO_2$ ,  $CO_2$ ,  $BF_3$ , dienic and unsaturated and aromatic hydrocarbons having electron acceptor substituents, etc.
- $\sigma$  acceptor: Brönsted acids, boranes, and alkanes having strong acceptor substituents like  $CHCl_3$ , halogens, etc.

Table 1 Possible acid-base adducts in terms of orbital properties

			Acceptor Orbital of the Acid		
			Non-bonding	Anti-bonding	
			n	$\sigma^*$	$\pi^*$
			n.n	n. $\sigma^*$	n. $\pi^*$
Donor Orbital of the Base	Non-bonding	n	n.n	n. $\sigma^*$	n. $\pi^*$
	Bonding	$\sigma$	$\sigma$ .n	$\sigma$ . $\sigma^*$	$\sigma$ . $\pi^*$
		$\pi$	$\pi$ .n	$\pi$ . $\sigma^*$	$\pi$ . $\pi^*$

**Fig. 2** Donor-acceptor molecular orbital interactions. HOMO represents the highest occupied molecular orbital and LUMO the lowest unoccupied molecular orbital

To summarize how acid-base reactions do work on the basis of molecular orbitals perturbation theory, the relative energies of the frontier orbitals HOMO and LUMO of a hypothetical species A and of the frontier orbitals of several hypothetical reaction partners B, C, D, E, and F are reported in Fig. 2. This figure is intended to represent possible variations of donor-acceptor properties in the broadest possible way.

According to Fig. 2, with respect to B, complete electron transfer from B to A will be favorable and A will act as an oxidizing agent. With respect to C, the A(LUMO)-C(HOMO) perturbation will be favorable and A will act as an acid. With respect to D, the A(HOMO)-D(LUMO) perturbation will be favorable and A will act as a base. Lastly, with respect to E, complete electron transfer from A to E will be favorable and A will act as a reducing agent. For F species, the frontiers orbitals energies are identical with those of A. Here neither species is clearly the donor or acceptor and species may display both behaviors simultaneously (case of multisite interactions encountered in concerted organic cycloaddition reactions).

### The Case of Hydrogen Bonding

In extension to the general discussion relative to Lewis acid-base interactions, it is important to understand that hydrogen bonding represents a typical example acid-base interaction. According to Pauling (1960), hydrogen bonding is partly covalent and partly ionic (polar). Nevertheless, it is obvious that electrostatic and charge transfer interactions are predominant for hydrogen bonds. In most cases, the principal charge transfer contribution is derived from the proton acceptor-proton donor charge transfer complex through the  $\sigma$ -type interactions.

247 To conclude, the chemical phenomena subsumed by the category of acid-base  
248 reaction are the following:

- 249 – Systems governed by the Arrhenius description, solvent system, Lux-Flood, and  
250 proton acid-base definitions.
- 251 – Traditional coordination chemistry and “nonclassical” complexes.
- 252 – Solvation and ionic dissociation phenomena in both aqueous and nonaqueous  
253 solutions.
- 254 – Electrophilic and nucleophilic reactions in organic and organometallic chemistry.
- 255 – Charge transfer complexes, molecular addition compounds, weak intermolecular  
256 forces, hydrogen bonds.
- 257 – Salt melting and salt formation.

### 258 **3.2.3 Chemical Forces and Covalent Bonding**

259 The last case that should be considered in order to describe adhesion improvement is  
260 the possibility to form chemical bonds between adherends. Even if covalent bonds  
261 are just one variety in the continuum of bond types introduced before, it would be  
262 discussed in a special section as covalent bonding is in numerous cases required  
263 when high level of adhesive strength and durability of adhesive joints are required.  
264 Chemical bonds formed at an interface can greatly participate to the level of  
265 adhesion. The short-range forces involved in chemical bonding are quantum  
266 mechanical in nature and generally attractive. These bonds are generally considered  
267 as primary bonds in comparison with physical interactions such as van der Waals,  
268 which are called secondary interactions. The typical strength of a covalent bond is of  
269 the order of 100–1000 kJ/mol, whereas that of van der Waals interactions and  
270 hydrogen bonds does not exceed 50 kJ/mol. Chemical bonds depend strongly on  
271 the reactivity of both adhesive and substrate. To obtain strong adhesion, it is  
272 necessary that stress transfer could be achieved across the adhesive/substrate inter-  
273 face, so that cohesive failure is obtained. This stress transfer across the interface can  
274 be achieved by (i) chemical reaction to form coupling chains at the interface,  
275 (ii) the use of coupling chains placed at the interface, or (iii) chain interdiffusion,  
276 if the materials are sufficiently miscible.

#### 277 **Chemical Reaction to Form Coupling Chains at the Interface**

278 One of the most important adhesion fields involving interfacial chemical bonds is the  
279 use of adhesion promoter molecules, so-called coupling agents, to improve assembly  
280 joint strength. These species are able to react chemically on both ends (on one side  
281 with the adhesive, on the other side with the substrate). Silane-based promoter  
282 molecules are the most common type of coupling agent, widely employed in systems  
283 involving thermoset adhesives and glass, silicon oxide, silica, aluminum, or steel  
284 substrates. A complete review is available by Plueddemann (1982). Studies of the  
285 impact on epoxy fracture energy of model silanes (APS, GPS, MPS, AEAPS, PAPS)  
286 adsorbed on silicone oxide surface were done in Kramer’s group (Nakamura et al.

287 2007). The influence of chemical bonds on the joint strength ( $W$ ), and more precisely  
288 on the intrinsic fracture energy ( $G_0$ ), of a glass/elastomer interface was investigated  
289 (Gent and Ahagon 1975). They have shown that  $G_0$  increases linearly with the  
290 surface concentration of vinylsilane coupling agent, between the glass substrate and  
291 the cross-linked elastomer. A second system that has been studied extensively  
292 because of its technical importance is the adhesion between epoxy resins and  
293 glass, particularly glass fibres. To improve the hydrolytic stability of the composite,  
294 the glass surfaces are normally modified by covering them with a thin layer of a  
295 silane-adhesion promoter. These silanes are well known to self-assemble into mono-  
296 molecular and multi-molecular layers on surfaces (Flinn et al. 1994). Studies of the  
297 impact on epoxy fracture energy of model silanes (APS, GPS, MPS, AEAPS, PAPS)  
298 adsorbed on silicone oxide surface were done in Kramer's group (Nakamura et al.  
299 2007). One end of the silane molecule typically has di or tri methoxy or ethoxy  
300 functionality whilst the other end normally has amine or epoxy functionality. The  
301 ethoxy functionality is believed to condense with the hydroxyl functionality on  
302 the surface of the glass whilst the amine functionality can react with the epoxy.  
303 The amount of silane typically used is much too great to form a monolayer. Also,  
304 as the silane has multimethoxy or multiethoxy functionality, it can self-condense.  
305 The relatively thick layer of silane is believed to form a network and then the epoxy  
306 both mixes into and reacts with the network. Although it is clear that the silane  
307 causes covalent bonding between the glass and the epoxy, there is no simple way to  
308 estimate the actual density of coupling produced. Moreover, the silane condensed  
309 layer can be viewed as a rather porous layer (low degree of condensation) in which  
310 small molecules or additives have the possibility to diffuse. Similar silanes are also  
311 used as adhesion promoters on silicon dioxide.

312 A second commonly used strategy to couple two bulk polymers is to introduce  
313 into one or both of the materials a small percentage of chemically modified chains  
314 (Lewis and Natarajan Gounder 1991; Tao et al. 2001) that can react with the other  
315 polymer to form coupling chains at the interface. A classic example (Laurens et al.  
316 1994) is the introduction into polypropylene of some maleic anhydride grafted  
317 polypropylene chains to induce coupling with a polyamide such as Nylon 6. The  
318 maleic anhydride functionality can react with hydroxyl end groups on the polyamide  
319 chain to form a graft or block copolymer at the interface. The molecular mechanism  
320 of interfacial failure can be either pullout or scission of these coupling chains.  
321 Pullout at low force can occur if either one of the blocks in the copolymer formed  
322 at the interface is rather short or if there are too many coupling chains at the interface.  
323 In systems where multiple grafts are possible on a single chain, then the coupling  
324 chains can become so densely packed at the interface that they exclude other chains  
325 and so cannot entangle well with the bulk material, causing pullout failure. This  
326 situation has been observed when the chains themselves were long enough to  
327 entangle.

### 328 Coupling Chains Placed at Polymer-Polymer Interfaces

329 Another case of interest concerns the adhesion between immiscible polymers.  
330 Adhesion is improved by the presence of diblock copolymers (Tirrel et al. 2001)

or grafted chains (Brochart-Wyart et al. 1994) at the interface. The diblock is chosen so as that each block dissolves in the respective homopolymer. The forces involved are in most cases physical like van der Waals interactions which drive the mixing of each of the blocks across the polymer-polymer interface. Blocks should also have masses higher than the critical molecular weight between entanglements ( $M_e$ ) of the respective homopolymer. The form of coupling, that is to say the mechanism of interface failure, has been found to depend on the molecular weight of the coupling chains. Short chains can pull out of the bulk material at a force that increases with the length of the pulled-out section. As the length of the chains increases to somewhere between one and four times the length required to form an entanglement in the melt, the force required for pullout becomes greater than the force to break chains, so they fail by scission of covalent bonds. The extent of adhesion is strongly affected by the molecular failure mechanism as tough interfaces are normally only obtained when the failure is by scission. However, scission failure does not guarantee a tough interface. Nevertheless, Brown has proposed a molecular interpretation of the toughness of glassy polymers (Brown 1991) which can be applied to the failure of interfaces between reinforced immiscible polymers, for which a covalent scission (Brown et al. 1989) of the copolymer chains is observed at the interface. Assuming that entangled chains in the material are drawn into fibril, the fracture energy  $W$  is found proportional to:

$$W \approx \nu^2 f^2 D / S \quad (8)$$

where  $\nu$  is the surface density of entangled chains,  $f$  is the force required to break a polymer chain,  $D$  is the fibril diameter and  $S$  is the local stress applied at fibril-bulk interface.

Moreover the chemist has the possibility to graft reactive functional groups on the blocks to promote chemical reactions between the blocks and the surrounding chains of the hosting polymer to improve adhesive strength by covalent bonding.

### Coupling Polymers Chains by Interdiffusion

Coupling by chain interdiffusion (Wool 1995) can occur if two polymeric materials are miscible in each other, or at least sufficiently miscible to form an interphase. Welding is the most common form of interdiffusional coupling, but chain interdiffusion is also important in solvent bonding. Polymer diffusion normally occurs by the process of reptation in which the chain moves a long 'tube' formed by its entanglements with all the other chains. Hence interface coupling is formed by a chain end initially crossing the interface and then slowly more of the chain following it across. Failure after short joining times is thus expected to be by chain pullout; Even if polymer chain interdiffusion is based on physical interactions that give rise to the original differences of the chemical potentials which drive the mixing, chain scission failure occurs (i.e., chemical bonds rupture) as the diffusion distance increases. Even if it is not the main topic of this chapter, there has been a considerable amount of work on polymer chain reptation concept (de Gennes and Léger 1982) and on the kinetic aspects of chain coupling but the problem is not

solved, as the location of chain end groups with respect to the interface is not easy to determine.

### 3.3 Experimental Determination of Adhesion Forces

#### 3.3.1 Adhesion Forces Contribution to the Work of Adhesion

The magnitudes of forces responsible for adhesion (van der Waals, acid-base) can generally be related to fundamental thermodynamics quantities, such as surface free energies and work of adhesion. The work required to separate reversibly the interface between two bulk phases 1 and 2 from their equilibrium interacting distance to infinite one (Dupré 1869), represented on Fig. 3, is termed the “work of adhesion” and is equal to:

$$W_{12} = \gamma_1 + \gamma_2 - \gamma_{12} \quad (9)$$

where  $\gamma_1$  and  $\gamma_2$  are the surface free energies of phases 1 and 2, respectively, and  $\gamma_{12}$  is the interfacial free energy between phases 1 and 2. The work of adhesion is the decrease of Gibbs free energy per unit area when an interface is formed from two individual surfaces. Thus, the greater the interfacial attraction, the greater the work of adhesion will be and the smaller the interfacial free energy between phases 1 and 2 will be. Thereby,  $\gamma_{12}$  can be linked to the properties of the two individual phases. In the specific case of solid-liquid contact, phases 1 and 2 are commonly denoted phases S (solid) and L (liquid) and neglecting the spreading pressure of the vapor phase (V) of the liquid onto the solid, the solid-liquid work of adhesion ( $W_{SL}$ ) is:

$$W_{SL} = \gamma_S + \gamma_{LV} - \gamma_{SL} = \gamma_{LV}(1 + \cos \theta) \quad (10)$$

**Fig. 3** Representation of Hertz and Johnson-Kendall-Roberts (JKR) contact shapes

**Fig. 4** Reversible separation of two interacting bodies. The corresponding work is called “work of adhesion”

where  $\theta$  is the equilibrium contact angle at the three-phase contact point (Young 1805) as represented in Fig. 5. The first part of Eq. 10 is known as Dupré equation and its physical meaning is also represented in Fig. 4. More detailed consideration on wetting phenomena, surface energies, and thermodynamic of adhesion are presented in chapters relative to “Wetting” and “Work of adhesion” of this handbook. The subsections below will expose some experimental possibilities available to assess adhesion forces and interactions energies.

### van der Waals Forces Contribution to the Work of Adhesion

To reflect the contribution of the fundamental nature of the long-range interaction forces across the interface, it was suggested (Fowkes 1964) that surface free energies and work of adhesion may be expressed (Eq. 11) by the sum of two terms: the first one representative of London’s dispersion interactions (superscript D) and the second representative of non-dispersion forces (superscript ND), this latter include Debye induction forces, Keesom orientation forces, and acid-base interactions.

$$\gamma = \gamma^D + \gamma^{ND} \quad \text{and} \quad W_{12} = W_{12}^D + W_{12}^{ND} \quad (11)$$

Fowkes proposes that the London dispersive part of the work of adhesion is quantified as twice the geometric mean of the dispersive component of the surface energy of solid 1 and 2. The total work of adhesion reduced to:

$$W_{12} = 2(\gamma_1^D \gamma_2^D)^{1/2} + W_{12}^{ND} \quad (12)$$

If only London’s forces are present across the interface, the work of adhesion is fully determined because the nondispersive part is equal to zero. Indeed  $\gamma_1^D$  and  $\gamma_2^D$  can be easily determined by wettability experiments (Wu 1982). The only existence of London interactions at the interface between two adherends leads to:

$$W_{12} \approx W_{12}^D \quad (13)$$

### Dispersive Work of Adhesion ( $W^D$ ) and Adhesive Contact Theories (Hertz, DMT, JKR)

These theories concern the description of the contact between two homogeneous elastic bodies, usually two hemispheres or one hemisphere and one flat. Considered forces at the interface are only physical (van der Waals interactions). Hertz firstly describe such an elastic contact (Hertz 1896). He makes the hypothesis that solids are elastic, have smooth surfaces, and have small contact area with respect to solids dimensions, and finally have negligible adhesion and no friction. Outputs of Hertz theory are the shape of contact area, the load dependence of contact radius and stresses and strains in the contact zone. Johnson-Kendall-Roberts (JKR) extended the Hertz theory for the shape of two contacting but non-adhering elastic spheres to solids that do adhere (Johnson et al. 1971). Contact shapes are represented in Fig. 5 for Hertz and JKR approaches. The adhesion is due to the fact that real solids possess a finite surface tension. In the JKR theory, the attractive forces between the spheres are of infinitely short range and, hence, these forces manifest themselves only in the contact area. Derjaguin-Muller-Toporov (DMT) argue that since the attractive forces between the surfaces have a finite range, these forces also act in a region outside the contact zone where the surfaces are only a small distance apart (Derjaguin et al. 1975). The magnitude of these attractive forces outside the region of contact is responsible for deformation within the contact zone and determines the contact radius. Both theories show that the pull-off or adhesive force depends only on the interfacial tension and the radius of curvature of the undeformed surface and is independent of the contact radius and the elastic constants of the material such as the Young's modulus and the Poisson's ratio.

From the JKR theory, the pull-off force or adhesion force of a sphere (radius  $R$ ) from a flat is  $3\pi R\gamma$ , where  $\gamma$  is the interfacial tension between the solid and the indenting sphere. The DMT theory predicts that the pull-off force is  $4\pi R\gamma$ , i.e., greater by a factor of  $4/3$  than the adhesion force predicted by the JKR theory. The two

**Fig. 5** Reversible separation of a liquid droplet from a surface. The corresponding work satisfies Dupré equation

theories thus disagree in their predictions of interfacial tension from force measurements by this constant. However, there are two major differences between the theories that can be tested experimentally. One is the shape of the interface in contact under no load conditions and the second is the contact radius at which the surfaces separate. The JKR theory predicts that when the pull-off adhesion force equals  $3\pi R\gamma$ , the surfaces separate from a finite area of contact and the radius at pull-off is 0.63 times the radius under no load conditions. On the other hand, the DMT theory predicts that at the instant of separation, the contact radius is 0, i.e., the surfaces separate only at the point where they have achieved their original undistorted shape.

More interesting DMT and JKR theories give access to the thermodynamic work of adhesion. Indeed, based on different attractive stress distributions, established elastic theories for spherical contact, JKR and DMT, prescribe the adhesion force,  $F_{Adh}$ , in two different ways as  $F_{Adh} = 3/2\pi RW_0$  and  $F_{Adh} = 2\pi RW_0$ , respectively, with  $R$  is the sphere radius and  $W_0$  is the thermodynamic work of adhesion between bodies in contact. The debates on the validity of these two theories continued until Maugis showed that these two competing models are the limiting cases of his self-consistent transition model (Maugis 1992). This model adopts an adhesive potential between the surfaces exterior to the contact that exerts a constant stress,  $\sigma$ , until a critical separation distance,  $h$ , is reached (Dugdale approximation). Typically the value of  $h$  is chosen such that  $W_0 = \sigma h$  matches that of a potential describing van der Waals interactions between the surfaces. Nevertheless two important considerations must be outlined concerning the validity of these contact theories. The first one is that the considered solids in contact are purely elastic. Therefore the viscoelastic character of polymers still causes big difficulties in that context. The same is for the contact between a liquid adhesive and a solid substrate. As a consequence, experimental conditions have a major influence on the validity of the obtained results. Loading and unloading must be achieved in the linear elastic strain regime (first step of the loading regime for instance). The second point concerns the thermodynamic equilibrium of the contact. Experiments should be done as close as possible to equilibrium, i.e., close to zero strain rate. Making experiments at different strain rates and considering extrapolation to zero strain rate, one can assess the thermodynamic (reversible) work of adhesion (Amouroux and Léger 2003). If it is not the case, experiments will give the integral work of contact disruption (out of equilibrium).

### Complications Arising from Capillary Forces

The presence of liquid vapors in atmosphere can significantly affect the adhesion properties of bodies in contact. The major effect concerns the capillary condensation of water around surface contact sites. Liquids that easily wet surfaces (small contact angles) will spontaneously condense from vapor into surface pores and cracks as bulk liquid. As a consequence, a liquid meniscus can be formed between interacting bodies. This effect can strongly influence the adhesion of systems where the contact area is smaller than the capillary length (contact between a nanometer probe (AFM, nano-indentation) and a surface, adhesion of nanoparticles, etc.) At equilibrium, the meniscus curvature is related to the

relative vapor pressure. For surfaces interacting via discrete contacts in ambient conditions, the validity of Dupré's equation (Dupré 1869) is not obvious as the homogeneity of the medium is broken by the formation of water meniscus. Hence, neither the Dupré equation nor elastic continuum theories can be used to describe a meniscus-mediated contact. The equilibrium meniscus radius ( $r$ ) is described by the Kelvin equation,  $r = \gamma_{LV} V/kT \ln(p/p_{sat.})$ , where  $\gamma_{LV}$  is the surface tension of water,  $V$  is the molar volume of water,  $k$  is the Boltzmann constant,  $T$  is temperature, and  $p/p_{sat.}$  is the relative vapor pressure. The validity of the equation was experimentally verified by using a surface force apparatus (Fisher and Israelachvili 1979), where the effect of surface roughness is minimized by using smooth mica surfaces. The results imply that the Laplace pressure,  $P_L = 2\gamma_{LV}/r$ , acting inside a meniscus results in the capillary force between two contacting bodies. Thus, the maximum attractive adhesion force between a spherical body (radius  $R$ ) and a flat surface due to the liquid bridge, at zero separation distance, and considering the direct solid-solid contact adhesion force inside the liquid annulus is (Israelachvili 1991):

$$F_{adh} = 4\pi R(\gamma_{LV} \cos \theta + \gamma_{SL}) = 4\pi R\gamma_{SV} \quad (14)$$

## 500 Acid-Base Forces Contribution to the Work of Adhesion

### 501 Acid-Base Work of Adhesion

The knowledge of both the strength of acid-base interaction, i.e., the enthalpy of interaction, and the number of moles of acid or base functional groups interacting per unit area across the interface allow the determination of the reversible acid-base work of adhesion. In the particular case of adhesion between solids, it rapidly appears (Israelachvili 1991) that the contribution of the polar interactions (Keesom, Debye) to the thermodynamic work of adhesion could be neglected compared with both dispersive and acid-base contributions as experimentally confirmed (Fowkes et al. 1984). The acid-base component of the work of adhesion can be related to the variation of enthalpy per mole of acid-base interfacial adducts interaction,  $\Delta H_{12}^{AB}$ , as follows:

$$W_{12}^{ND} \approx W_{12}^{AB} = f(-\Delta H_{12}^{AB})n_{12}^{AB} \quad (15)$$

where  $n_{12}^{AB}$  is the number of mole of acid-base bonds per unit interfacial area and  $f$  is equal to:

$$f = [1 - d(\ln W_{12}^{AB})/d(\ln T)]^{-1} \quad (16)$$

$f$  is taken equal to unity in the case of the nondependence of  $W_{12}^{AB}$  with temperature.

The quantitative determination of these quantities can be either theoretical or experimental.

Theoretical determinations are mainly based on the assumption that the initial perturbation of the orbital of interacting species determines the course of a reaction or an interaction. In terms of equation of state, the perturbation theory was firstly developed. In terms of energy gap between HOMO and LUMO, acids and bases were defined by their hardness and softness. The Hard-Soft Acid-Base principle (Pearson 1963) describes some basic rules about kinetics and equilibrium of the acid-base interactions. The HSAB principle will be described as it has evolved in recent years on the basis of the density-functional theory (Parr and Yang 1989). For organic interactions, the following statements were proposed:

- A hard acceptor has a high energy LUMO and usually a positive charge.
- A soft acceptor has a low energy LUMO but does not necessarily have a positive charge.
- A hard donor has a low energy HOMO and usually a negative charge.
- A soft donor has a high energy HOMO but does not necessarily have a negative charge.

The principle states that hard acid prefers to interact with a hard base, and vice versa, a soft acid with a soft base. A hard-hard interaction is fast because of large Coulombic attraction; a soft-soft interaction is fast because of large orbital overlap between HOMO and LUMO. However, the problem is what is the physical meaning of hardness?

Berkowitz and Parr (1988) give a theoretical support to the absolute hardness,  $\eta$ . The absolute hardness determines the resistance of species to lose electrons. According to frontier orbital method, the relationship between  $\eta$  and the HOMO and LUMO energies is reduced to:

$$\eta = -1/2[E_{\text{HOMO}} - E_{\text{LUMO}}] \quad (17)$$

where  $\eta$  is the absolute hardness,  $E_{\text{HOMO}}$  is the energy level of the HOMO orbital, and  $E_{\text{LUMO}}$  is the energy level of the LUMO orbital.

Moreover, the absolute softness is defined as the reciprocal of the absolute hardness. The apparent success of the density-functional theory is to provide two parameters from which we can calculate the number of electrons transferred resulting mainly from the charge transfer between two molecules, i.e., from electrons flow until chemical potential reaches an equilibrium. As a first approximation, the number of electron transferred ( $N_{\text{Trans}}$ ) is given by (Shankar and Parr 1985):

$$N_{\text{Trans}} = [\mu_B - \mu_A]/2(\eta_A - \eta_B) \quad (18)$$

where  $\mu_A$  is the chemical potential of the acid,  $\mu_B$  is the chemical potential of the base,  $\eta_A$  is the absolute hardness of the acid, and  $\eta_B$  is the absolute hardness of the base. Calculation for various solid polymers could be found in a paper of Lee (1991).

The subsections below will emphasize the experimental options for getting quantitative data on adhesion interaction enthalpy ( $\Delta H^{AB}$ ).

### Effect of Ionocity and Covalency: Drago's Concept

Similar to the perturbation theory, Drago and Wayland proposed a four-parameter equation for predicting reaction enthalpies between acid and base species (Drago and Wayland 1965). Both species are each characterized by two independent parameters: an  $E$  value which measures their ability to participate in electrostatic bonding, and a  $C$  value which measures their ability to participate in covalent bond, leading to:

$$-\Delta H^{AB} = E_A E_B + C_A C_B \quad (19)$$

where  $\Delta H^{AB}$  is the enthalpy of acid-base adduct formation,  $E_A$  is the ability of the acid to participate in electrostatic bonding,  $E_B$  is the ability of the base to participate in electrostatic bonding,  $C_A$  is the ability of the acid to participate in covalent bonding, and  $C_B$  is the ability of the base to participate in covalent bonding.

A self-consistent set of  $E$  and  $C$  values is available (Drago 1973) for 33 acids and 48 bases, allowing  $\Delta H^{AB}$  prediction for over 1584 adducts. It is assumed that the conditions under which measurements are made (gas phase or poorly coordinating solvents) give rather constant entropy contribution and that most of the adducts are of one-to-one stoichiometry. The validity of Eq. 19 was clearly evidenced for polymer adsorption on various substrates.

Even if Drago's concept is an attempt to circumvent the quantum mechanical consideration of bond formation, the major importance of the above four parameters is their relationship with the HSAB principle. Actually, through the plot of  $E_A$  versus  $C_A$  for several liquids on a solid, one can obtain indirectly the values of the chemical softness  $1/\eta$  from the slope of  $C/E$ , as represented by the following equation:

$$E_A = [-\Delta H^{AB}/E_B - C_A C_B/E_B] \quad (20)$$

With the chemical hardness  $\eta$  and the chemical potential, one can easily apply the HSAB principle to acid-base interaction and calculate the number of electron transferred (Eq. 18).

### Effect of Amphotericity of Acid-Base Interaction: Gutmann's Numbers

Solvation, solvolysis, and ionic dissociation phenomena, in both aqueous and nonaqueous solutions are subsumed by the Lewis definitions. In addition to the previous discussion of the dual polarity character of Lewis acids and bases, it should be noted that many of them are amphoteric, by definition. Donor number,  $DN$ , were developed (Gutmann 1977) in order to correlate the behavior of a solute in a variety of donor solvents with a given basicity or donicity. A relative measurement of the basicity of a solvent is given by the enthalpy of its reaction with an arbitrarily chosen reference acid ( $\text{SbCl}_5$  in Gutmann's scale). Latter, an acceptor number  $AN$  was introduced as the relative  $^{31}\text{P}$  Nuclear Magnetic Resonance (NMR) shift induced by triethylphosphine, and relative to acidic strength ( $AN = 0$  for hexane and 100 for

SbCl<sub>5</sub>). These  $AN$  numbers were modified (Riddle and Fowkes 1990) to express them in the correct enthalpic unit (kcal/mol).

The most important assumption of Gutmann's approach is that the order of base strengths established remains constant for all other acids (solutes), the value of the enthalpy of formation of a given adduct being linearly related to the donor number of the base (solvent) through Eq. 21:

$$-\Delta H^{AB} = a_A DN_B + b_A \quad (21)$$

where  $\Delta H^{AB}$  is the enthalpy of acid-base adduct formation,  $DN_B$  is the donor number of the base, and  $a_A$  and  $b_A$  are constants characteristic of the acid.

Graphically, this means that a plot of  $DN_B$  for a series of donor solvents versus  $-\Delta H$  of their adduct formation with a given acid gives a straight line, allowing the determination of  $a_A$  and  $b_A$ . By experimentally measuring the enthalpy of formation of only two adducts for a given acid, one can predict, through the resulting  $a_A$  and  $b_A$  values, the enthalpy of adduct formation of this acid with any other donor solvent for which  $DN_B$  is known. Gutmann also proposes that the enthalpy of acid-base interaction could be approximated by a two-parameter equation of the form:

$$-\Delta H^{AB} = (AN_A DN_B) / 100 \quad (22)$$

where  $\Delta H_{AB}$  is the enthalpy of acid-base adduct formation,  $DN_B$  is the donor number of the base, and  $AN_A$  is the acceptor number of the acid.

The factor of 100 convert the  $AN_A$  value from a percentage of the SbCl<sub>5</sub> value to a decimal fraction. But one had to remind that on the 171  $DN_B$  values reported in the literature (Marcus 1984), only 50 were determined precisely, i.e., by flow microcalorimetric experiments.

Nevertheless Gutmann's approach has some limitation in the way it constitutes rather a prediction concept than an absolute way of determination of  $\Delta H^{AB}$ . Indeed this concept can be used to assess the determination of  $\Delta H^{AB}$  for probed liquids on a solid surface to assess the acid-base nature of the surface.

### IR Spectroscopic Tools to Assess Acid-Base Strength

For specific functional groups involved in acid-base interaction, the enthalpy of acid-base adduct formation is related to the infrared wavenumber shift,  $\Delta\nu$ , of its absorption band (Fowkes et al. 1984) according to the following equation:

$$\Delta H^{AB} = k_{AB} \Delta\nu_{AB} \quad (23)$$

Where  $\Delta H^{AB}$  is the molar enthalpy of acid-base adduct formation,  $\Delta\nu_{AB}$  is the infrared wavenumber shift, and  $k_{AB}$  is a correlation constant between IR wavenumber shift and enthalpy.

$k_{AB}$  is a characteristic constant of the functional group determined on the basis of compared infrared and microcalorimetric results of adduct formation. As an example, for the carbonyl functional group, C = O,  $k_{AB}$  is equal to  $-0.99 \text{ kJ/cm/mol}^{-1}$ .

The stretching wavenumber of the C = O vibration band is decreased by an amount  $\Delta\nu_{AB}$  proportional to the enthalpy of acid-base bonding  $\Delta H^{AB}$  according to  $k_{AB}$ . Such a methodology has been confirmed and case studies are available not only for polymer-solvent adduction but also for polymer/ polymer (Coleman et al. 1991) and polymer/metal adduction (Brogly et al. 1996, 1997). Moreover, infrared shifts can be used to determine Drago's  $E$  and  $B$  constants of unknown polymers or substrates. If a test acid of known  $C_A$  and  $E_A$  gives a  $\Delta\nu_{AB}$  shift allowing the determination of  $\Delta H^{AB}$  then Eq. 19 is reduced to:

$$E'_B = -\Delta H^{AB}/E_A - C'_B(C_A/E_A) \quad (24)$$

where  $E'_B$  and  $C'_B$  are "trial" values. The actual values of  $E_B$  and  $C_B$  occur at one point on the straight line obtained from Eq. 24. The use of multiple test acids shows that straight lines intersect at  $E_B$  and  $C_B$ .

Concerning the limitation of this approach, one must consider that best results are obtained from infrared transmission spectra. This technique is well adapted for the study of solution (polymer/solvent acid-base interactions) or thin films (polymer/polymer acid-base interactions). In the case of polymer/metal acid-base interaction, one can prefer infrared reflexion-absorption spectroscopy (IRAS) or polarization modulated infrared reflexion-absorption spectroscopy (PM-IRAS). Nevertheless this approach is a continuum-based (i.e., macroscopic) approach and it is important to understand that adhesion forces are not specified explicitly even if acid-base interactions contributed to  $\Delta H^{AB}$ .

### Adhesion Forces Measured by Atomic Force Microscopy

Advances in nanotechnology and miniaturization of devices have led to the requirement of an increased understanding of the interactions and adhesion phenomena present in nanoscale contacts. The forces involved include van der Waals forces, hydrogen bonds, electrostatic forces, as well as chemical bond in some cases. Although van der Waals forces are only short range (nanometer range), they often rule the adhesion between two materials and are therefore responsible for contact interactions. In recent years, Atomic Force Microscopy (AFM) has become a powerful tool, sensitive enough, to detect small surface forces and to study adhesion at the nanoscale. Retraction profiles from Force-Distance AFM measurements provide quantitative, chemically sensitive, adhesion information at the nanoscale between probe tips and sample surfaces. Information about local adhesion, friction, or surface stiffness is readily obtainable. The purpose and scope of this section is to describe the experimental method that enables one to assess nanoadhesion forces. Indeed, the quantitative determination of the work of adhesion gives rise to numerous experimental and theoretical approaches. Nevertheless, all these approaches are mainly macroscopic and not made "in situ." As a consequence, characterizations of local properties have stimulated widespread interest. Recent works have contributed to the understanding of adhesion mechanisms at a local scale. Burns et al. (1999) have demonstrated the influence of adhesion on sliding and on friction forces on chemically modified surfaces. Jones et al. (2002) have studied the effects of relative

humidity, roughness, and surface treatment on adhesive properties of glass-glass contact. But few studies have been devoted to the contact between a local probe and a chemically modified surface or polymer surface. Dissipative phenomena in the adhesive contact by using dynamic AFM were nevertheless studied (Boisgard et al. 2002). Finally Brogly et al. (2009) have done experiments on chemically modified polymer surfaces in order to investigate the interplay between surface chemistry and mechanical properties at a local scale.

### Force Versus Distance Measurements with an AFM

Force measurements with AFM, in the contact mode, consist in detecting the deflection of a spring (or cantilever) bearing tip at its end, when interacting with the sample surface. The deflection of the cantilever is detected by an optical device (four quadrant photodiode) while the tip is vertically moved forward and backward thanks to a piezoelectric ceramic (or actuator). Thus, provided that the spring constant of the cantilever is known, one can obtain a Deflection-Distance (DD) curve and then a Force-Distance (FD) curve, by using Hooke's law. The DD curves presented in this chapter were performed in air. A schematic representation of a DD curve obtained when probing a hard surface is reported in Fig. 6.

In zone A, the cantilever is far from the surface and stays in a state of equilibrium (no interaction with the surface). The cantilever deflection is zero. During the approach toward (or withdrawal from) the surface, the tip interacts with the sample and a jump in (or jump-off) contact occurs (zones B (for loading) and E (for unloading)). These instabilities take place because the cantilever becomes mechanically unstable. Usually, for undeformable surfaces, because of mechanical instabilities, jump-in contact is not significant to determine attractive van der Waals forces. When in contact, the cantilever deflection is equal to the piezoelectric ceramic displacement provided no indentation of the substrate occurs (zones C (for loading) and D (for unloading)). An undeformable reference sample (cleaned silicon wafer) is used to scale the DD curve in deflection by fixing to unity the slope value of the

**Fig. 6** Schematic representation of a Force-Distance curve

contact line. Due to adhesion forces during contact, the jump-off is more interesting than the jump in and occurs in position D. Considering the cantilever like a spring, knowing its spring constant, one can obtain the adhesion force ( $F_{\text{Adh.}}$ ) between the tip and the sample by using Hooke's law:

$$F_{\text{Adh.}} = k_{\text{tip}} \cdot D^{\text{pull-off}} \quad (25)$$

where,  $k_{\text{tip}}$  represents the spring constant of the cantilever and  $D^{\text{pull-off}}$  represents the jump off deflection during retraction of the tip from the surface. The DMT theory also establishes a relationship between the adhesion force ( $F_{\text{adh}}$ ), the tip radius ( $R$ ), and the thermodynamic work of adhesion ( $W_0$ ):

$$F_{\text{adh}} = 2\pi R W_0 \quad (26)$$

Strictly speaking, experimental measurement is made out of equilibrium leading determination of the integral work of disruption rather than reversible work of adhesion. On the basis of this relation, one can deduce  $W_0$  from experimental adhesion forces. In order to carry out a quantitative analysis, different experimental points should be taken into consideration such as: selection of tips that possess apex spherical shape (SEM imaging), cantilever spring constant, tip radius, linearity of the photodiodes, piezodriver hysteresis, cantilever and piezo thermal stabilities and tip contamination (Noel et al. 2004).

### 3.4 Case Study: In Situ Determination of the Work of Adhesion

#### 3.4.1 Force – Distance Experiments on Self-Assembly Monolayers (SAMs)

In order to quantitatively and in situ measure the work of adhesion between an AFM tip and a given surface, one has to proceed according to a proper procedure that enables to control surface chemistry and thus surface forces. Organosilane molecules spontaneously organize to form self-assembly monolayers (SAMs). Such a self-organizing process gives rise to the elaboration of homogeneous model surfaces of controlled surface chemistry. Three different techniques are frequently used to obtain SAMs: Langmuir-Blodgett techniques, involving an air-water interface to transfer the assembled film to a solid substrate, solution adsorption of film molecules onto the substrate, and vapor-phase molecular self-assembling technique, which uses vapor deposition of the film onto the substrate. This last technique should be preferred, because the lack of solvent prevents the SAMs of a possible incorporation of small solvent molecules contamination and defects. Molecular films prepared with this method are homogeneous, stable, and resistant. Hydrophobic model surfaces could be prepared by using hexadecyltrichlorosilane ( $\text{C}_{16}\text{H}_{42}\text{Cl}_3\text{Si}$  or  $\text{Si}_{\text{CH}_3}$ ) and 1H,1H,2H,2H-perfluorodecylmethyldichlorosilane ( $\text{C}_{11}\text{H}_7\text{Cl}_2\text{F}_{17}\text{Si}$  or  $\text{Si}_{\text{CF}_3}$ ) and

hydrophilic model surfaces by using (6-aminohexyl)-aminopropyltrimethoxysilane ( $C_{12}H_{30}N_2O_3Si$  or  $Si_{NH_2}$ ) and 2(carbomethoxy)ethyltrichlorosilane ( $C_4H_7Cl_3O_2Si$  or  $Si_{ester}$ ), for instance. Equilibrium contact angle measurements with water droplets and surface energy (determined by wettability using various probed liquids (water, tricresyl phosphate,  $\alpha$ -bromonaphtalene, diiodomethane)) values obtained on silicon wafer grafted with such organosilanes are gathered in Table 2. It is important to note that surface roughness is extremely low ( $<0.2$  nm) and that the wetting liquids do not modify the physicochemical properties of the SAMs.

Table 2 shows that surface energy can be easily tuned, from highly hydrophobic to highly hydrophilic, in an elegant way by grafting SAMs on a dedicated surface. Fig. 7 shows AFM Deflection-Distance curves during retraction of the AFM tip from SAM modified silicon wafers. Results show clearly that force-distance curves are sensitive to a surface chemical modification by organosilane grafting. It is important to understand that during retraction of the cantilever, deflection is equal to the piezoelectric ceramic displacement (slope equal to unity) provided no indentation of the substrate occurs. On Fig. 7, all the experimental curves were horizontally shifted on the x-axis in order fix the beginning of pull-off at a value of x equal to zero.

**Fig. 8** Thermodynamic work of adhesion ( $W_0$ ) deduced from AFM (Derjaguin – Muller – Toporov (DMT) theory) versus surface energy of self-assembly monolayers (SAMs)

When jump-out of contact occurs, the corresponding pull-off deflection is measured. Pull-off deflection values ( $D^{\text{pull-off}}$ ) increases in the following order:

$$D^{\text{pull-off}}_{\text{SiCF}_3} < D^{\text{pull-off}}_{\text{SiCH}_3} < D^{\text{pull-off}}_{\text{SiCOOR}} < D^{\text{pull-off}}_{\text{SiNH}_2} < D^{\text{pull-off}}_{\text{SiOH}}$$

Knowing the pull-off deflection, one can easily deduce (Eq. 25) the adhesion force, knowing the cantilever spring constant  $k_{\text{tip}}$ . The pull-off deflection and thus the adhesion force value increases with the hydrophilicity of the surface. The measured adhesion force depends strongly on the tip radius in the case of purely rigid substrates (for which the slope in the deflection vs. piezo displacement is equal to unity, i.e., for 1 nm of piezo displacement the tip is deflected of 1 nm), the adhesion force being proportional to the tip radius. The DMT theory, also establish a relationship (Eq. 26) between the adhesion force ( $F_{\text{adh}}$ ), the tip radius ( $R$ ), and the work of adhesion ( $W_0$ ). On the basis of this relation one can deduce  $W_0$  from experimental adhesion forces. Fig. 8 shows that the work of adhesion,  $W_0$ , is proportional to the surface energy deduced from classical wettability measurements. If both the AFM tip and the silicon wafer are grafted with the same self-assembly monolayers, then the  $W_0$  should be equal to twice the surface energy (either of the wafer or the tip). Such an experiment (Noel et al. 2006) is an elegant way to demonstrate the possibility that give AFM to quantitatively measure both adhesion forces, work of adhesion and surface energy.

### 3.4.2 Influence of Capillary Forces on Adhesion Forces

In the case of hydrophilic surfaces (Si-NH<sub>2</sub>, Si-OH), the AFM tip interacts with the water layer adsorbed on the surface and the measured adhesion force results from the adhesion between water adsorbed on the both surfaces (tip and sample) and from the adhesion force due to the van der Waal forces between the NH<sub>2</sub> or OH sites existing at the grafted wafer surface. On the contrary, during wettability experiments the water droplet deposited on the surface is not sensitive to OH sites existing at the hydroxylated wafer surface but only to water molecules adsorbed on the hydroxylated surface.

Under these conditions, the influence of the capillary forces cannot be neglected. When AFM experiments are conducted in air medium, one has to suspect the existence of a capillary bridge (Kim et al. 2008). On the theoretical point of view, the minimum thickness of the water capillary film is expressed as (de Gennes 1985):

$$e = a_0(\gamma_w/S) \quad (27)$$

Where  $e$  is the film thickness,  $\gamma_w$  the surface tension of water,  $a_0$  a capillary length, and  $S$  the spreading coefficient ( $S = \gamma_S - \gamma_{SL} - \gamma_L$ ). As a consequence, the force measured by AFM includes the contribution of van der Waals and capillary forces. The total adhesion force is given by the following expression:

$$F_{adh} = F_{cap} + F_{VDW} \quad (28)$$

One can wonder about considering forces or energies. As in the present case, the slope in the deflection vs. piezo displacement is equal to unity during tip retraction is obvious, to a first approximation that the adhesion force (proportional to pull-off deflection) and energy of contact disruption (integral work of contact disruption) vary in proportion. Work will be done on forces. The capillary condensation induces the formation of a meniscus between the two surfaces and generates a capillary force which is given in the case of sphere-plane contact, by (Riedo et al. 2002):

$$F_{cap} = 2\pi R\gamma_w(\cos \theta_{w/tip} + \cos \theta_{w/wafer}) \quad (29)$$

where  $\gamma_w$  is the surface tension of water,  $R$  the tip radius, and  $\theta$  the contact angle between water and the tip or between water and the wafer. One can wonder about the possibility to apply Eq. 29, which derive from macroscopic considerations, to the case of nanoscopic measurements. In fact Environmental scanning electron microscopy can be used (Weeks et al. 2005) to image water meniscus formation between an AFM tip and a surface. Values of  $W_0$  obtained after correction from capillary force contribution on Si-NH<sub>2</sub> and Si-OH hydrophilic surfaces are represented by black circles in Fig. 8. Values of capillary force and van der Waals forces in the case of hydrophilic contacts were gathered in Table 3.

Taking into account the contribution of capillary forces, Fig. 8 shows that a good correlation is observed between the work of adhesion ( $W_0$ ) and the surface energy of the chemically modified solids ( $\gamma_s$ ). As a consequence, these results demonstrate that AFM Force-Distance experiments could be used to determine quantitatively the contribution of van der Waals forces and capillary force to the adhesion force.

### 3.5 Conclusions

Adhesion is a complex phenomenon and cannot be interpreted using a single model in view of the diversity of forces, materials, and process involved. However, the forces developed during adsorption and molecular contacts are believed to be one of the most important mechanisms in achieving adhesion. Diffusion and wetting are merely kinetic means to obtain good adsorption at the interface. By diffusion and wetting, the adsorbed molecules can reach an intimate contact with the substrate and allows the van der Waals and/or acid-base interactions to take place, which are predominant in numerous situations. Nevertheless, rigorous computation of van der Waals forces remains difficult. The same is for acid-base interaction energies on the basis of molecular orbital approach or quantum mechanical consideration. Thus, the knowledge of the surface properties of materials on the bases of continuum-based theories (hence macroscopic) allows an estimation of solid-solid or solid-liquid interfacial interactions, which is a necessary condition prior to any study on adhesion. In that sense, understanding the fundamentals of forces involved in adhesion helps to create conditions that will promote or reduce the attractive forces between interacting bodies and thus control adhesion. Development of local probe techniques (surface force apparatus (SFA), atomic force microscopy (AFM)) allows accessing directly adhesion force measurements. But one has to remind that the influence of capillary forces is obvious considering the nanometric size of the probes (nanoindentation, AFM). Other successful methods to quantify specific (acid-base) interaction energies are based on enthalpy or heat of adsorption measurements. Flow microcalorimetry, inverse gas chromatography (IGC), and spectroscopic techniques (FTIR) are particularly dedicated. To conclude one has also to consider that the specific case of biological adhesion was not treated in this chapter. Many other forces should then be involved in biological adhesion such as solvation, hydrophobic, entropic, and nonequilibrium forces.

## Abstract

The contact between a solid and a liquid involves the phenomenon of wetting. This is the intuitive, intimate contact between the two phases. We consider here thermodynamic aspects of wetting, which involves three phases in fact, since the environment must be taken into account. Methods for determining wetting characteristics are discussed.

## 4.1 What Is Wetting?

When you “wet” your hands under the tap, or in a bowl of water, you are implicitly assuming that the water is directly, intimately, contacting your skin. Water is wet, apparently even etymologically. The Indo-European root of water is \*wed-, “wet.” However, this important, implicit connotation of the term wetting clearly fails if you are so unlucky as to break an old mercury thermometer or barometer and get the liquid on your skin. The mercury tucks itself up into little beads and apparently does not “wet” your skin. What is the fundamental difference? This can be explained by the concept of “contact angle,”  $\theta$ . For present purposes, it will suffice to discuss the “static” contact angle,  $\theta_0$ . Let us consider the case of a small drop of liquid deposited on a flat, solid surface (Most real solid surfaces are, of course, rough. The consequences will be considered below in Sect. 5), from an intuitive viewpoint. A *meniscus* (Greek: *mēniskos* = crescent), corresponding to the liquid/air environment, is formed. After *spreading* (cf. chapter Spreading of Liquids on Substrates) to rest (equilibrium) has occurred, a *sessile* (“sitting”), static drop of the liquid is present. Angle  $\theta_0$  is that subtended between the solid/liquid interface and the tangent to the liquid/air interface, as shown schematically in Fig. 1. It is measured perpendicularly both to the solid surface and to the triple line of contact where solid, liquid, and air come together. (For definiteness, the surrounding medium is regarded as “air.” More precisely, the surrounding gas, air or otherwise, *always* contains vapor of the liquid and, in principle, of the solid. However, the vapor pressure of most solids is very low.)

Of course, the gas phase could be a second liquid, provided it has a miscibility gap with the first liquid. Henceforth, the envrioning phase will generally be referred to as “vapor” while bearing in mind the previous comment. Referring to Fig. 1, it may be seen that the case on the left represents a contact angle of less than  $90^\circ$  ( $\pi/2$  rad), and may be called “good wetting,” whereas that on the right is such that  $\theta_0 > 90^\circ$ , and this represents “poor wetting.” In the extreme case of  $\theta_0 \rightarrow 0$ , the liquid becomes a thin film (e.g., oil deposited on a steel sheet). This is often called

**Fig. 1** Schematic representation of low (*left*) and high (*right*) static contact angles,  $\theta_0$ . Interfacial tensions are represented by *arrows* and termed  $\gamma_{ij}$  (*S* solid, *L* liquid, *V* vapor/surrounding fluid phase)

*spreading*. Although it will not be treated here, the thickness of such films depends on long-range molecular forces, which may span the entire liquid thickness of the film, leading to what is effectively “interference” between the two interfaces, liquid–solid and vapor–liquid (cf. chapter Spreading of Liquids on Substrates). However, this is beyond the scope of the present chapter as such spreading is fundamentally different from simple wetting. At the other extreme, the case of  $\theta_0 \rightarrow 180^\circ$ , non-wetting, may be considered. This cannot, in fact, exist if the solid is truly smooth and if the environment is only gaseous but can in some cases when two liquids are involved (Shanahan et al. 1982). The importance of contact angle is that it determines the extent of (solid) surface coverage by a liquid. It is intuitively clear that the interfacial area covered by a sessile drop of given, fixed volume  $V$  of liquid increases as contact angle decreases, but this may be readily written formally in the case of a spherical, cap-shaped drop of contact radius  $r$  and height  $h$ . Writing  $t = \tan(\theta_0/2) = h/r$ , and with a standard trigonometric formula for the volume,  $V$ , of a spherical segment:  $V = \pi h(3r^2 + h^2)/6$ , it is readily shown that the contact area,  $A$ , is given by

$$A = \pi \cdot r^2 = \pi^{1/3} \left[ \frac{6V}{t(3 + t^2)} \right]^{2/3} \quad (1)$$

In the range of possible contact angles,  $0^\circ \leq \theta_0 \leq 180^\circ$ ,  $t$  is a monotonically increasing function of  $\theta_0$ , and therefore,  $A$  increases as  $\theta_0$  decreases, at constant  $V$ .

So, decreasing  $\theta_0$  implies better coverage, or wetting, but what controls  $\theta_0$ ? Between the solid and liquid and liquid and vapor phases, there are *phase boundaries* of the different substances. These can be imagined as 2D faces, or interfaces, but nature is never so clear-cut, and a vague transition zone, the interphase, typically of the order of a few nm (nanometers) or a few tens of nm thick constitutes the changeover. It has to be mentioned that an interphase and its width is not a uniquely defined thing as it has to be attributed to the macroscopic physical or chemical quantity of interest. In other words, each thermodynamic quantity of a heterogeneous system can possess its particular spatial function across its own interphase. The interphase will be considered in Sects. 2 and 3. However, accepting as a first approximation that 2D interfaces separate phases, it can be seen in the typical case exemplified in Fig. 1 that there are three *interfaces*: SL, LV, and SV (S, solid; L, liquid; V, vapor/surrounding medium), each of which has associated with it an *interfacial tension*  $\gamma_{IJ}$  where  $I$  and  $J$  refer to S, L, and V (see Sect. 2 for definition). Note that the very concept of “force/distance” is meaningless in absolute terms, since the force will have no area to “pull” or “push” on: the idea of a “stress” becomes vague. In fact, it is Gibbs’ concept of “surface excess” (cf. Sect. 2) that allows one to see that the forces are, in fact, acting over a thin layer at the interface, and thus the concept of stress is still valid. The three phases, and therefore interfaces, meet at the drop periphery, at what is termed term the *triple line* or *contact line*. Again, this is not really a line, but a “tube,” but the concept of line is adequate in Gibbs’ treatment. A force balance between the various  $\gamma_{IJ}$  exists at the triple line, and, at equilibrium, this is principally what governs the value of  $\theta_0$  (see below for details).

Accepting the concept of contact angle, its importance may be appreciated in many sectors, biological and industrial. Without resorting to equations, it is intuitive (and correct) to realize that it is more difficult to remove an oil film from steel (contact angle ca.  $0^\circ$ ) than a drop of mercury from glass (contact angle ca.  $130^\circ$ ). Not only is adherence of the oil intrinsically better, but for a given volume, coverage is superior. The same, of course, has to apply to paints and inks. If an insecticide is applied to a leaf, it is clearly inefficient if, when the leaf slopes, the liquid simply rolls off. Therefore, a small, preferably zero, contact angle is required. In the case of adhesives, this significant coverage and propensity to wet the solid in contact is crucial in forming a good bond as it gives the molecules the *opportunity* to form adhesive interactions, even if the “true,” chemical, bond is produced later by hardening of the adhesive (drying, chemical reaction, cooling). If the surface is rough, the same wetting tendency will help ensure filling the interstices. This not only increases true contact area, but reduces stress concentrations, liable to be crack initiators.

There are, of course, many cases where *poor* wetting is required. Nature masters this beautifully in the case of, for example, duck feathers and lotus leaves (Zhang et al. 2009). Mankind attempts to exploit it with PTFE and other polymers as cooking utensil coatings and raincoat treatments.

The main objective of this chapter is to consider in more detail the phenomenology of wetting, specifically in the static case (kinematics are covered in chapter Spreading of Liquids on Substrates). In other words, the triple phase line will principally be considered to be at rest. The description will now be couched in terms of the needs of thermodynamic equilibrium.

## 4.2 Thermodynamics of a Phase Boundary: An Introduction

As mentioned above, the boundary between two thermodynamic phases must be a vague transition zone for any physical quantity because nature does not like sharp steps. Hence, in principle, any real phase boundary extends in three dimensions – the *interphase* (cf. Fig. 2a). This apparently innocent comment has the important result that all extensive thermodynamic quantities, such as concentrations, energies, entropy, etc., will depend on position across the interphase. This causes trouble when it comes to an exact description of a thermodynamic system with more than one phase, because there is virtually no experimental access to the spatial dependence of thermodynamic quantities across the phase boundary. Moreover, the beauty of classic thermodynamics is very much due to the assumption that parameters remain constant across a phase. The exact volume  $V$  of such a two-phase system is given by the total

$$V = V_A + V_B + V_{\text{Interphase}} \quad (2)$$

where the terms on the right-hand side refer, respectively, to the two “bulk” phases and to the interphase. Hence, a method to circumvent the problem is needed. A pioneer in this subject (among many others!) was J.W. Gibbs, who introduced in a standardized way the notion of a “discontinuity” (Bumstead and Van Name 1961;

**Fig. 2** Schematic drawing for an interphase in a radially configuration of spherical symmetry of two phases  $A$  and  $B$ . The interphase shown in (a) (left) is replaced by the 2D discontinuity face (b) (right) in interface thermodynamics

Gaydos et al. 1996). A brief version of this thermodynamic description for phase boundaries is now introduced.

#### 4.2.1 Brief Description of Gibbs' Model for a Phase Boundary

The “real” interphase (Bakker 1902) is replaced by the “artificial” *discontinuity face* (D-face) with a certain area  $A_{AB}^D$  – cf. Fig. 2b. (For example, see (Rusanov 1978; Rusanov and Prokhorov 1996) for more details.) The position of the D-face can be chosen *arbitrarily, but only once*, from the theoretical point of view or, in measurements, is fixed by the experiment itself. Indeed, the experimenter is unable to select the position of the D-face deliberately. Usually, he does not know that position exactly. Although the D-face and the interface are very similar in many cases, the term “D-face” will be used here because similarity does not mean identity from the theoretical viewpoint. As a first consequence, (2) must be replaced by

$$V = V_A + V_B \quad (3)$$

for the two-phase system, i.e., the interphase volume  $V_{\text{Interphase}}$  is “eliminated,” being arbitrarily attributed partially to each of phases  $A$  and  $B$  according to the given position of the D-face.

Moreover, the balance of any extensive thermodynamic quantity,  $Y$ , in the two-phase system is no longer

$$Y = Y_A + Y_B + Y_{\text{Interphase}} \quad (4)$$

but is written as

$$Y = Y_A + Y_B + Y_{AB}^D \quad (5)$$

Here,  $Y_{AB}^D$  denotes the *excess of*  $Y$  with respect to the D-face. It is a correction that guarantees the correct value for  $Y$  in the whole two-phase system after the interphase has been ignored. Note that any excess quantity can adopt positive and negative values as well. The extensive  $Y$  can be referred to the D-face area  $A_{AB}^D$ , thus providing the corresponding intensive quantity  $y$

$$y = \frac{Y}{A_{AB}^D} = y_A + y_B + y_{AB}^D \quad (6)$$

For example, the number of moles  $n_i$  of a component  $i$  in the system

$$n_i = n_{i,A} + n_{i,B} + n_{\text{Interphase}} \quad (7a)$$

$n_{i,A}$ ,  $n_{i,B}$ ,  $n_{\text{Interphase}}$  = number of moles of component  $i$  in phases  $A$  and  $B$  and in the interphase is replaced by

$$n_i = n_{i,A} + n_{i,B} + n_{i,AB}^D = c_{i,A} \cdot V_A + c_{i,B} \cdot V_B + n_{i,AB}^D \quad (7b)$$

$n_{i,AB}^D$  = excess number of moles of  $i$  for the given D-face

$c_{i,A}$ ,  $c_{i,B}$  = concentrations of  $i$  (mole  $\text{m}^{-3}$ ) in phases  $A$  and  $B$

A simple rearrangement of (7b) provides the definition of the *absolute adsorption of component  $i$*  in a thermodynamic system with  $N$  components

$$\Gamma_{i,AB}^D \stackrel{\text{def}}{=} \frac{n_{i,AB}^D}{A_{AB}^D} = \frac{n_i - c_{i,A} \cdot V_A - c_{i,B} \cdot V_B}{A_{AB}^D} \quad \text{with } i = 1 \dots N \quad (8)$$

Indirectly, these  $N$  excess quantities replace the concentration profiles of all components in the system. Obviously, the value for any of the  $\Gamma_{i,AB}^D$  depends on  $A_{AB}^D$  and hence on the position for the D-face. As that position can be chosen only once for a given phase boundary, only one of the  $\Gamma_{i,AB}^D$  can be made zero, while all other  $(N - 1)$   $\Gamma_{j,AB}^D$  adopt nonzero values. (This naïve statement will be important for the coming discussions.)

The *interfacial tension* is another important quantity for the thermodynamics of interfaces. The starting point stems from continuum mechanics for deformable solids where the balance of forces at point  $\vec{r}$  in the solid is given by

$$\frac{d \vec{F}(\vec{r})}{dV} = \vec{f}(\vec{r}) = \text{Div } \vec{\sigma}(\vec{r}) \quad (9)$$

$\vec{f}(\vec{r})$  = density of the external force that deforms a solid

$\vec{\sigma}(\vec{r})$  = tensor of internal stresses in the deformed solid

171 and the mechanical work of deformation  $\Delta W$  of the volume  $V$

$$\Delta W = \int_V \sum_{i,k} (\sigma_{ik} \cdot \delta e_{ik}) dV \quad (10)$$

172  $\sigma_{ik}$ ,  $\delta e_{ik}$  = components of the stress and the deformation tensors,  $\vec{\sigma}(\vec{r})$ ,  $\vec{e}$   
 173  $(\vec{r})$ , respectively.

174 In thermodynamics, pressure is preferred, but now it is a tensor which is defined  
 175 as

$$\vec{e}(\vec{r}) = -\vec{\sigma}(\vec{r}) \quad (11)$$

176 All three tensors  $\vec{\sigma}(\vec{r})$ ,  $\vec{p}(\vec{r})$ ,  $\vec{e}(\vec{r})$  are symmetric, and hence they can be  
 177 transformed into diagonal form, provided a suitable system of coordinates is chosen.  
 178 Then, the analysis of (10) for the boundary between the two phases will provide a  
 179 definition for interfacial tension. As an illustration, the derivation is considered for  
 180 the case of an *isotropic horizontal planar phase boundary*. The D-face spans the  $x,y$ -  
 181 plane of the Cartesian coordinate system, and the  $z$ -axis is parallel to, but in the  
 182 opposite direction to, the gravitational force which is the external field here

$$\vec{f}(z) = -g \cdot \rho(z) \cdot \vec{k} \quad (12)$$

183  $g$  = gravity acceleration

184  $\rho(z)$  = mass density

185  $\vec{k}$  = unit vector for  $z$ -direction.

186 From (Eqs. 9, 11, and 12), it follows that

$$\text{Div} \begin{pmatrix} p_{xx} & 0 & 0 \\ 0 & p_{yy} & 0 \\ 0 & 0 & p_{zz} \end{pmatrix} = \begin{pmatrix} \frac{\partial p_{xx}}{\partial x} \\ \frac{\partial p_{yy}}{\partial y} \\ \frac{\partial p_{zz}}{\partial z} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ -g \cdot \rho(z) \end{pmatrix}$$

187 and hence

$$p_{xx}(z) = \text{const}; \quad p_{yy}(z) = \text{const}; \quad p_{zz}(z) - p = -g \cdot \int_{-\infty}^z \rho(z) dz \quad (13a - c)$$

188  $p$  = isostatic external pressure.

The two tangential pressure components  $p_{xx}$  and  $p_{yy}$  have to be equal for any  $z$ , by symmetry

$$p_{xx}(z) = p_{yy}(z) \equiv p_T(z) \quad (13d)$$

$p_T$  = pressure in the  $x,y$ -plane at  $z$

Usually, the interphase is very thin ( $d \approx 10^{-9}$ – $10^{-7}$  m) and (13c) can be approximated by

$$g \cdot \int_{-\frac{d}{2}}^{\frac{d}{2}} \rho(z) \, dz \approx 0 \rightarrow p_{zz}(z) \equiv p_N \approx p = \text{const} \quad (13e)$$

$p_N$  = pressure component in  $z$ -direction.

With (13), (10) is now

$$\begin{aligned} \Delta W &= - \int_V [p_T \cdot (\delta e_{xx} + \delta e_{yy}) + p \cdot \delta e_{zz}] \, dV \\ &= - \int_V [p_T \cdot (\delta e_{xx} + \delta e_{yy}) - p \cdot (\delta e_{xx} + \delta e_{yy}) + p \cdot (\delta e_{xx} + \delta e_{yy}) + p \cdot \delta e_{zz}] \, dV \\ &= \int_V [(p - p_T) \cdot (\delta e_{xx} + \delta e_{yy})] \, dV - p \cdot \int_V (\delta e_{xx} + \delta e_{yy} + \delta e_{zz}) \, dV \end{aligned}$$

and for small deformations

$$\Delta W = \Delta A_{AB}^D \cdot \int_{-\infty}^{\infty} (p - p_T) \, dz - p \cdot \Delta V \quad (14a)$$

The second term is the well-known work of volume expansion, while the first term

$$\Delta W_{AB}^D = \Delta A_{AB}^D \cdot \int_{-\infty}^{\infty} (p - p_T) \, dz \quad (14b)$$

gives the work for increasing the area of the D-face by  $\Delta A_{AB}^D$ .

Equation (14) implies the definition of the *interfacial tension for the* chosen isotropic planar D-face:

$$\gamma_{AB}^D \stackrel{\text{def}}{=} \int_{-\infty}^{\infty} (p - p_T) \, dz \quad (15a)$$

201 With an assumed *spherical shape for the isotropic interphase*, a similar mathe-  
 202 matical treatment provides the *interfacial tension for the spherical D-face of*  
 203 *radius  $r_D$*

$$\gamma_{AB}^D = \frac{1}{r_D^2} \left[ \int_0^{r_D} (p_A - p_T) r^2 dr + \int_{r_D}^{\infty} (p_B - p_T) r^2 dr \right] \quad (15b)$$

204  $p_A, p_B$  = isostatic pressures inside the phases A and B. They are different due to the  
 205 curved interphase.

206 These two examples illustrate that  $\gamma_{AB}^D$  is, in general, an excess quantity for a  
 207 given D-face. As a consequence of this result, there is no physical difference  
 208 between interfacial and surface tension in thermodynamic equilibrium. In the  
 209 literature, the term surface tension is attributed to the D-face, or interface, between  
 210 a condensed phase and the corresponding vapor phase. Some authors define the  
 211 surface tension as the interfacial tension of a condensed phase in contact with  
 212 vacuum. This is incorrect in the framework of equilibrium thermodynamics. A  
 213 condensed phase will fill a vacuum with its vapor phase to be at thermodynamic  
 214 equilibrium. Hence, any interfacial tension results from a defined pair of phases,  
 215 never from a single phase, and they need to be marked by the subscript “AB” or  
 216 similar. Otherwise, the interfacial tension would be ill-defined.  $\gamma_{AB}^D$  accounts for  
 217 the real distribution of pressure or stress inside the phase boundary. It is called a  
 218 tension because it possesses the dimension of a force per unit length [ $\text{N m}^{-1}$ ] in  
 219 the 2D space of the D-face and indeed acts somewhat like the tension in a  
 220 membrane (except that there is no elastic proportionality between the tension  
 221 and extension). Moreover, (15b) reveals that the value for  $\gamma_{AB}^D$  usually depends on  
 222 the position, here  $r_D$ , chosen for the given D-face.  $\gamma_{AB}^D$  is always positive. This is a  
 223 condition of stability for the interphase and hence for the phase itself, and it is  
 224 proven by experiment and also by statistical mechanics calculations. The value  
 225 remains almost constant when  $p$  decreases. Therefore,  $p_T$  must be negative, at least  
 226 inside the dominant part of the interphase, and as a consequence, the interphase  
 227 and the corresponding D-face will adopt the minimum volume and area,  
 228 respectively.

229 To apply thermodynamic energy balances (first law), knowledge of how *mechan-*  
 230 *ical work* changes the state of the system must be available. As the phase boundary is  
 231 included, the usual equations have to be revised. Figure 3 depicts the situation for the  
 232 volume expansion  $\delta V$  of the phase A that is accompanied by a change of the principal  
 233 radii of curvature from  $R_1, R_2$  to  $(R_1 + \delta z), (R_1 + \delta z)$ , respectively. Now, the  
 234 mechanical work can be split into *four parts*. The first one comes from the work  
 235 of volume expansion

$$\delta W^V = -p_A \cdot dV_A - p_B \cdot dV_B \quad (16a)$$

236 Part two results from the corresponding increase of area of the D-face according to (14b)

**Fig. 3** Geometric scheme for the of the volume increase  $\delta V$  of a phase  $A$  with a curved D-face ( $D \rightarrow D'$ )

$$\delta W_{AB}^D = \gamma_{AB}^D \cdot dA_{AB}^D \quad (16b)$$

237 The increase of D-face area can be accompanied by a change of the radii of  
 238 curvature. This corresponds to the third contribution to the mechanical work:

$$\delta W_{\text{curvature}}^D = A_{AB}^D \cdot C_1 \cdot d\left(\frac{1}{R_1}\right) + A_{AB}^D \cdot C_2 \cdot d\left(\frac{1}{R_2}\right) \quad (16c)$$

239  $C_1, C_2 =$  proportionality factors.

240 The fourth and last part is related to the action of external forces such as gravity.

241 The D-face possesses the total excess mass

$$m_{AB}^D = \sum_{i=1}^N m_{i,AB}^D = \sum_{i=1}^N M_i \cdot n_{i,AB}^D = A_{AB}^D \cdot \sum_{i=1}^N M_i \cdot \Gamma_{i,AB}^D$$

242 which is raised by a height  $dh$  when the D-face shifts in the gravitational field.

243 Hence, the corresponding work is

$$\delta W_{\text{gravitation}}^D = A_{AB}^D \cdot \sum_{i=1}^N \left( M_i \cdot \Gamma_{i,AB}^D \right) \cdot g \cdot dh \quad (16d)$$

244 The total work is equal to

$$\begin{aligned}
\delta W = & -p_A \cdot dV_A - p_B \cdot dV_B + \\
& + \gamma_{AB}^D \cdot dA_{AB}^D + A_{AB}^D \cdot C_1 \cdot d\left(\frac{1}{R_1}\right) + A_{AB}^D \cdot C_2 \cdot d\left(\frac{1}{R_2}\right) + \\
& + A_{AB}^D \cdot \sum_{i=1}^N \left( M_i \cdot \Gamma_{i,AB}^D \right) \cdot g \cdot dh
\end{aligned} \tag{16f}$$

245 In this equation, however, the work would seem to depend on  $A_{AB}^D$  and hence on the  
 246 arbitrarily chosen position of the D-face. This is impossible from a physical point of  
 247 view and terms of (16f) must clearly correct for this implicitly. The paradox is  
 248 revealed from a virtual displacement  $\delta N$  of the D-face along its normal  $\vec{N}$ . The  
 249 corresponding virtual mechanical work is  $\delta W = 0$ . Another expression available is

$$\begin{aligned}
\delta V_A = A_{AB}^D \cdot \delta N, \quad \delta V_B = -A_{AB}^D \cdot \delta N, \quad dA_{AB}^D = A_{AB}^D \left( \frac{1}{R_1} + \frac{1}{R_2} \right) \delta N, \\
\delta N = \delta R_1 = \delta R_2
\end{aligned}$$

250 and (16f) now provides the *generalized Laplace equation*

$$p_A - p_B = \gamma_{AB}^D \left( \frac{1}{R_1} + \frac{1}{R_2} \right) - \frac{C_1}{R_1^2} - \frac{C_2}{R_2^2} + \sum_{i=1}^N \left( M_i \cdot \Gamma_{i,AB}^D \right) \cdot g \cdot \cos \varphi \tag{17a}$$

251 where  $\varphi$  = angle between  $\vec{N}$  and vertical direction.

252 The complete condition for mechanical equilibrium of a two-phase system with a  
 253 curved phase boundary in a gravitational field is now available. It shows that the  
 254 pressure difference between two curved phases depends on the properties of the  
 255 D-face: interfacial tension, curvature, and adsorptions  $\Gamma_{i,AB}^D$ . Usually, the absolute  
 256 adsorptions  $\Gamma_{i,AB}^D$ , as well as  $C_1$  and  $C_2$ , are small. Then, the following approximation  
 257 of (17a) can be used:

$$p_A - p_B = \gamma_{AB}^D \left( \frac{1}{R_1} + \frac{1}{R_2} \right) \tag{17b}$$

258 This is known as Laplace's equation.

259 For an *anisotropic* phase boundary such as in the case of oriented molecules, the  
 260 interfacial tension becomes a diagonal tensor

$$\vec{\gamma}_{AB}^D = \begin{pmatrix} \gamma_{11} & 0 \\ 0 & \gamma_{22} \end{pmatrix} \tag{18a}$$

261 and the trace of the tensor provides the value for the interfacial tension

$$\gamma = \frac{1}{2} (\gamma_{11} + \gamma_{22}) \tag{18b}$$

262 Finally, the corresponding forms of Equation (17) become

$$p_A - p_B = \frac{\gamma_{11}^D}{R_1} + \frac{\gamma_{22}^D}{R_2} - \frac{C_1}{R_1^2} - \frac{C_2}{R_2^2} + \sum_{i=1}^N \left( M_i \cdot \Gamma_{i,AB}^D \right) \cdot g \cdot \cos \varphi \quad (19a)$$

$$p_A - p_B = \frac{\gamma_{11}^D}{R_1} + \frac{\gamma_{22}^D}{R_2} \quad (19b)$$

263 With these results, the energy balance of the two-phase system can be evaluated  
264 in detail.

### 265 4.2.2 Energy Balance for a Two-Phase System: Thermodynamic 266 Potentials

267 The *thermodynamic potential for the internal energy*  $U$  in any thermodynamic  
268 system provides the starting point

$$dU = T \cdot dS + \delta W + \sum_i \mu_i \cdot dm_i$$

269  $T$  = absolute temperature

270  $S$  = entropy  $\mu_i$ ,  $m_i$  = chemical potential and mass of component  $i$ .

271 Using (5 and 16f) for a system with the isotropic phases A and B, the following  
272 relation is obtained

$$\begin{aligned} dU &= dU_A + dU_B + dU_{AB}^D \\ &= T \cdot (dS_A + dS_B + dS_{AB}^D) - p_A \cdot dV_A - p_B \cdot dV_B \\ &\quad + \gamma_{AB}^D \cdot dA_{AB}^D + A_{AB}^D \cdot C_1 \cdot d\left(\frac{1}{R_1}\right) + A_{AB}^D \cdot C_2 \cdot d\left(\frac{1}{R_2}\right) \\ &\quad + A_{AB}^D \cdot \sum_{i=1}^N \left( M_i \cdot \Gamma_{i,AB}^D \right) \cdot g \cdot dh + \sum_i \mu_i \cdot (dm_{i,A} + dm_{i,B} + dm_{i,AB}^D) \end{aligned} \quad (20)$$

273 The terms for the D-face are easily identified. For clarity and brevity, however, the  
274 following treatment is restricted to a *plane interface* and *neglect gravity*. Then, (20)  
275 reduces to

$$\begin{aligned} dU &= dU_A + dU_B + dU_{AB}^D = T \cdot (dS_A + dS_B + dS_{AB}^D) - p_A \cdot dV_A - p_B \cdot dV_B + \\ &\quad + \gamma_{AB}^D \cdot dA_{AB}^D + \sum_i \mu_i \cdot (dm_{i,A} + dm_{i,B} + dm_{i,AB}^D) \end{aligned} \quad (21)$$

Integration provides the full internal energy of the two-phase system

$$U = T(S_A + S_B + S_{AB}^D) - p_A V_A - p_B V_B + \gamma_{AB}^D A_{AB}^D + \sum_i \mu_i \cdot (m_{i,A} + m_{i,B} + m_{i,AB}^D) \quad (22)$$

and the *excess internal energy of the force-free plane D-face*

$$U_{AB}^D = T \cdot S_{AB}^D + \gamma_{AB}^D A_{AB}^D + \sum_i \mu_i \cdot m_{i,AB}^D \quad (23)$$

Now, *specific* quantities are introduced

$$u_{AB}^D = \frac{U_{AB}^D}{A_{AB}^D} = T \cdot s_{AB}^D + \gamma_{AB}^D + \sum_i \mu_i \cdot \Gamma_{i,AB}^D \quad (24)$$

$s_{AB}^D = \frac{S_{AB}^D}{A_{AB}^D}$  = specific excess entropy of the D-face

in order to get intensive thermodynamic quantities.

Moreover, the *excess Helmholtz free energy* is

$$F_{AB}^D = U_{AB}^D - T \cdot S_{AB}^D = \gamma_{AB}^D A_{AB}^D + \sum_i \mu_i \cdot m_{i,AB}^D \quad (25)$$

with the corresponding *specific excess Helmholtz free energy*

$$f_{AB}^D = \frac{F_{AB}^D}{A_{AB}^D} = u_{AB}^D - T \cdot s_{AB}^D = \gamma_{AB}^D + \sum_i \mu_i \cdot \Gamma_{i,AB}^D \quad (26)$$

These results give access to the *interfacial tension as a thermodynamic excess quantity of the force-free plane D-face*. Note that the interfacial tension and the absolute adsorptions of all components contribute to the interfacial energy, both the specific excess internal energy and the specific excess Helmholtz free energy. At a first glance, this statement is very natural, indeed. In the literature, however, interfacial tension and interfacial energy are very often considered as synonymous. This is incorrect.

Finally, the total differential for (23) is derived and compared with the corresponding terms in (21). This yields the *Gibbs adsorption equation*

$$d\gamma_{AB}^D = -s_{AB}^D dT - \sum_i \Gamma_{i,AB}^D d\mu_i \quad (27)$$

Equation (27) depicts the interfacial tension as a function of temperature and, via the chemical potentials, of pressure and composition of the two-phase system.

### 4.3 Thermodynamic Equilibrium of Three Phases: Basics

From Sect. 1, it is clear that wetting and the contact angle depend on all *three* contacting phases. Hence, the Gibbs concept of excess quantities as thermodynamic quantities for phase boundaries has to be extended in an appropriate way. For a sessile drop on a *flat, homogeneous* solid, the situation is illustrated in Fig. 4. The three phases create a new microscopic boundary region at their “line” of common contact. For the sessile drop, this region forms a curved tube along the rim of the drop on the solid. Inside the tube, the three D-faces for the three two-phase boundaries respond by deforming, shown very much exaggerated in the drawing.

The real three-phase region (tube) is replaced by a *triple line* (TL) as the new model element for thermodynamic considerations. In theory, its position results from the extrapolation of the three *undisturbed* D-faces to their common intersection. Accordingly, the tangent lines on these extrapolated D-faces  $D_{SL}$  and  $D_{LV}$  to the point of intersection lead *by definition* to the *thermodynamic contact angle*  $\theta_e$ . For reasons of exactness,  $\theta_e$  is introduced for the thermodynamic equilibrium of the three-phase system. The static contact angle  $\theta_0$  in Sect. 1 refers to the triple line at rest, i.e., to mechanical equilibrium which is a necessary but insufficient condition for thermodynamic equilibrium.  $\theta_e$  is the first excess quantity for the TL. As the position of any of the three D-faces can be chosen arbitrarily, the position of the TL and the value for  $\theta_e$  are arbitrary too. Fortunately, this vagueness is of no serious consequence as long as the two-phase and three-phase boundaries possess microscopic thicknesses. Note that  $\theta_e$  is a *local property* of the given TL in thermodynamic equilibrium. Hence, for isotropic phases,  $\theta_e$  possesses one and only one value!

**Fig. 4** Sketch of the cross section through a sessile drop of liquid L on a *flat* solid S, both immersed in their common vapor atmosphere V. The D-faces  $D_{LV}$ ,  $D_{SV}$ , and  $D_{SL}$  describe the corresponding phase boundaries. T marks the triple line as the new model element for the three-phase boundary region (---) between the phases S, L, and V.  $\theta_e$  = contact angle in thermodynamic equilibrium

The pressure tensor  $\vec{p}$  will also vary in the three-phase region as compared with the two-phase boundary. Hence, a *line tension*  $\kappa_{\text{SLV}}$  has to be introduced as the corresponding excess quantity for the TL. Although the mathematical derivation is omitted here,  $\kappa_{\text{SLV}}$  follows from the same physical arguments that resulted in the definition of the interfacial tension in Sect. 2. It acts along the tangent of any point of the TL and has the dimension of a force as it refers to a tension in a 1D space.

By analogy with a D-face, new excess quantities have to be introduced for all extensive thermodynamic quantities with respect to the TL. Details are not given here. For brevity, only a result of consideration of the Helmholtz free energy for a three-phase system in thermodynamic equilibrium *under the influence of gravity* is mentioned. It leads to a condition for the *mechanical equilibrium at the TL on a solid with an arbitrary surface profile (roughness)*:

$$\gamma_{\text{SV}} = \gamma_{\text{SL}} + \gamma_{\text{LV}} \cdot \cos \theta_e + \left( \frac{\kappa_{\text{SLV}}}{R_0} + \frac{d\kappa_{\text{SLV}}}{dR_0} \right) \cdot |\cos \varphi_s| \quad (28)$$

$\gamma_{\text{LV}}$  = interfacial tension of the  $D_{\text{LV}}$ -face far from the TL

$R_0$  = radius of curvature in the considered point of the TL

$\varphi_s$  = angle of inclination of the extrapolated  $D_{\text{SV}}$ -face in the considered point of the TL.

Accordingly,  $\theta_e$  does not only depend on the three interfacial tensions but also on the line tension and on the curvature of the TL.  $\kappa_{\text{SLV}}$  is of the order of  $10^{-10}$  N for solids in general. Nevertheless, it deserves attention when the phases are soft and one of the contacting phases becomes very small.

Figure 5 illustrates the situation for a sessile liquid drop on a *rough homogeneous* solid surface.  $\theta_e$  is defined as before. However, the true value of  $\theta_e$  cannot be obtained from the plane optical projection of the sessile drop anymore as the experimenter cannot look into the local surface profile in order to get the local inclination of the tangent on the  $D_{\text{SL}}$ -face.

**Fig. 5** Schematic cross section through a sessile liquid drop on a *rough* solid, both immersed in their common vapor. Now, the tangent on the extrapolated  $D_{\text{SL}}$ -face at a selected point of the TL is inclined according to the solid surface profile.  $\theta_e$  is defined as before

**Fig. 6** Schematic cross section through a sharp solid edge with the constant local  $\theta_e$  of a moving TL (liquid meniscus not shown)

Experimentally, it seems as if the contact angle varies substantially whenever the TL moves over a sharp edge. Figure 6 shows that this is just an optical illusion because the experimenter cannot resolve the local microscopic curvature of the edge. At a *very* sharp, angle on the solid, the contact angle may be considered to become indeterminate, an effect known as *canthotaxis*. However, this proposition assumes continuum mechanics, which clearly breaks down at this scale.

#### 4.4 Experimental Aspects of Static Wetting

In Sects. 2 and 3 the concept of interfacial tension and interfacial free energy was defined, and their importance in wetting was noted, without going into details.

For TLs with large radii of curvature ( $R_0 > 10^{-6}$  m), (28) can be approximated by

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV} \cdot \cos \theta_e \quad (29)$$

The thermodynamic contact angle is still a local excess property of the TL. Treating the  $\gamma_{LJ}$  as tensions (i.e., with dimensions of force/distance or mass/time<sup>2</sup> in some old literature!), as opposed to energies (i.e., dimensions of energy/area), in Fig. 1a balance of tensions at the triple line may be considered. This results directly in (29). This classic equation is usually referred to as *Young's* equation, although Thomas Young never, in fact, wrote the expression in his often-cited paper (Young 1805)! If it is preferred to treat the  $\gamma_{LJ}$  as interfacial free energies, and apply a simple argument of “virtual work,” the same relation is obtained. Having applied a force balance horizontally, this must be possible vertically, so what “resists”  $\gamma_{LV} \sin \theta_e$ ? Strictly, the action of tensions at the TL, specifically  $\gamma_{LV}$ , deforms the solid surface, but it is only under conditions in which the solid is very soft that the effect is noticeable. The slight “bump” on the solid in Fig. 4 has a height given approximately by  $\gamma_{LV} \cdot \sin \theta_e / G$ , where  $G$  represents the (elastic) shear modulus of the solid. Simple insertion of typical values shows that the effect becomes noticeable only for  $G < \approx 1$  MPa (Shanahan and de Gennes 1986).

As an example, aluminum has a value of  $G$  of ca. 25 GPa, and for water  $\gamma_{LV}$  is ca. 70 mN m<sup>-1</sup>. Taking  $\sin \theta_e$  as 1, it is found that the “wetting ridge” height is

ca.  $3 \cdot 10^{-12}$  m: well below atomic dimensions and thus meaningless in a continuum approach! In general, the effect perpendicular to the solid is negligible. However, the wetting ridge can be significant on soft solids and even modify wetting kinetics (Shanahan and Carré 1995).

In (29), it may be noted that each surface tension has two suffixes representing two of the three, S, L, and V, although the use of  $\gamma_{LV} = \gamma_L$  or  $\gamma_{SV} = \gamma_S$  often found in the literature. In the case of the solid,  $\gamma_{SV}$  changes a lot when it shares a common vapor phase with a liquid because the significant part of the surrounding vapor is due to the liquid. In the above thermodynamic treatment, allowance is already made for this effect. However, many workers prefer to adopt the alternative notion of equilibrium spreading pressure,  $\pi_e = \gamma_S - \gamma_{SV}$ , where  $\gamma_{SV}$  means the solid surface tension in presence of a liquid now.  $\pi_e$  is often considered negligible for low activity solids, such as polymers. (Figure 15 demonstrates that this assumption should be checked!)

The importance of (29) is that it may, in principle, allow one to estimate the surface tension of a solid,  $\gamma_{SV}$ , albeit indirectly, from knowledge of the surface tensions,  $\gamma_{LV}$ , of “probe” liquids and their contact angles on the solid surface in question. Knowledge of  $\gamma_{SL}$  is required too, and the problem is considered in Sect. 5 and chapter Thermodynamics of Adhesion.

Whereas liquid surface tension is readily measured (see below), that of a solid is inaccessible directly from experiment due to the intrinsic lack of molecular mobility. Firstly, liquid tension will be considered.

#### 4.4.1 Liquid Surface Tension

##### Maximum Bubble Pressure

If a tube of radius  $r$  is immersed vertically in a liquid to a depth  $h$ , the local pressure will be  $\rho gh$ , where  $\rho$  is liquid density (more precisely, the difference between liquid density and that of the local vapor environment, but the difference is generally negligible) and  $g$  is gravitational acceleration. When air is blown through the tube, it will cause bubbles to form at the immersed end of the tube. Laplace’s equation (17b) relating the excess pressure on the curved side of the meniscus,  $\Delta p$ , to the principal radii of curvature  $R_1$  and  $R_2$  (both equal to  $R$  for a spherical surface) is given by

$$\Delta p = \gamma_{LV} \left( \frac{1}{R_1} + \frac{1}{R_2} \right) = \frac{2\gamma_{LV}}{R} \quad (30)$$

The internal bubble pressure is therefore  $\Delta p + \rho gh$ . When the bubble first starts to grow, it will have a large value of  $R$ , which will then decrease until the bubble becomes a hemisphere. Thereafter, the radius grows again. Thus, when the bubble is a hemisphere, of radius  $r$ , the pressure is maximal. Thus maximal bubble pressure,  $p_{\max}$ , is given by

$$p_{\max} = \frac{2\gamma}{R} + \rho gh \quad (31)$$

**Fig. 7** Schematic representation of maximum bubble pressure method

If the air line is fitted to a pressure gauge, the value of  $p_{\max}$  may be measured and the value of liquid surface tension,  $\gamma_{LV}$ , then readily calculated (Fig. 7).

### Drop Weight

An appealingly simple, but rather inaccurate, method to obtain liquid surface tension values is that of letting a drop accumulate at the end of a circular orifice of radius  $R$ , mounted horizontally like a tap. When sufficiently large, the drop will drop. On weighing the fallen liquid, a pseudo-equilibrium may be drawn between drop weight at separation,  $mg$ , and the hitherto surface tension-based retaining force,  $2\pi R\gamma_{LV}$ . Since some liquid is generally left behind, and since it is not entirely clear that the correct surface tension term to be used is that given above, generally a correction factor,  $\phi$ , is invoked where typically  $1 < \phi < 2$ . Surface tension is then estimated from

$$\gamma_{LV} = \frac{mg\phi}{2\pi R} \quad (32)$$

There is also a method for estimating  $\gamma_{LV}$  from the shape of a hanging, or pendent, drop *before* it falls, invoking the conflicting effects of gravity and surface tension (Padday 1971; Hartland and Ramakrishnan 1975). However, the mathematical complexities put this beyond the scope of the present text. Briefly, Laplace's equation (17b), allowing for *changing* pressure with height within the drop (hydrostatic head), can be rewritten as a second-order differential equation. It is this which is solved when drop size is comparable to capillary length (see chapter Thermodynamics of Adhesion). The resulting drop profile forms as a "compromise" between gravity (flattening) and surface forces (minimizing surface area and therefore seeking sphericity) (Fig. 8).

### Capillary Rise

A thin, circular capillary tube, of internal radius,  $R$ , may be immersed in a liquid vertically, and the height of ascension of the liquid within,  $h$ , can be used to calculate the surface tension of the liquid, with the proviso that the solid of the tube inner is completely wet by the liquid (i.e., zero contact angle). This is generally assumed for

**Fig. 8** Schematic representation of drop weight method

**Fig. 9** Schematic representation of capillary rise method

organic liquids, at least, by using glass tubes which have recently undergone some aggressive internal cleaning treatment, such as that by sulfochromic acid or similar. The liquid rises in the tube in order to counteract Laplace's reduced pressure in the meniscus by hydrostatic pressure. For thin tubes, those of interest, having the greatest capillary rise, deviation of the meniscus shape from sphericity may be neglected, and the resulting expression for surface tension is

$$\gamma_{LV} = \frac{R\rho gh}{2} \quad (33)$$

where  $\rho$  is liquid density and  $g$ , as before, is gravitational acceleration (Fig. 9).

### Wilhelmy Plate

If a smooth, flat solid is immersed in a wetting liquid (i.e.,  $\theta_0 < 90^\circ$ ), such that its surface is perpendicular to the horizontal, liquid surface, a meniscus forms toward

**Fig. 10** Schematic representation of Wilhelmy plate

**Fig. 11** Schematic representation of du Noüy ring

the upper size, whose effective downward force, or “weight” is given by  $\gamma_{LV} \cdot \cos \theta_0$  per unit length measured along the triple line cf. Fig. 10. Provided a “high surface tension” solid is chosen, in general, a platinum plate that has been pre-roughened and pre-cleaned (e.g., by flaming in a Bunsen flame), the contact angle is zero and thus the “weight” per unit length is simply  $\gamma_{LV}$ . If the plate is thin and of length  $l$  (along the triple line), the upward meniscus force,  $F$ , is  $2l\gamma_{LV}$ , neglecting plate thickness. The method described wherein such a platinum blade is attached to a fine balance and meniscus weight evaluated, leading to  $\gamma_{LV} = F/2l$ , is known as the Wilhelmy plate technique. It is simple, but complications can however arise. If the plate is too thick, buoyancy must be allowed for acting on the submerged part of the plate (see [Fibers](#) below). In some cases, whether the blade is *immersed* or *emersed* from the liquid, it can give different results, due to wetting hysteresis (see below).

### Du Noüy Ring

This technique (Fig. 11) is a variation on the Wilhelmy plate, requiring a smaller quantity of expensive platinum! Notwithstanding, the platinum must be correctly formed into the shape of a circular ring of radius  $R$ . The ring is made from circular, platinum wire of sectional radius,  $\epsilon$ .

The primary part is thus a torus, although it is attached symmetrically to a small frame allowing it to be attached to an accurate balance. The principle is that when the ring is emersed from a liquid, a meniscus will form on both sides of the wire and all

459 around the ring. Neglecting difference in radius for inner and outer circles ( $R \gg \varepsilon$ ),  
460 it may be expected that the upward meniscus force will be given by  $F = 4\pi R\gamma_{LV}$  (see  
461 [Wilhelmy Plate](#)). However, spurious effects occur (interference across the ring  
462 diameter?) leading to the adoption of an empirical correction factor,  $\beta$ . Liquid  
463 surface tension is then given by

$$\gamma_{LV} = \frac{\beta F}{4\pi R}$$

(34)

464 where  $\beta$  is a function of  $R$  (and  $\varepsilon$ ). Table 1 gives a few examples of  $\beta$  as a function of  
465  $R$  and  $\varepsilon$ .

466 **4.4.2 Contact Angle**

467 Contact angle is the angle subtended, in the liquid, between the tangent to the liquid/  
468 vapor interface and the solid/liquid interface at the triple, or three-phase, line, in the  
469 plane perpendicular to this line. In Sect. 3, it was shown from thermodynamics that  
470 the contact angle at thermodynamic equilibrium,  $\theta_e$ , is a function of many quantities:  
471 the interfacial tensions of the three D-faces, line tension, the curvature of the triple  
472 line, and surface profile (cf. 28). For real solids in wetting experiments, the list of  
473 influences can be extended by surface heterogeneity in terms of locally varying  
474 interfacial tension, by adsorption layers, and by other “imperfections.” As a result,  
475 measured static contact angles *always* show some hysteresis  $\Delta\theta$ . The so-called static  
476 advancing contact angle  $\theta_{e,a}$  measured after the triple line has advanced onto a  
477 previously unwetted surface area is always larger than the so-called static receding  
478 angle,  $\theta_{e,r}$ , found after the triple line has receded onto a solid surface region that was  
479 previously in contact with the liquid

$$\Delta\theta = \theta_{e,a} - \theta_{e,r} > 0$$

(35)

480 Static contact angle hysteresis summarizes the difference in wetting of real  
481 surfaces and of ideally smooth homogeneous solids. The hysteresis can be even  
482 larger under dynamic measuring conditions. The static contact angle hysteresis does  
483 not depend on the experimental setup used for contact angle measurement provided  
484 the same solid and the same liquid are used and equilibrium is attained. As a  
485 consequence, the simplified equation (29) cannot be applied before the thermody-  
486 namic contact angle for the corresponding smooth solid has been deduced from  $\theta_{e,a}$   
487 and  $\theta_{e,r}$ . It should be mentioned that the contact angle hysteresis is not a consequence  
488 of (28) only. Moreover, gravity causes some kind of stick–slip behavior that depends

**Table 1** Two examples of  $\beta$  for different values of  $R$  and  $\varepsilon$  for the du Noüy ring

$R$ (cm)	$\varepsilon$ (cm)	$\beta$	t.1
1	0.02	0.93	t.2
1.85	0.03	0.88	t.3

on the slope of the roughness asperities when the three-phase boundary moves over the rough solid surface. It can be shown that static contact angle hysteresis depends upon this effect (e.g., Bartell and Shepard 1953a, b; Johnson and Dettre 1964; Busscher et al. 1984; Bischof et al. 1988).

Various propositions, such as

$$\cos \theta_{\text{meas}} = r \cdot \cos \theta_e; \quad r = \frac{A_{\text{true}}}{A_{\text{geom}}} \quad (36)$$

(Wenzel 1936)

$A_{\text{geom}}$  = macroscopic area of the solid surface, i.e., width by length

$A_{\text{true}}$  = microscopic area due to surface roughness within  $A_{\text{geom}}$ .

$$\theta_e = \theta_{e,a} \quad (37)$$

(Thiessen and Schoon 1940)

$$\theta_e = \frac{1}{2} (\theta_{e,a} + \theta_{e,r}) \quad (38)$$

(Adam and Elliott 1962)

have been proposed in the literature to tackle this problem. However, inspection of experimental data reveals that none of these formulae solves the problem totally and satisfactorily – cf. Fig. 12 as an example.

Instead, it is clear from experimental results that the functions  $\theta_{e,a}(\Delta\theta)$  and  $\theta_{e,r}(\Delta\theta)$  follow straight lines

$$\theta_{e,a} = \theta_e + a \cdot \Delta\theta \quad (39)$$

$$\theta_{e,r} = \theta_e - b \cdot \Delta\theta \quad (40)$$

As roughness is a major cause of  $\Delta\theta$  on homogeneous solids, the intersection of these lines with the ordinate is the value  $\theta_e$  being sought (Schulze et al. 1989). Hence, the equilibrium contact angle can, in principle, be determined from a suitable experiment.

In the following sections on experimental methods for contact angle measurement, we shall summarize  $\theta_{e,a}$  and  $\theta_{e,r}$  as  $\theta_0$ , for brevity. Of course, both advancing and receding angles must be measured for a complete appraisal.

## Goniometry

Contact angles may be assessed by various techniques, of which a few of the better ones will be mentioned. The simplest involves a plane optical projection of the three interfaces and the triple line. The tangent to the projection of the liquid/vapor interface at the triple line is estimated and the angles measured relative to the flat

**Fig. 12**  $\theta_{e,a}$  and  $\theta_{e,r}$  data measured with various liquids on homogeneous polymer surfaces after stepwise increases of roughness following grinding with abrasive cloth of increasing grade

projection of the possibly rough solid surface. There is equipment available on the market to do this, using in the simpler cases an eyepiece with two, independent goniometers, one to align with the projection of the solid surface and one to form the tangent to the projection of the liquid/vapor interface. It is relatively easy to set up an optical bench arrangement, either to observe the drop directly or to project its magnified image onto a screen, and then to draw the requisite tangents.

However, placing a tangent to a curve is always somewhat subjective. An alternative method is to use the following procedure. Firstly, when posing a drop on the flat, horizontal surface, ensure from the top that its contact area is circular. (This may be done with a transparent slide, onto which are printed circles of various diameters. By adjustment of drop-to-transparent distance, it is possible to find a position at which a circle should coincide with drop circumference.) Any deviation of the triple line from a circle is a clear proof that the solid surface is either rough or inhomogeneous. The surface tension,  $\gamma_{LV}$ , of the liquid (necessary anyway, to exploit (29)) and also its density,  $\rho$  are required. Large drops tend to flatten (“puddles”), whereas small drops stay as spherical caps (“dew drops”). The approximate contact radius,  $r \approx a$ , below which the drop is sufficiently close to sphericity, is given by the liquid’s capillary length:  $a = (\gamma_{LV}/\rho g)^{1/2}$  where  $g$  is gravitational acceleration. For water, for example,  $a$  is ca. 2.8 mm. Having checked circularity of the contact area and droplet size,  $\theta_0$  can be readily estimated from the simple formula for a spherical cap:

$$\tan\left(\frac{\theta_0}{2}\right) = \frac{h}{r} \quad (41)$$

where height,  $h$ , and radius are as shown in Fig. 1.

### “Puddle”

At the other extreme from “dew drops,” a “puddle” may form (see Fig. 13). If the drop radius,  $r$ , considerably exceeds  $a$ , gravity flattens the liquid bulk. If  $\gamma_{LV}$  is known, e.g., by one of the above methods, then the contact angle may be calculated from a measurement of drop height (in the flat part):

$$\cos\theta_0 = 1 - \frac{\rho g h^2}{2 \gamma_{LV}} \quad (42)$$

As for the pendent drop (above), there exists an intermediate size range between the “dew drop” and the “puddle” for which  $\gamma_{LV}$  may be estimated from drop shape (slightly deformed from sphericity), but its treatment is beyond the scope of this chapter (Padday 1971; Hartland and Ramakrishnan 1975). Modern equipment on the market comes with software that approximates the projection of the liquid meniscus to a solution of the corresponding differential equations.

### Capillary Rise and Wilhelmy Plate

The principle here is the same as discussed above, the only differences being that the liquid surface tension is assumed to be known and that the contact angle is nonzero. If the  $\theta_0$  are greater than zero, capillary rise in a tube is less marked, and may even become capillary *descent*, if  $\theta_0 > \pi/2$ . The liquid level in the tube is lower than the surrounding liquid bath. When the  $\theta_0$  are nonzero, (33) includes a term in  $\cos\theta_0$ , and, after rearrangement, the following expression is obtained:

$$\theta_0 = \cos^{-1} \frac{R \rho g h}{2 \gamma_{LV}} \quad (43)$$

In much the same way, the Wilhelmy plate technique may be used, where force,  $F$ , becomes  $2 l \gamma_{LV} \cos\theta_0$ . The disadvantage for both of these is that the solid of interest must be made into a suitable geometric form, which is not always convenient or even possible!

### Fibers

The special case of fibers will be given, since knowledge of their surface properties is essential in composite technology. In principle, the method for obtaining contact

**Fig. 13** Schematic representation of “puddle” of height  $h$  and contact angle  $\theta_0$

angle on a fiber is the same as for the Wilhelmy plate: A liquid meniscus forms round the fiber immersed in a liquid bath, and its weight, detected by a microbalance, can be used to obtain  $\theta_0$ . It is assumed, for simplicity, that the fiber is of circular section of radius  $r$ . With  $F_0$  being the force on the balance corresponding to the weight of the fiber before immersion, and  $F$  that measured with the fiber partially immersed, vertically, axis perpendicular to free liquid surface and to depth,  $l$ , an expression for the difference,  $\Delta F$ , is obtained given by

$$\Delta F = F - F_0 = 2 \pi r \gamma_{LV} \cos \theta_0 - \pi r^2 l \rho_L g \quad (44)$$

In this equation,  $\rho_L$  is liquid density (or more precisely, the difference between density of liquid and air), and thus the right-hand term is a buoyancy correction. Since the surface tension term scales with  $r$ , and the buoyancy term with  $r^2$ , clearly the correction becomes very small for thin fibers. (The same basic argument is used when employing a thin Wilhelmy plate, above.)

## 4.5 Free Energy Balance of Wetting

With the thermodynamic background (cf. Sects. 2 and 3) and with the experimental steps for getting  $\theta_{e,a}$ ,  $\theta_{e,r}$  and the thermodynamic contact angle for the smooth homogeneous solid,  $\theta_e$ , (Sect. 4), the picture can now be completed by discussing the excess Helmholtz free energy of wetting which is often called the Helmholtz free energy of adhesion. Wetting is indeed the adhesion of a liquid on a solid.

Figure 14 illustrates the situation before and after wetting at thermodynamic equilibrium. For simplicity, consider a solid with at least one smooth and flat part of its surface. In the initial state (superscript 1), the solid has a phase boundary with the common vapor only. Hence, there are two D-faces with the areas  $A_{SV}^1$ ,  $A_{LV}^1$  in the initial state. The solid is lowered until the flat part of its surface is just isothermally wetted at constant pressure by the flat liquid meniscus. This is the final state (superscript 2) with three D-faces (areas  $A_{SV}^2$ ,  $A_{LV}^2$ ,  $A_{SL}^2$  and one triple line. (Any immersion of the solid into the liquid would simply create new area of the D-faces.

**Fig. 14** Schematic representation of a solid in vapor (*left*) being led to contact a liquid surface (*right*).  $A_{LV}^1, A_{LV}^2$  denote the areas of the corresponding D-faces

Such motion only complicates the thermodynamic free energy balance without giving any additional insight.)

Note that the constitution of the system, i.e., the components, their number  $N$ , their concentrations, and chemical potentials  $\mu_i$  as well as pressure and temperature is the same in the initial and the final state. Hence, the state of the bulk phases does not change. Moreover, the interfacial tensions  $\gamma_{SV}$  and  $\gamma_{LV}$  and the  $2N$  values for the absolute adsorptions  $\Gamma_{i,SV}$ ,  $\Gamma_{i,LV}$  will not change either.

Now (26) is employed and the excess Helmholtz free energies of all five D-faces may be written

$$F_{SV}^1 = \gamma_{SV} A_{SV}^1 + \sum_i^N \mu_i \Gamma_{i,SV} A_{SV}^1 \quad (45a)$$

$$F_{LV}^1 = \gamma_{LV} A_{LV}^1 + \sum_i^N \mu_i \Gamma_{i,LV} A_{LV}^1 \quad (45b)$$

$$F_{SV}^2 = \gamma_{SV} A_{SV}^2 + \sum_i^N \mu_i \Gamma_{i,SV} A_{SV}^2 \quad (45c)$$

$$F_{LV}^2 = \gamma_{LV} A_{LV}^2 + \sum_i^N \mu_i \Gamma_{i,LV} A_{LV}^2 \quad (45d)$$

$$F_{SL}^2 = \gamma_{SL} A_{SL} + \sum_i^N \mu_i \Gamma_{i,SL} A_{SL} \quad (45e)$$

where  $\Gamma_{i,IJ}$  = absolute adsorption of component  $i$  on the D-face  $IJ$ .

A relationship between the areas of the D-faces exists

$$A_{SL} = A_{LV}^1 - A_{LV}^2 = A_{SV}^1 - A_{SV}^2 \quad (46)$$

Therefore, wetting is considered to be an isothermal, isochoric, and isobaric change of state, and the contribution from the triple line is neglected. As a result, the change of Helmholtz free energy of the whole system is given by the change of the excess Helmholtz free energy at the D-faces

$$F^2 - F^1 = F_{SV}^2 - F_{SV}^1 + F_{LV}^2 - F_{LV}^1 + F_{SL}^2 \equiv F^{\text{wett}} \quad (47)$$

That is the *excess Helmholtz free energy of wetting*. Inserting (Eqs. 45 and 46), the following equation is obtained

$$F^{\text{wett}} = -(\gamma_{SV} + \gamma_{LV} - \gamma_{SL}) A_{SL} - A_{SL} \cdot \sum_i^N \mu_i \cdot (\Gamma_{i,SV} + \Gamma_{i,LV} - \Gamma_{i,SL}) \quad (48)$$

and for the specific value (per unit area)

$$f^{\text{wett}} = \frac{F^{\text{wett}}}{A_{\text{SL}}} = -(\gamma_{\text{SV}} + \gamma_{\text{LV}} - \gamma_{\text{SL}}) - \sum_i^N \mu_i \cdot (\Gamma_{i,\text{SV}} + \Gamma_{i,\text{LV}} - \Gamma_{i,\text{SL}}) \quad (49)$$

which is usually called the *adhesion energy* for the liquid–solid contact.

The first term on the right-hand side corresponds to the so-called reversible specific or thermodynamic, work of adhesion (to within a sign change)

$$W^{\text{adh}} = \gamma_{\text{LV}} - \gamma_{\text{SL}} \quad \text{Dupre's rule} \quad (50)$$

as introduced by Dupré (1869). Note that Dupré formulated his rule on an empirical basis long before Gibbs developed the thermodynamics for interfaces in the form used here.

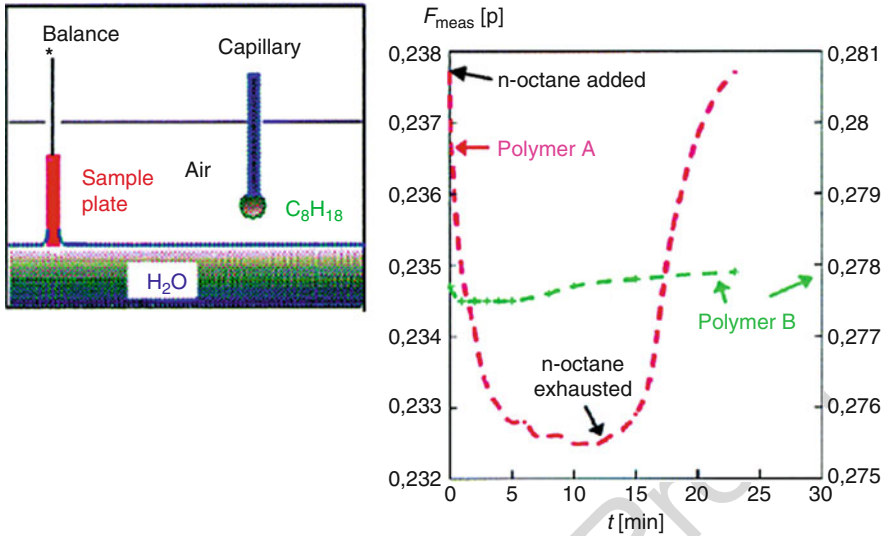

However, there is a second term that covers the energetic contribution from the composition of the three-phase boundaries (via the absolute adsorptions), and hence the specific Helmholtz free energy of wetting may not be reduced to a balance of the interfacial tensions involved.

A simple experimental test can be used to demonstrate that this is more than just a theoretical statement. Figure 15 depicts the change of the wetting equilibrium of polymer samples at a Wilhelmy balance (cf. Fig. 10) owing to a slight compositional change of the common vapor phase. The sample plate at the fine balance consists of either polymer A or polymer B, the test liquid is water, and there is the common gas phase in the compartment (Fig. 15, left scheme). At the starting point  $t = 0$  min (Fig. 15, plot on the right), the plate just touches the water surface for wetting. The capillary in the setup is still empty so that the common gas phase consists of air and water vapor only. For that equilibrium, the wetting causes a certain force change  $F_{\text{meas}}(t = 0)$  as compared to the dry polymer sample A or B. As the next step ( $t > 0$ ), only the vapor phase is contaminated by a small amount of n-octane evaporating from a pendent drop hanging from the glass capillary now (cf. Fig. 15, left). n-Octane is “immiscible” with water. (N.B. According to thermodynamics, all substances mix, at least to some extent. Hence, the word “immiscible” corresponds to common usage.) As a saturated hydrocarbon, n-octane forms only weak physical interactions with water and the polymers. Nevertheless, the wetting force  $F_{\text{meas}}(t)$  at the Wilhelmy balance changes immediately and significantly whenever a small amount of n-octane vapor is added and then removed! This is due to a change of the wetting equilibrium which in turn is determined by the three D-faces LV, SV, and SL. In fact, this is the type of experiment that may be used to introduce the convenient “spreading pressure,” representing reduction in surface tension due to adsorption, as mentioned earlier.

For wetting, the extra force acting on the Wilhelmy balance is

$$F - F_0 = L \cdot (\gamma_{\text{SV}} - \gamma_{\text{SL}}) - \text{buoyancy of the sample} \quad (51)$$

**Fig. 15** Sketch (*left*) for the Wilhelmy balance with sample plate and a capillary for n-octane evaporation into the common gas phase (air) above the wetting liquid (water).  $F_{\text{meas}}$  = load change in gram force  $p$  as measured at the balance. For two polymers A and B (different types of cellulose), the right-hand graph shows the quick response of the wetting equilibrium when a little amount of octane is evaporated into the gas phase at  $t > 0$  min and when the atmosphere is replaced by fresh air after some time (return of  $F_{\text{meas}}$  to the initial value)

$F_0$  = force due to the weight of the dry polymer sample before wetting

$L$  = length of the TL on the wetted polymer sample.

The sample immersion depth does not change when n-octane is added to the composition of the vapor phase, and hence the measured change of force is

$$\Delta F = L \cdot (\Delta\gamma_{\text{SV}} - \Delta\gamma_{\text{SL}}) = L \cdot [\Delta\gamma_{\text{LV}} \cdot \cos\theta_0 + \gamma_{\text{LV}} \cdot \Delta(\cos\theta_0)] \quad (52)$$

Since  $\Delta\gamma_{\text{SL}} > 0$ , according to (26), the change of the wetting equilibrium is accompanied by a change of the specific excess Helmholtz free energy of each D-face:

$$\Delta f_{\text{D}}^{\text{D}} = \Delta\gamma_{\text{D}}^{\text{D}} + \sum_i \left( \Delta\mu_i \cdot \Gamma_{i,\text{D}}^{\text{D}} + \mu_i \cdot \Delta\Gamma_{i,\text{D}}^{\text{D}} \right) \quad (53)$$

Therefore, the addition of n-octane to the vapor phase not only changes the interfacial tensions *but* also the chemical potential (via the compositional change) and the absolute adsorptions (mainly for the LV and SV interfaces).

As the consequence, an error results from utilizing Dupré's rule (50) instead of the full expression (49) for the specific Helmholtz free energy of wetting. The magnitude of the error cannot be deduced from wetting experiments since they do not provide information on adsorption at the D-faces in the system.

## 4.6 Concluding Remarks

It may be seen from the preceding sections that a variety of methods are available to obtain both liquid surface tensions and static contact angles. Some are cheap, or easily constructed, others less so. They all have their various merits, depending on the (geometric) presentation of the solid to be characterized. They also have their respective disadvantages, e.g., the sessile drop technique is simple, but care must be exercised in assuring correct drop size range and circularity of the triple line; the maximum bubble pressure is precise and capable of measurement of transient surface tensions but generally requires relatively advanced apparatus.

All techniques for contact angle measurement are prone to static wetting hysteresis effects. Wetting hysteresis has its origins in surface roughness, microheterogeneities, and other “imperfections” and can be of the order of 10 s of degrees. It is rarely less than  $2^\circ$  or  $3^\circ$ , so the commonly seen habit of specifying contact angles to one, sometimes two, decimal places is pointless. This leaves another question: If static advancing and receding contact angles are measured, what is the equilibrium value  $\theta_e$  on a flat smooth homogeneous surface? It is  $\theta_e$  that is needed for Young’s equation. The experimental procedure described in the context of (39 and 40) provides the answer.

Bearing in mind the limitations and approximations made for Dupré’s rule (50) and Young’s equation (29), finally consider the common treatment of contact angle data which makes use of the combination of the two equations:

$$W^{\text{adh}} = \gamma_{\text{LV}}(1 + \cos \theta_e) \approx -f^{\text{wett}} \quad (54)$$

This is the *estimated* specific wetting energy, provided that the surface tension  $\gamma_{\text{LV}}$  of the wetting liquid is measured using one of the techniques mentioned and that equilibrium contact angle for the flat surface  $\theta_e$  is derived correctly from the contact angle hysteresis. Nevertheless, it is unclear whether it is justified to neglect the adsorption terms in the energy balance.

Additional conditions needed for such interpretation of wetting data are as follows:

Pure liquids that neither swell nor dissolve the solid must be used.

Solids should be “ideal” (flat, homogeneous, etc.).

Small curvature of the triple line must be ensured.

Interfacial tension is an excess property of the phase boundary of *two* phases and responds remarkably to minute changes of the composition!

The use of literature data for  $\gamma_{\text{LV}}$  of liquids should be avoided. Conditions of use can vary.

Finally, there is another price to be paid for using (54): The interfacial tensions  $\gamma_{\text{SL}}$  and  $\gamma_{\text{SV}}$  of the solid have been eliminated, and hence, they cannot be deduced from wetting experiments. This obstacle was the reason for the development of so-called thermodynamic adhesion theories which introduce various proposals for a

relationship between the liquid–solid interfacial tension  $\gamma_{SL}$  and the surface tensions  $\gamma_{LV}$  and  $\gamma_{SV}$ . These theories are considered in chapter Thermodynamics of Adhesion.

## Abstract

A short overview of relevant processes and parameters in spreading of liquids on substrates is presented. In a simplified view, the dynamics of these processes can be understood as being controlled by the balance of driving forces and resistance due to dissipative processes. Analogies between spreading and dewetting are discussed.

## 5.1 Introduction

Spreading of a liquid on a substrate represents an elementary step in many processes like adhesion, coating, or painting. Spreading is the dynamic route of covering a substrate with a liquid up to the point when an equilibrium state is reached (Dussan 1979; de Gennes 1985; Cazabat 1987; Good 1992; Leger and Joanny 1992; Blake 2006; De Coninck and Blake 2008; Bonn et al. 2009; Marmur 2009). Many practical

**Fig. 1** Schematic side-view representation of spreading of a drop toward a thin film (*left*) and dewetting of an unstable thin film via nucleation and growth of a dry patch surrounded by a rim (cross-sectional view) collecting the removed liquid

applications require the knowledge of how fast a liquid droplet, once deposited on a substrate, can spread out and cover a given area of the substrate.

Because the complementary process to spreading, that is, the retraction or dewetting of a liquid from a substrate (see Fig. 1), is determined by the same intermolecular forces and the corresponding dissipation routes, both processes can be treated in analogous ways (de Gennes 1985; Brochard-Wyart and de Gennes 1992).

Of course, the properties of the substrate represent equally relevant parameters as can be demonstrated by modifying the surface chemistry by standard chemical means (e.g., silanization, plasma treatment) (Israelachvili 1995). The process of liquid spreading is determined by short-ranged surface forces mainly controlled by surface chemistry but also by forces acting over longer distances up to some tens of nanometers (long-ranged forces). Moreover, chemical and physical heterogeneities are responsible for hysteretic behavior (Dussan 1979), which can significantly affect spreading and dewetting up to the point of prohibiting it. Generally, all spreading phenomena are governed by the interplay of surface and interfacial interactions, in particular in the region where the liquid meets the yet uncovered solid, the region of the three-phase contact line (de Gennes 1985).

## 5.2 Equilibrium Conditions

As stated already in 1805 by Thomas Young (1805), at thermodynamic equilibrium (no temperature gradients, concentration gradients, i.e., no net forces acting) the three surfaces that meet at the three-phase contact line define an equilibrium contact angle ( $\theta_{eq}$ ). Using a vector description for the forces (per unit length of the contact line), which are balanced at their contact, it can be seen that the surface tension ( $\gamma_{SV}$ ) between substrate and the surrounding medium (which is often the vapor of the liquid in question) has to be equal to the interfacial tension ( $\gamma_{SL}$ ) between substrate and liquid plus the projection of the interfacial tension ( $\gamma_{LV}$ ) between liquid and the surrounding medium onto the  $\gamma_{SL}$ -vector, resulting in the Young-equation:

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV} \cos \theta_{eq} \quad (1)$$

**Fig. 2** Schematic representation of the balance of interfacial forces (represented by the arrows for  $\gamma_{SV}$ ,  $\gamma_{LV}$ , and  $\gamma_{SL}$ , which meet at the contact line (indicated by a small circle)). This force balance determines the equilibrium contact angle  $\theta_{eq}$

Using Young's Eq. 1 and knowing  $\gamma_{SV}$  and  $\gamma_{LV}$ ,  $\gamma_{SL}$  may be obtained by measuring the contact angle  $\theta_{eq}$  (see Fig. 2) (Zisman 1964).

It should be noted that the equilibrium contact angle is a direct consequence of the balance of molecular interactions among the three materials at the contact line. At equilibrium, the contact line will not be set in motion and a drop will never spread. On the contrary, spreading occurs for a closed nonequibrated system that tries to reach equilibrium. Alternatively, a liquid may be forced to spread under the influence of an external force.

From a mechanical point of view, the balance of forces within the plane of the substrate neglects the force component  $\gamma_{LV} \sin \theta_{eq}$  in the direction normal to the substrate. Usually one assumes that the substrate is completely rigid and not deformable. Thus, this vertical force component is balanced by a reaction force of the solid, which is equal to  $-\gamma_{LV} \sin \theta_{eq}$ . Furthermore, it is assumed that the solid is not generating a force component parallel to the surface when getting in contact with a liquid. In such a situation, the forces acting at the contact line could be balanced by any value of the contact angle (Dussan 1979). On liquid or deformable (e.g., thin membranes or elastomers) substrates, however, this normal force component leads to a vertical displacement of the contact line, that is, the formation of a wetting ridge (Shanahan and Carré 1995; Carré et al. 1996). The Neumann triangle construction can account for this case (Chen et al. 1996).

### 5.3 The Spreading Coefficient

Based on these three interfacial tensions, a spreading coefficient  $S_{eq}$  may be defined, which characterizes the tendency of a liquid to spread out (or not) on a substrate:

$$S_{eq} = \gamma_{SV} - (\gamma_{SL} + \gamma_{LV}) \quad (2)$$

Using Eq. 1, this relation may be rewritten as:

$$S_{eq} = \gamma_{LV} (\cos \theta_{eq} - 1) \quad (3)$$

As pointed out by de Gennes (1985), in equilibrium,  $\gamma_{SV}$  can never be larger than  $\gamma_{SL} + \gamma_{LV}$ . If it were, the total free energy of the system could be lowered by removing the solid–vapor interface, that is, by coating the substrate with a (thick) layer of liquid. Then only a solid–liquid and a liquid–vapor interface would remain, that is, the solid is wetted (coated) by the liquid. In other words, the “true” equilibrium value of  $\gamma_{SV}$  is identical to  $\gamma_{SL} + \gamma_{LV}$ . However, if the solid to be coated is initially not in equilibrium with the surrounding vapor, the initial spreading coefficient  $S_{in}$  may be larger than zero.

In particular for nonvolatile liquids (these cannot reach equilibrium by evaporation and condensation but only by diffusion on the surface of the substrate)  $S_{in}$  can be defined by referring to the interfacial tension  $S_{SO}$  between the dry substrate and vacuum.

$$S_{in} = S_{SO} - (\gamma_{SL} + \gamma_{LV}) \quad (4)$$

In equilibrium, some molecules from the liquid will be adsorbed on the substrate, lowering  $\gamma_{SO}$  to  $\gamma_{SV}$ . Consequently,  $S_{in}$  is larger than  $S_{eq}$  and accordingly, after depositing a drop of liquid onto a dry substrate, flow will start (the drop spreads) until the equilibrium value of the contact angle is reached.  $\theta_{eq}$  may well be zero representing the situation where the liquid will cover the substrate by a film of homogenous thickness.)

## 5.4 The Flow Profile and Energy Dissipation

In spreading, the whole liquid wedge close to the contact line moves with the velocity  $U$  of the contact line. A standard boundary condition for liquid flow on solid substrates is typically the no-slip at the substrate. Liquid molecules at a solid substrate experience (significant) interactions responsible for adhesion. Thus, in contrast to liquid molecules in contact with other liquid molecules, they are not moving easily on this substrate. As a consequence, the velocity of these molecules is approximated by zero velocity (= no-slip boundary condition). However, applying this boundary condition strictly would not allow for any displacement of a liquid on a solid substrate. Thus, to account for the experimental fact that contact lines can and do move, various assumptions, partially based on molecular mechanisms, have been proposed (see, e.g., Bonn et al. 2009). In general, a cutoff length, typically as small as the size of the molecules, has to be introduced (de Gennes 1985; Huh and Scriven 1971).

For small contact angles (allowing to approximate  $\sin\theta_{eq} \approx \theta_{eq}$  [in radians]), the flow pattern close to the contact line (the wedge region) can be approximated by the so-called lubrication approximation, which compares the flow in the wedge with flow in a thin film: the velocity of fluid molecules is only determined by their distance  $z$  to the substrate, that is, the molecules move preferentially in the  $x$ -direction parallel to the substrate and less in the direction away from the substrate.

Thus, at any point  $x$  from the contact line the velocity  $v(z)$  is only a function of  $z$  [ $v_x(z) = v(z)$ ; see Fig. 3].

As interactions between liquid molecules, and thus their viscosity  $\eta$ , are assumed to be independent of the distance  $z$  to the substrate also the relative velocity difference between molecules should be constant. Thus, in a film of local thickness  $h(x)$  that moves at the mean velocity  $U$  of the contact line, a decrease in velocity is found when going from the film surface toward the substrate with a velocity gradient  $dv(z)/dz$  inside the film. Thus,  $U$  is the average along the normal to the surface, that is, the  $z$ -direction, of this velocity profile

$$U = h^{-1} \int_0^h dz \, v(z) \quad (5)$$

Accordingly, a parabolic velocity profile is obtained (de Gennes 1985) (with the boundary conditions that the velocity vanishes at the solid side and the derivative of the velocity at the liquid/gas interface is zero, that is, there is no tangential stress):

$$v(z) = \frac{3U}{2h^2(x)} (-z^2 + 2h(x)z) \quad (6)$$

and the rate of viscous dissipation (within one slice of the film) due to viscous friction of the liquid molecules that are moving past each other, integrated over the film depth  $h(x)$ :

$$\int_0^{h(x)} dz \, \eta \left[ \frac{dv_x(z)}{dz} \right]^2 = \frac{3\eta U^2}{h(x)} \quad (7)$$

Integration now over the whole moving object, from its lowest thickness at the contact line having a minimum thickness of  $h_{\min}(x)$  to its thickest part with the maximum thickness of  $h_{\max}(x)$ , using the approximation  $h(x) \approx x \cdot \theta_{\text{dyn}}$  (with  $\theta_{\text{dyn}}$

**Fig. 3** Schematic representation of the velocity profile of liquid flow within a thin film (lubrication approximation). For the no-slip boundary condition (broken line) the velocity at the substrate ( $z = 0$ ) is zero. In the case of slippage (full line), the liquid velocity is not zero at the substrate surface and only extrapolates to zero at a distance  $b$  ( $=$  slippage length) within the substrate

being the dynamic contact angle at the contact line) yields the total viscous dissipation per unit time and unit length of the contact line during spreading (Bonn et al. 2009):

$$D_{\text{diss}} \cong \int_{h_{\min}}^{h_{\max}} \frac{3\eta U^2}{h(x)} dx = \frac{3\eta U^2}{\theta_{\text{dyn}}} \ln \frac{h_{\max}}{h_{\min}} \quad (8)$$

Clearly, if  $h_{\min}$  would be zero the dissipated energy would be infinite. However, such a value is not physical because the smallest lengthscale in the problem is related to the moving molecules. Thus, it is plausible to set the lower cutoff length proportional to the size of the molecules.

Basically, the same procedure can be applied to the case where the liquid is slipping on the substrate by introducing an extrapolation length (slippage length)  $b$  within the substrate (see Fig. 3) where the flow velocity would be zero, that is, the nonslip boundary would be reached at a virtual interface inside the solid. Thus, one expects  $h_{\min} \sim b$  (de Gennes 1985). Slippage is particularly relevant in the case of entangled polymer melts spreading or dewetting on a smooth surface (de Gennes 1985; Reiter and Khanna 2000a, b). A large number of experimental studies on slippage have been recently reviewed (Neto et al. 2005).

## 5.5 The Dynamic Contact Angle

While a well-defined equilibrium situation allows a clear characterization of  $\theta_{\text{eq}}$ , the displacement of the contact line (which evidently implies a velocity of displacement) requires a deviation from this value, resulting in a dynamic contact angle  $\theta_{\text{dyn}}$  (see Fig. 4). In fact, whenever on ideal surfaces the contact angle deviates from  $\theta_{\text{eq}}$  (which represents the absolute minimum in free energy of the system) the contact line will show the tendency to move in order to try to reestablish equilibrium. In

**Fig. 4** Schematic representation of the difference between the equilibrium contact angle  $\theta_{\text{eq}}$  and the dynamic contact angle ( $\theta_{\text{dyn}}$ ). In equilibrium, the force vectors for  $\gamma_{\text{SV}}$ ,  $\gamma_{\text{LV}}$  and  $\gamma_{\text{SL}}$  add up to zero within the plane of the substrate. However, in the case of an advancing (left) or retracting (right) liquid front a net force remains, indicated by the big (red) arrows on top

general, the stronger  $\theta_{\text{dyn}}$  deviates from  $\theta_{\text{eq}}$ , the faster will be the movement of the contact line (see Fig. 5). Thus, for  $\theta_{\text{dyn}} \neq \theta_{\text{eq}}$ , instead of a perfect balance of interfacial tensions at equilibrium, a net force  $F$  (per unit length of the contact line) remains:

$$F = -\gamma_{\text{SV}} + \gamma_{\text{SL}} + \gamma_{\text{LV}} \cos \theta_{\text{dyn}} \quad (9)$$

Using Eq. 1,  $(-\gamma_{\text{SV}} + \gamma_{\text{SL}})$  can be replaced by  $(-\gamma_{\text{LV}} \cos \theta_{\text{eq}})$  and finally the so-called unbalanced Young force is obtained (Brochard-Wyart and de Gennes 1992)

$$F = \gamma_{\text{LV}} (\cos \theta_{\text{dyn}} - \cos \theta_{\text{eq}}) \quad (10)$$

For small contact angles the cos-term can be approximated by the first term of its series expansion, that is,  $\cos \theta \sim 1 - \frac{1}{2}\theta^2$ . This leads then to

$$F = \frac{1}{2}\gamma_{\text{LV}} (\theta_{\text{eq}}^2 - \theta_{\text{dyn}}^2) \quad (11)$$

If the viscous forces are significantly smaller than the surface tension (as expressed by a capillary number  $Ca$  much less than 1:  $Ca = U \cdot \eta / \gamma_{\text{LV}}$ , with  $U$  being the velocity of the contact line and  $\eta$  the viscosity of the liquid), the shape of

**Fig. 5** Qualitative representation of the variation of the contact angle as a function of the contact line velocity (a negative velocity represents retraction, a positive velocity represents spreading). On heterogeneous substrates, a difference between the values of the contact angle at zero velocity will be observed, depending on how zero velocity is approached, in the advancing ( $\theta_{\text{advancing}}$ ) or receding ( $\theta_{\text{receding}}$ ) direction. Contact angle hysteresis is defined as:  $\Delta\theta = \theta_{\text{advancing}} - \theta_{\text{receding}}$ . In some cases, for example, when heterogeneity is caused by substrate roughness, the equilibrium contact angle may be approximated by  $\theta_{\text{eq}} = \frac{1}{2}(\theta_{\text{advancing}} + \theta_{\text{receding}})$ . However, this last relation is not generally applicable

the drop can be reasonably well approximated by a spherical cap. Laplace pressure  $P_L(P_L = 2\gamma_{LV} \cdot C$ , for a spherical cap of radius  $R$  the curvature  $C = 1/R$  and thus  $P_L = 2\gamma_{LV}/R$ ) will be able to assure the same curvature everywhere, except for the region very close to the contact line, where long-range molecular interactions, for example, van der Waals forces, become important. At a macroscopic level, a spreading drop, for example, on a wettable substrate, can be well described by an apparent contact angle  $\theta_{ap} = 4V/\pi R^3$  (valid for small values of this contact angle): as the drop spreads, the apparent contact angle decreases as  $1/R^3$ .

## 5.6 The Rate of Spreading

The speed of spreading is determined by the balance of driving forces (corresponding to surface energy, represented by the contact angle, and, for big drops, gravity) and velocity-dependent dissipative forces. In many cases, the major contribution to dissipation originates from the velocity gradient experienced by the liquid molecules moving in the wedge region close to the contact line. The diverging increase of dissipation as the contact line is approached (see Eq. 8) represents the most important mathematical problem in the context of moving a three-phase contact line, as first pointed out by Huh and Scriven (1971).

For the complete wetting case ( $S \geq 0$ ), a thin film of dynamical origin (off-equilibrium) forms ahead of the apparent contact line of the drop. The formation of a precursor film avoids that viscous dissipation diverges near the (geometrically apparent) contact line. Thus, macroscopic spreading of a droplet of a nonvolatile liquid (with surface tension  $\gamma_{LV}$ ), which wets the substrate, proceeds via the formation of such a thin precursor film ahead of the “visible” (apparent) contact line (Checco 2009). The thickness of this precursor film is truncated at a value given by:

$$h_0 = a\sqrt{2\gamma_{LV}/2S_{in}} \quad (12)$$

with the molecular length scale  $a = \sqrt{2A/\gamma_{LV}}$  (where  $A$  is the Hamaker constant for the liquid on the substrate).  $h_0$  is usually larger than the molecular size  $a$ , because typically  $\gamma \gg S_{in}$ . In the equilibrium situation (after spreading being completed),  $h_0$  represents the final thickness of the so-called final pancake, that is, the resulting wetting film, which can be easily derived from the free energy  $\mathcal{F}$  of an initial droplet of volume  $\Omega$  (Brochard-Wyart et al. 1991):

$\mathcal{F} = \mathcal{F}_0 - A \cdot S_{in} + P(h) \cdot A$  with the constraint that  $\Omega = A \cdot h$ .  $\mathcal{F}_0$  is the free energy of the system without droplet,  $A$  is the area covered by the droplet,  $S_{in}$  is the initial spreading coefficient, and  $P(h)$  is the contribution to the free energy that arises as the thickness is less than infinity. Thus, the limiting values of  $P(h)$  are:  $P(h \rightarrow \infty) = 0$  and  $P(h \rightarrow 0) = S_{in} = \gamma_{SO} - \gamma_{SL} - \gamma_{LV}$ . For cases where van der Waals forces dominate the long-range interaction,  $P(h) = A/12\pi h^2$  is obtained. Minimization of  $\mathcal{F}$  with respect to  $h$  leads to Eq. 12 ( $h_0 = \sqrt{A/4\pi S_{in}} = a\sqrt{3\gamma_{LV}/2S_{in}}$ ).

A typical spreading experiment starts by depositing at time  $t = 0$  a spherical liquid droplet of volume  $V$ , characterized by the base radius  $R_0$ , onto an ideal, planar, and horizontal substrate, either solid or liquid. Suppose that the liquid is nonvolatile and that the initial shape of the now sessile droplet is part of a sphere with a macroscopic contact angle  $\theta_0$  (for simplicity, the case of  $\theta_0 \leq \pi/2$  is assumed). This droplet is surrounded by a nonreactive and nonmiscible fluid phase (either gas or liquid). When  $S \geq 0$ , the droplet spreads spontaneously and tends to separate solid and surrounding fluid phase. For a finite volume of the initial droplet, spreading continues only until the liquid layer, covering the solid surface reaches a mesoscopic or microscopic thickness controlled by the disjoining pressure (originating from long-range forces like van der Waals forces), which in most cases tends to thicken this layer, and which effectively competes with the capillary forces. Thus, the final thickness of the extended liquid structure is determined by the interplay between the spreading power and the liquid/gas interfacial tension (see Eq. 12).

For negative values of the spreading coefficient ( $S < 0$ ), the liquid droplet only partially wets the solid. If the liquid was forced to cover the substrate, it will retract (dewet) from it until one or many (macroscopic) liquid droplets with the equilibrium shape of a spherical cap have formed. If the liquid is deposited as a spherical droplet, it will spread out until it reaches its equilibrium shape, characterized by  $\theta_{eq}$ .

In describing spreading and the local molecular processes directly at the contact line, two different types of descriptions of sessile droplet spreading exist: hydrodynamic and molecular kinetic, which differ from each other mostly in the consideration of the dominant dissipation channel (de Gennes et al. 1990; Cazabat et al. 1997; Blake 2006).

In the molecular kinetic theory of Eyring, adapted to describe the kinetics of wetting phenomena (Blake and Haynes 1969; Blake 2006; de Coninck and Blake 2008), the focus is put on the dissipative processes occurring in the vicinity of advancing contact line, mainly due to the attachment/detachment processes of molecules from the liquid onto the solid. This approach yields for the dynamics of the base radius  $[R(t)]$  and contact angle  $[\theta_{dyn}(t)]$ ,  $R(t) \sim t^{1/7}$  and  $\theta_{dyn}(t) \sim t^{-3/7}$ , respectively.

When dissipation is due to viscous flows generated in the core of the spreading droplet, a relation (see Eq. 8) between spreading velocity  $U$ , viscosity  $\eta$ , surface tension  $\gamma_{LV}$  of the liquid (all represented by the capillary number  $Ca = U \cdot \eta / \gamma_{LV}$ ), and the value of the contact angle  $\theta_{dyn}(t)$  as a function of spreading time  $t$  can be formulated. This relation yields simple scaling laws determining the time evolution of the contact angle and of the droplet's base radius  $R(t)$ . For the case of spreading of circular droplets, one finds  $R(t) \sim t^{1/10}$  and  $\theta(t) \sim t^{-3/10}$ . These scaling laws have been examined experimentally and shown to agree fairly well with experimental data for many liquid/solid systems (Tanner 1979; de Gennes 1985; Cazabat and Cohen Stuart 1986; Brochard-Wyart et al. 1991; Marmur 1997).

De Gennes (1985) suggested that during the spreading process, the energy resulting from the unbalanced Young force is balanced by the total energy dissipation in the core of the droplet, at the advancing contact line and in a precursor film. Balancing the corresponding capillary driving force (given by Eq. 11) with the viscous force acting at the contact line (related to Eq. 8:  $D_{diss} = F_{visc} \cdot U$

(de Gennes 1985) with the viscous force  $F_{\text{visc}}$  being proportional to viscosity  $\eta$  and the velocity  $U$  at which the liquid moves) leads then to:

$$\frac{1}{2}\gamma_{LV}(\theta_{\text{dyn}}^2 - \theta_{\text{eq}}^2) = -(\eta \cdot U / \theta_{\text{dyn}}) \ln \frac{h_{\text{max}}}{h_{\text{min}}} \quad (13)$$

## 5.7 Dewetting

When a liquid is forced to cover a substrate, which it does not like to wet, the film is either metastable or completely unstable (de Gennes 1985; Brochard-Wyart and de Gennes 1992; Leger and Joanny 1992). Initiated by a defect or some other perturbation, a hole may be nucleated and grow in diameter. The liquid removed from the dry circular spot (the hole in the liquid film) is collected in a liquid ridge (the “rim”) (see Fig. 1). The shape of this rim may be described approximately as a portion of a cylinder that is characterized by two contact angles  $\theta_{\text{dyn}}$  and  $\phi$  (see Fig. 6).

In analogy to the complete wetting (see Eq. 13), for the movement of the contact line (position F) in the partial wetting case (with dewetting velocity  $V$ ), the following relation may be obtained:

$$\gamma_{LV}(\theta_{\text{dyn}}^2 - \theta_{\text{eq}}^2)\theta_{\text{dyn}} = -L_F \cdot \eta V \quad (14)$$

Here,  $L_F$  is an abbreviation for  $\ln \frac{h_{\text{max}}}{h_{\text{min}}}$  evaluated at the position F.

For hole diameters much larger than the width of the rim, both ends of the rim (denoted by F and R in Fig. 6) move at approximately the same velocity. Moreover, at the position R the equilibrium value of the contact angle is zero (rim in contact with the film of the same liquid) and thus yields:

$$\gamma_{LV}\phi^3 = -L_R \cdot \eta V \quad (15)$$

Here,  $L_R$  is an abbreviation for  $\ln \frac{h_{\text{max}}}{h_{\text{min}}}$  evaluated at the position R.

For large rims, small values of  $Ca = U\eta/\gamma$  and assuming that Laplace pressure is the same everywhere within the rim (i.e., the same curvature is assumed to exist everywhere in the rim) requires that  $\phi \cong \theta_{\text{dyn}}$ . As can be seen from Eqs. 8 and 13, the values of  $L_F$  and  $L_R$  are representing the logarithmic factor  $\ln \frac{h_{\text{max}}}{h_{\text{min}}}$ . While the

**Fig. 6** Schematic representation of the rim forming in the course of dewetting of a thin liquid film. At the front position F of the rim, the contact angle assumes its dynamic value  $\theta_{\text{dyn}}$  and at the rear position R it takes the value  $\phi$ . The width of the rim is given by  $w$

maximum size is represented by width of the rim and is the same for both values, the minimum length scale is different for the positions F (proportional to the size of the molecules) and R (proportional to the thickness of the film). Thus, for very thin films in the nanometer range, this difference between of  $L_F$  and  $L_R$  is small as the width of the rim is typically much larger than the film thickness or the size of the molecules. Consequently, a highly useful relation is obtained between dynamic and equilibrium contact angle for the case of viscous dewetting:

$$\gamma_{LV}(\theta_{\text{dyn}}^2 - \theta_{\text{eq}}^2)\theta_{\text{dyn}} = \gamma_{LV}\phi^3 \quad (16)$$

$$\phi \cong \theta_{\text{dyn}} \quad (17)$$

$$\theta_{\text{dyn}} = \theta_{\text{eq}}/\sqrt{2} \quad (18)$$

and a constant dewetting velocity of

$$V \sim \frac{\gamma_{LV}}{\eta} \cdot \theta_{\text{eq}}^3 \quad (19)$$

or with  $V^* = \gamma_{LV}/\gamma$

$$V \sim V^* \cdot \theta_{\text{eq}}^3 \quad (20)$$

It should be noted that a constant dewetting velocity, as predicted by Eq. 20, will only be observed as long as the assumption of nonslip boundary conditions applies, that is, main dissipation in the liquid wedge close to the contact line that is independent of the actual size of the rim. However, in the case of slippage as it occurs for polymer melts on “ideal” substrates (Reiter and Khanna 2000a, b), dissipation occurs over the whole moving interface that is proportional to the width of the moving rim. Thus, as the size of the rim increases in time, dissipation increases also. The driving capillary force, however, is constant and consequently the dewetting velocity is decreasing in time.

## 5.8 Concluding Remarks

The above presented concepts of liquid spreading and dewetting apply only in situations where the substrates are “perfect,” that is, chemically homogeneous and physically smooth. For example, on rough substrates spreading (Cazabat and Cohen Stuart 1986; Rolley et al. 1998) and dewetting (Zhang et al. 2005) dynamics will be modified. Moreover, in contrast to spreading of pure and simple fluids, the process can also be quite different for mixtures or solutions. For example, polymer solutions (Fondecave and Brochard-Wyart 1998) or surfactant solutions (Troian et al. 1990; Nikolov et al. 2002) can exhibit quite complex spreading behavior. Spreading will

become even more complex when a chemical reaction between liquid and substrate is involved like in reactive spreading (Eustathopoulos 1998).

In addition to spreading and dewetting driven by capillary forces, these processes may be “forced” by applying an external electric field like in “electrowetting” (Vallet et al. 1999; Verheijen and Prins (1999), Mugele and Baret 2005) or a mechanical force by inclining or moving the substrates. The latter process is highly relevant in coating technologies, for example, in the paper industry.

As a general summary, the dynamics of spreading and dewetting is controlled by the balance of driving forces (e.g., capillary forces, gravity, or electric forces) and resistance due to dissipative processes that may be increasingly more complicated when complex fluids rather than simple ones are used.

## Abstract

Although practical adhesion depends on more than just interfacial bonds, clearly the latter are fundamental: the stronger the links, the higher the adhesion. In many cases, interfacial bonding is of a physical nature and is closely akin to wetting, with the same types of physical phenomena occurring. These can be treated from a thermodynamic standpoint. Wetting data may be used to *estimate* the thermodynamic energy of adhesion, provided certain assumptions are made and suitable models constructed for, in particular, a relationship between interfacial tensions. Several models have been established with greater or lesser success. The main ones are reviewed here, underlining their essential assumptions.

## 6.1 Introduction

As measured by mechanical tests, adhesion strength is not a quantity of reversible thermodynamics. This is due to various factors but mainly related to the dissipation of energy connected with the *irreversible* process of separation. The act of separation induces local stresses, and if the intrinsic adhesion is sufficiently strong, these are often sufficient to lead to irreversible, or at least time-dependent reversible, strain in one or both members in contact. Anyway, the deformation beyond strictly elastic behavior leads to an input of energy that is not restituted mechanically at all as it dissipates in part as heat or in an entropy term. Another part may be returned on a longer time scale than the separation process. This means that the actual, pragmatic energy of adhesion, as measured in a macroscopic mechanical test, is often far greater than the energy required theoretically for reversible separation at the interface between adhesive and adherend. The effect was shown initially by Gent and Petrich (1969) and later found by many others. Moreover, it has to be pointed out that for the majority of mechanical adhesion tests, the fracture face is not located at that interface. Some residual adhesive is often found on the adherend (or vice versa) as can be shown by surface-sensitive experimental techniques such as infrared external reflection spectroscopy, X-ray photoelectron spectroscopy, thermo-desorption mass spectrometry, secondary ion mass spectroscopy, etc. Nevertheless, the stresses responsible for this behavior require an interfacial linkage or adhesive bonding mechanism (cf. ► Chaps. 2, “Theories of Fundamental Adhesion” and ► 3, “Forces Involved in Adhesion,” of this book). In cases of good adhesion, this may be due to chemical bonds, but in many cases, physical interactions may be adequate to withstand the applied stresses.

It is only the energy for the *reversible* separation at the very interface that is considered within the framework of thermodynamics. As a starting point, the thermodynamic equations, considered in ► Chap. 4, “Wetting of Solids” for wetting (this book), can be easily adopted by replacing the liquid by a solid adhesive  $S_1$  and considering the former solid as the adherend  $S_2$  now. Hence, the specific energy of adhesion,  $f_{S_1S_2}^{adh}$ , for the solid–solid contact takes the form

$$f_{S_1S_2}^{adh} = \frac{F_{S_1S_2}^{adh}}{A_{S_1S_2}} = -(\gamma_{S_1V} + \gamma_{S_2V} - \gamma_{S_1S_2}) - \sum_i^N \mu_i \cdot (\Gamma_{i,S_1V} + \Gamma_{i,S_2V} - \Gamma_{i,S_1S_2}) \quad (1)$$

where  $F_{S_1S_2}^{adh}$  is excess Helmholtz free energy of adhesion and  $A_{S_1S_2}$  is D-face area between solid adhesive  $S_1$  and adherend  $S_2$ . The D-face describes the true interphase (cf. ► Chap. 4, “Wetting of Solids”),  $\gamma_{IJ}$  = interfacial tension for the D-face IJ,  $\mu_i$  = chemical potential of component  $i$  in the system, and  $\Gamma_{i,IJ}$  = absolute adsorption of component  $i$  on the D-face IJ.

Clearly, the interfacial tensions and the adsorption state of all three D-faces contribute to this specific excess Helmholtz free energy of adhesion. In comparison, Dupré’s rule (Dupré 1865) for the *reversible* specific work of adhesion

$$W_{S_1S_2}^{adh} = \gamma_{S_1V} + \gamma_{S_2V} - \gamma_{S_1S_2} \approx -f_{S_1S_2}^{adh} \quad (2)$$

considers the part from the interfacial tensions only. As shown in ► Chap. 4, “Wetting of Solids”, it is hard to verify this approximation, and hence a considerable portion of energy could be disregarded without notice.

Notwithstanding, three unknown quantities still remain in Eq. 2: the solid interfacial tensions. In ► Chap. 4, “Wetting of Solids”, a way to estimate the specific wetting energy from contact angle measurement is given provided the same level of approximation is chosen and Young’s equation is employed. This was the origin of the idea to deduce the reversible work of adhesion with Dupré’s rule by exploiting wetting experiments in a clever way. A number of such so-called thermodynamic adhesion models can be found in the literature, and they will be discussed in Sect. 3 of this chapter. However, before doing this, it is helpful to have a closer look at the very nature of the problem. Assuming that some test liquid, L, is used to characterize the wetting of both the solid adhesive and adherend, two Young’s equations are obtained:

$$\gamma_{S_1V} = \gamma_{S_1L} + \gamma_{LV} \cos \theta_{e,S_1L}$$

$$\gamma_{S_2V} = \gamma_{S_2L} + \gamma_{LV} \cos \theta_{e,S_2L}$$

where  $\theta_e$  refers to equilibrium contact angle. Note that the vapor phases are not exactly the same as the solids vary. Moreover, it should be pointed out again that Young’s equation applies neither to advancing nor to receding contact angles. The equilibrium contact angle,  $\theta_e$ , is needed (cf. Sects. 3 and 4 in ► Chap. 4, “Wetting of Solids” of this book).

Equation 2 becomes

$$W_{S_1S_2}^{adh} = \gamma_{S_1L} + \gamma_{LV} \cos \theta_{e,S_1L} + \gamma_{S_2L} + \gamma_{LV} \cos \theta_{e,S_2L} - \gamma_{S_1S_2}$$

Obviously, the reversible work of adhesion cannot be estimated because the solid interfacial tensions  $\gamma_{S_1V}$  and  $\gamma_{S_2V}$  cannot be deduced explicitly from wetting measurements as outlined at the end of ► Chap. 4, “Wetting of Solids”. Even if they could,  $\gamma_{S_1S_2}$  would remain as an unknown quantity. Obviously there are simply less physical equations than unknowns to be found. This has motivated researchers to propose model equations that are supposed to solve this dilemma. These model equations make use of some general features of physical interactions that are summarized in Sect. 2.

## 6.2 A Few Aspects of Intermolecular Interactions

Molecular interactions inside a phase boundary are the microscopic driving forces for the formation of the interphase as introduced in Sect. 2 of ► Chap. 4, “Wetting of Solids.” Energies are additive, and hence the contributions from any type of physical and chemical interaction sum up to the internal energy of the phase boundary. As outlined in ► Chap. 3, “Forces Involved in Adhesion”, the theory of physical

interactions (also known as van der Waals interactions due to their “prediction” in his well-known modification to the ideal gas equation) between *two* free molecules *A* and *B* provides the approximate equations for the interaction energy of dipolar, induction, and dispersion forces, respectively:

$$E_{AB}^{dipole} = -\frac{C_{AB}^{dipole}}{R^6} \quad \text{with} \quad C_{AB}^{dipole} = \frac{2\vec{p}_A^2 \vec{p}_B^2}{3(4\pi\epsilon_0)^2 kT} \quad (3)$$

$\vec{p}_J$  = permanent dipole moment of molecule *J*,  $\epsilon_0$  = absolute dielectric constant,  $k$  = Boltzmann constant,  $T$  = absolute temperature

$$E_{AB}^{induction} = -\frac{C_{AB}^{induction}}{R^6} \quad \text{with} \quad C_{AB}^{induction} = \frac{\vec{p}_A \vec{\alpha}_B \vec{p}_A + \vec{p}_B \vec{\alpha}_A \vec{p}_B}{(4\pi\epsilon_0)^2} \quad (4)$$

$\vec{\alpha}_J$  = electric polarizability tensor of molecule *J*

$$E_{AB}^{dispersion} = -\frac{C_{AB}^{dispersion}}{R^6} \quad \text{with} \quad C_{AB}^{dispersion} = f(\vec{\alpha}_A, \vec{\alpha}_B, \text{other parameters}) \quad (5)$$

They all possess the same dependence on the distance,  $R$ , between the *two* molecules, and hence they sum up to the energy of an attractive physical interaction:

$$\begin{aligned} E_{AB}^{phys \text{ interact}} &= E_{AB}^{dipole} + E_{AB}^{induction} + E_{AB}^{dispersion} \\ &= -\frac{C_{AB}^{dipole} + C_{AB}^{induction} + C_{AB}^{dispersion}}{R^6} \end{aligned} \quad (6)$$

In addition, theory shows that the interaction constants,  $C_{AB}$ , can be estimated by

$$C_{AB} = \sqrt{C_{AA} \cdot C_{BB}} \quad (7)$$

from the interactions between equal molecules A-A and B-B. (In the literature, the harmonic mean is found instead of the geometric mean sometimes.)

Starting from these microscopic pair interactions, the Hamaker concept (Hamaker 1937) provides the approximate interaction energy per contact area of the *macroscopic* phases A and B at distance,  $d$

$$u_{AB}^{phys \text{ interact}} = -\left(C_{AB}^{dipole} + C_{AB}^{induction} + C_{AB}^{dispersion}\right) \cdot f(d) \quad (8)$$

Equation 8 gives the contribution of intermolecular physical interactions to the specific internal energy,  $u_{AB}$ . (Things become more complicated when the intermolecular distance,  $d$ , is of the order of a few molecular diameters.)

Correspondingly, the specific excess internal energy of a D-face owing to physical interaction can be written as

$$u_{AB} = u_{AB}^{dipol} + u_{AB}^{ind} + u_{AB}^{disp} \quad (9)$$

with

$$u_{AB}^{dipol} \approx 2\sqrt{u_{AA}^{dipol} \cdot u_{BB}^{dipol}}, \quad u_{AB}^{ind} \approx 2\sqrt{u_{AA}^{ind} \cdot u_{BB}^{ind}}, \quad u_{AB}^{disp} \approx 2\sqrt{u_{AA}^{disp} \cdot u_{BB}^{disp}} \quad (10)$$

The interaction energies of chemical bonds are additive, too. It is important to note, however, that no such formulae as Eqs. 3, 4, 5, 6, and 7 apply in general. Hence, Eq. 8 must not simply be extended by another additive term for chemical bonds.

Finally, an entropy balance is needed for a complete description of the thermodynamic equilibrium. The specific excess entropy,  $s$ , of the D-face between the two phases  $A$  and  $B$  cannot be deduced from the concept of summation of pair interactions described. Statistical mechanics concepts are needed, which have still not been developed to the necessary quantitative level.

In conclusion, only the specific internal energy part,  $u$ , of the specific excess free Helmholtz energy for a given D-face

$$f_{AB} = u_{AB} - T \cdot S_{AB} = \gamma_{AB} + \sum_i \mu_i \cdot \Gamma_{i,AB} \quad (11)$$

can be described, while the specific entropy part,  $Ts$ , is still missing.

### 6.3 Thermodynamic Models of Adhesion

All thermodynamic models of adhesion aim to exploit wetting experiments on solids for a determination of the surface tension of solids and, as far as possible, of the thermodynamic energy of adhesion. As mentioned briefly in Sect. 1, the wetting experiment provides only the difference

$$\gamma_{SV} - \gamma_{SL} = \gamma_{LV} \cos \theta_{e,SL} \quad (12)$$

thus leaving us with the two unknown interfacial tensions  $\gamma_{SV}$  and  $\gamma_{SL}$  of the solid.

Clearly, an additional equation of state

$$\gamma_{SV} = f(\gamma_{SL}, \gamma_{LV}) \quad (13)$$

is needed to solve the problem. The existence of such an equation can be shown by thermodynamics, but it cannot be given explicitly. That is the starting point for the thermodynamic adhesion models: An explicit expression for Eq. 13 is constructed that should possess general validity. It should nevertheless be noted that none of the models is universally accepted and research continues in this field.

This issue and the common thermodynamic adhesion models will be discussed below. But as a first illustration, the widely forgotten approach by Antonov (1907) will be considered here. Antonov's empirical rule for low energy solids ( $\gamma_{LV} > \gamma_{SV}$ )

$$\gamma_{SL} \approx \gamma_{LV} - \gamma_{SV} \quad (14)$$

is such an assumption for the equation of state (13). Inserting Eq. 14 into Eq. 12 results in

$$\cos \theta_0 \approx \frac{2\gamma_{SV}}{\gamma_{LV}} - 1 \quad (15)$$

Accordingly, the solid surface tension  $\gamma_{SV}$  may be estimated from the wetting experiment with a single liquid but advancing and receding contact angle are not distinguished.

### 6.3.1 The Zisman Approach

In the light of the inaccessibility of two  $\gamma$  terms in Eq. 12, Fox and Zisman (1952) (Zisman 1962) postulated the following approach. The idea is based on the concept of *critical* surface tension (of the solid),  $\gamma_C$ . They took a homologous series of liquids, e.g., *n*-paraffins,  $C_nH_{2n+2}$ , in their liquid state at ambient temperature with  $n = 5-16$  and measured their equilibrium contact angle,  $\theta_0$ , on a given solid. It is not reported if these were the advancing or the receding contact angles. Now,  $\gamma_{LV}$  increases with  $n$ , and values are known. Plotting  $\cos \theta_0$  versus  $\gamma_{LV}$  for the various liquids, they obtained a straight line with slope ( $-k$ ) and constant term  $a$ :

$$\cos \theta_0 = -k \cdot \gamma_{LV} + a \quad (16a)$$

whose *extrapolated* value of  $\gamma_{LV}$  for  $\cos \theta_0 = 1$  was termed the critical surface tension,  $\gamma_C$ , of the solid. With that, Eq. 16a changes into

$$\cos \theta_0 = -k \cdot \gamma_{LV} + k \cdot \gamma_C + 1 \quad (16b)$$

and Young's Eq. 12 reduces to

$$\gamma_{SV} - \gamma_{SL} = \gamma_{LV} \equiv \gamma_C \quad (17)$$

Zisman also mentioned, however, that it depends very much on the chosen set of liquids whether the plot of  $\cos \theta_0$  versus  $\gamma_{LV}$  provides a straight line. Curves or even irregular scattering are also sometimes observed. Moreover, Eqs. 16 presume a straight line for  $\cos \theta_0$  versus  $\gamma_{LV}$  while Eq. 15 does so for  $\cos \theta_0$  versus  $\gamma_{LV}^{-1}$ .

Zisman was careful to avoid saying this was the true solid surface tension, although it should be close. In fact, the hypothetical liquid *just* spreading on the solid should indeed have a surface tension close to that of the solid, provided  $\gamma_{SL}$  is

quite small (cf. Eq. 17). This last supposition is plausible if the liquids and solid are chemically similar. To give two examples, it was found that polyethylene had a  $\gamma_C$  of ca. 31 mN·m<sup>-1</sup> and poly(tetrafluoroethylene), ca. 18.5 mN·m<sup>-1</sup>.

As a next step, Zisman combines Dupré's rule with Eqs. 12 and 17 to give

$$W_{SL}^{adh} = \gamma_{LV}(1 + \cos \theta_0) = -k\gamma_{LV}^2 + (2 + k\gamma_C)\gamma_{LV} \quad (18a)$$

This reversible work of wetting possesses a maximum at

$$\gamma_{LV}^{max} = \frac{1}{k} + \frac{\gamma_C}{2}, \quad W_{SL}^{adh, max} = \frac{1}{k} + \gamma_C + \frac{k}{4}\gamma_C^2 \quad (18b)$$

By way of a prediction, Zisman considered this particular liquid as the optimal adhesive provided it retains all its interfacial interactions when it solidifies.

### 6.3.2 The Concept of Girifalco and Good

Although Zisman's approach had the merit of originality, it clearly was not general. Despite being rarely true, Antonov's rule (14) inspired Girifalco and Good (1957, 1960) to follow a suggestion by Berthelot (for molecular attractions) and write  $\gamma_{SL} \approx \sqrt{\gamma_S \gamma_L}$ . However, the interfacial interaction should surely include additive contributions from each contiguous phase, and thus they arrived at

$$\gamma_{SL} = \gamma_S + \gamma_L - 2\sqrt{\gamma_S \gamma_L} = \left(\gamma_S^{1/2} - \gamma_L^{1/2}\right)^2 \quad (19)$$

Indeed, Eq. 19 goes back to Rayleigh (1890). It predicts zero interfacial tension if  $S$  and  $L$  are identical, as would be expected. All this assumed equal molecular sizes for  $S$  and  $L$ . If different, allowance had to be made, and the final version became

$$\gamma_{SL} = \gamma_S + \gamma_L - 2\phi\sqrt{\gamma_S \gamma_L} \quad (20a)$$

The dimensionless interaction parameter,  $\phi$ , expresses implicitly the effect of all interactions in the given interphase on the interfacial tension,  $\gamma_{SL}$ . In the framework of the Girifalco–Good concept, Eq. 20a represents the form proposed for the equation of state (13). Hence, Eq. 20a has to refer to *all* phases involved and should be written more precisely as

$$\gamma_{SL} = \gamma_{SV} + \gamma_{LV} - 2\phi_{SL}\sqrt{\gamma_{SV}\gamma_{LV}} \quad (20b)$$

Good pointed out himself that he had reduced the subscripts only for convenience. Equation 20b clearly shows that the parameter  $\phi$  refers to two well-defined phases in a wetting experiment. Experiments with two “immiscible” liquids serve to estimate  $\phi$  because  $\gamma_{SV}$  is replaced by the known surface tension  $\gamma_{L_2V}$  for the second liquid.  $\phi_{AB} > 1$  indicates that intermolecular interactions appear in the interphase

$A-B$ , which are not present inside the phases. Specifically  $\phi_{L_1L_2}$  is found to vary from 0.32 to 1.17 for 137 pairs of liquids. However, only 15% of these  $\phi_{L_1L_2}$  values are in the interval  $0.95 \leq \phi \leq 1.05$  (Girifalco and Good 1957).

Moreover, it is obvious that Eqs. 20 do not solve the problem of the missing equation of state (13) because a new unknown is introduced, viz.,  $\phi_{SL}$ .

This point will be considered more closely below. Here it is asked first how Eq. 20b relates to the balance of the excess energy for the interface and what the consequences for the wetting experiment are. These questions are important since the specific interactions in an interphase add their interaction *energies* to the balance, not the corresponding *forces*. For a liquid wetting a solid, the specific excess Helmholtz free energy of the SL interface is given by (cf. Sect. 2 of ► Chap. 4, “Wetting of Solids”)

$$f_{SL} = \gamma_{SL} + \sum_i \mu_i \cdot \Gamma_{i,SL} \quad (21)$$

where  $\mu_i$  is chemical potential of component  $i$  and  $\Gamma_{i,SL}$  is absolute adsorption of component  $i$  at the SL interface.

Therefore, consideration of only the interfacial tensions with Eqs. 20 means that the effect of adsorption is neglected in the Girifalco–Good concept:

$$f_{SL}^D \approx \gamma_{SL}^D \quad (22)$$

If this approximation is accepted, Young’s and Dupré’s equations may be again introduced in Eq. 20b yielding

$$\phi_{SL} \sqrt{\gamma_{SV}} = \frac{1 + \cos \theta_e}{2} \sqrt{\gamma_{LV}} \quad (23a)$$

Again, Eq. 23a reveals the problem. The wetting experiment with one test liquid  $L$  does not provide  $\gamma_{SV}$  since  $\phi_{SL}$  cannot be derived independently from wetting data. To circumvent the problem, Good proposed to combine a series of test liquids and to plot  $\cos \theta_e$  versus  $\gamma_{LV}^{-0.5}$  according to Eq. 23a rewritten in the form

$$\cos \theta_e = 2\phi_{SL} \sqrt{\gamma_{SV}} \cdot (\sqrt{\gamma_{LV}})^{-1} - 1 \quad (23b)$$

A straight line passing through  $(-1)$  on the ordinate should be obtained if  $\phi_{SL}$  possesses the same value for all the liquids used. This cannot be true in a strict sense since, by definition,  $\phi_{SL}$  cannot be independent of the given liquid. Moreover, the Good plot implies that the changes in the common vapor phase V can be ignored when the test liquid is changed in the experiment. It was shown in Sect. 4.5, however, that these changes may not be neglected. Also, it has to be noted that Good et al. ignore the difference between the measured static contact angles  $\theta_a$ ,  $\theta_r$  and the equilibrium contact angle  $\theta_e$ . If, in addition,  $\phi_{SL}$  is assumed to be close to one, an approximate value for  $\gamma_{SV}$  follows from the slope of the straight line.

In the literature many authors have followed Good's advice, but there is no way reliably to find the resulting error for  $\gamma_{SV}$ . An additional and significant source of error is the use of the advancing (or receding) contact angle instead of  $\theta_e$ .

Finally, Dupré's reversible work of adhesion is considered in the framework of the Girifalco–Good concept. Assuming that the surface tensions  $\gamma_{S_1V}$  and  $\gamma_{S_2V}$  of the solid adhesive and of the solid adherend, respectively, were estimated from wetting experiments in the way described above, Eq. 20b is modified to

$$\gamma_{S_1S_2} = \gamma_{S_1V} + \gamma_{S_2V} - 2\phi_{S_1S_2} \sqrt{\gamma_{S_1V}\gamma_{S_2V}} \quad (20c)$$

It has to be noted in passing that the vapor phase has changed again. It does not contain the components of the test liquid anymore.

Dupré's Eq. 2 becomes

$$W_{S_1S_2}^{adh} = \gamma_{S_1V} + \gamma_{S_2V} - \gamma_{S_1S_2} = 2\phi_{S_1S_2} \sqrt{\gamma_{S_1V}\gamma_{S_2V}} \quad (24)$$

Obviously, the dilemma still exists: The new interaction parameter  $\phi_{S_1S_2}$  is not available, and the specific reversible work of adhesion is inaccessible. In Good and Elbing (1970) and Good (1977), Good et al. derive an equation that can be written in a generalized form as

$$\phi_{AB} \approx \frac{C_{AB}^{dipole} + C_{AB}^{inductive} + C_{AB}^{dispersion}}{\sqrt{(C_{AA}^{dipole} + C_{AA}^{inductive} + C_{AA}^{dispersion})(C_{BB}^{dipole} + C_{BB}^{inductive} + C_{BB}^{dispersion})}} \quad (25)$$

for the calculation of  $\phi_{AB}$  for the interface between phases *A* and *B* using the basic formulae of intermolecular physical interactions (cf. Eqs. 3, 4, and 5). However, this is also another approximation.

### 6.3.3 The Fowkes Approach and Its Modifications

Fowkes (1962, 1963, 1964, 1967) provided another approach for the analysis of wetting experiments by proposing that a surface tension  $\gamma$  (solid or liquid) may be expressed as the sum of a number of various components:

$$\gamma = \gamma^d + \gamma^p + \gamma^i + \gamma^C + \dots \quad (26a)$$

where the superscripts refer to contributions due to the intermolecular interaction forces of various types: dispersion, dipoles, induction interactions, covalent contributions, etc. In practice, he stopped after polarity, assuming most wetting interactions will not involve significant induction or chemical contributions:

$$\gamma = \gamma^d + \gamma^p \quad (26b)$$

At this point, it must be emphasized again that a surface or interfacial tension is a tensor by its physical origin (cf. ► Chap. 4, “Wetting of Solids”) and hence it may not be split into additive scalar components in general. Such additivity holds for the energy, and referring again to Eq. 11 for the specific excess free Helmholtz energy for a surface of phase  $A$  in equilibrium with its vapor phase

$$f_{AV} = u_{AV} - T \cdot S_{AV} = \gamma_{AV} + \sum_i \mu_i \cdot \Gamma_{i,AV} \quad (27)$$

It is seen that one formally arrives at

$$f_{AV} \approx u_{AV} \approx \gamma_{AV} \quad (28)$$

only by neglecting the specific excess entropy  $s_{AV}$  and all absolute adsorptions  $\Gamma_{i,AV}$ .

Using Eq. 9,  $u_{AV}$  is now written as

$$u_{AV} = u_{AV}^p + u_{AV}^i + u_{AV}^d \approx \gamma_{AV}^p + \gamma_{AV}^i + \gamma_{AV}^d \quad (29)$$

and with Eqs. 28 and 26, one gets

$$u_{AV}^p = \gamma_{AV}^p, u_{AV}^i = \gamma_{AV}^i, u_{AV}^d = \gamma_{AV}^d \quad (30)$$

Hence, Eqs. 28, 29, and 30 provide justification for the Fowkes Eqs. 26, and they illustrate the implied approximations.

As his explicit version for the general equation of state (13), Fowkes assumes that only dispersion interactions are present in the interphase, and he proposes (for the case of wetting)

$$\gamma_{SL} = \gamma_{SV} + \gamma_{LV} - 2\sqrt{\gamma_{SV}^d \gamma_{LV}^d} \quad (31)$$

We add the subscript V here for the sake of correctness. In the original work, no reference is made to the corresponding vapor phase that must exist for thermodynamic equilibrium at the surface of any condensed phase (cf. Sect. 4.2).

Obviously, Eq. 31 refers to the dispersion components of the solid and the liquid surface tensions that are new unknown quantities. Fowkes deduces the polar components  $\gamma_{LV}^d$  of the surface tensions for a series of liquids from mutual liquid–liquid wetting experiments, and  $\gamma_{LV}^p$  is determined from Eq. 26b. It is noted that the vapor phase is specific for any pair of liquids. Hence, the values derived for  $\gamma_{LV}^d$  and  $\gamma_{LV}^p$  depend on the partner liquid too! The results reported by Fowkes indicate that this is proven in his liquid–liquid wetting experiments.

However, if additional interactions (e.g., induction) contribute to the state of the liquid–liquid interphase, there are again more unknowns than equations!

Following Fowkes proposition, various workers postulated, more or less successfully, extensions to Eq. 31 in order to include other types of interphase interactions. It

must be emphasized that the term “extended Fowkes equations” is really a misnomer, since Fowkes did not condone their use. However, the two best-known versions are attributable to Owens and Wendt (1969):

$$\gamma_{SL} = \gamma_S + \gamma_L - 2\sqrt{\gamma_S^d \gamma_L^d} - 2\sqrt{\gamma_S^p \gamma_L^p} \quad (32)$$

and to Wu (1971):

$$\gamma_{SL} = \gamma_S + \gamma_L - \frac{4\gamma_S^d \gamma_L^d}{(\gamma_S^d + \gamma_L^d)} - \frac{4\gamma_S^p \gamma_L^p}{(\gamma_S^p + \gamma_L^p)} \quad (33)$$

These two variants, based on geometric and harmonic means for the surface tension components according to Fowkes, are often used, but their theoretical basis is questionable as will be shown below.

A further variant of Fowkes early work is due to van Oss et al. (1988). It is based on the concept that weak acid–base interactions (of the Lewis type) may contribute to interfacial tensions. Couched in a formalism inspired by Fowkes’ earlier work, it is proposed that a (general) surface tension may be written as

$$\gamma = \gamma_{LW} + \gamma^{AB} \text{ where } \gamma^{AB} = 2\sqrt{\gamma^+ \gamma^-} \quad (34)$$

In Eq. 34,  $\gamma^{LW}$  represents the dispersion and polar components of Fowkes’ expression (26b), all together, and  $\gamma^{AB}$  is the acid–base, or electron acceptor/donor, contribution. The terms  $\gamma^+$  and  $\gamma^-$  represent electron acceptor and electron donor characteristics of the phase. After some algebra, it is shown that in this approach, the expression for  $\gamma_{SL}$  becomes

$$\begin{aligned} \gamma_{SL} = & \left( \sqrt{\gamma_S^{LW}} - \sqrt{\gamma_L^{LW}} \right)^2 + 2 \left( \sqrt{\gamma_S^+ \gamma_S^-} + \sqrt{\gamma_L^+ \gamma_L^-} \right) \\ & - 2 \left( \sqrt{\gamma_S^+ \gamma_L^-} + \sqrt{\gamma_S^- \gamma_L^+} \right) \end{aligned} \quad (35)$$

The second term on the right amounts to the *internal* acid–base interactions, and the last is due to *interfacial* acid–base interactions. Some doubt has been cast on the validity of this formulation, but the intrinsic physical chemistry of allowing for electron acceptor and electron donor characteristics seems sound.

Let us now look at the implications of Eqs. 31, 32, and 33. Using Eqs. 9, 10, and 28, the specific excess Helmholtz free energy can be expressed as

$$f_{SL} \approx u_{SL} = u_{SL}^p + u_{SL}^i + u_{SL}^d = 2\sqrt{u_{SV}^p \cdot u_{LV}^p} + 2\sqrt{u_{SV}^i \cdot u_{LV}^i} + 2\sqrt{u_{SV}^d \cdot u_{LV}^d} \quad (36)$$

Dupré’s reversible work of wetting is introduced as

$$W_{SL}^{adh} = \gamma_{SV} + \gamma_{LV} - \gamma_{SL} \approx -f_{SL} \approx -u_{SL} \quad (37)$$

and with Eq. 30 follows

$$W_{SL}^{adh} = \gamma_{SV} + \gamma_{LV} - \gamma_{SL} \approx -2\sqrt{\gamma_{SV}^p \cdot \gamma_{LV}^p} - 2\sqrt{\gamma_{SV}^i \cdot \gamma_{LV}^i} - 2\sqrt{\gamma_{SV}^d \cdot \gamma_{LV}^d} \quad (38)$$

which is a generalized form of Eqs. 31 and 32. A corresponding form for Eq. 33 would follow by replacing geometric by harmonic means. As before,  $W_{SL}^{adh}$  could be obtained from a proper wetting experiment.

All these concepts suffer from the same problem as the thermodynamic adhesion model proposed by Girifalco and Good. Provided that attention is confined to polar and dispersion interactions and the use of the values for  $\gamma_{LV}^d$  and  $\gamma_{LV}^p$  from the liquid–liquid wetting is made, one still has two unknowns in Eq. 38:  $\gamma_{SV}^d$  and  $\gamma_{SV}^p$ .

In the literature, this problem is circumvented (but not solved!) by incorporating the wetting results from a second liquid (or even a series of test liquids) for the data analysis: With any additional liquid, Eq. 38 can be rewritten, thus expanding the starting point from a single equation into an unlimited system of simultaneous equations. Although mathematically correct, this procedure is inconsistent with several aspects of the fundamental thermodynamic concept of the interphase and its corresponding D-face or interface (cf. ► Chap. 4, “Wetting of Solids”). As a result, the reliability of data deduced for  $\gamma_{SV}^d$ ,  $\gamma_{SV}^p$ ,  $\gamma_{SV}^i$ , and hence  $\gamma_{SV}$  cannot be assessed.

Bearing this in mind, now a brief look at the work of adhesion between solid adhesive and adherend in the framework of Fowkes’ general approach is taken. Equation 38 is of the form

$$\begin{aligned} W_{S_1S_2}^{adh} &= \gamma_{S_1V} + \gamma_{S_2V} - \gamma_{S_1S_2} \\ &\approx -2\sqrt{\gamma_{S_1V}^p \cdot \gamma_{S_2V}^p} - 2\sqrt{\gamma_{S_1V}^i \cdot \gamma_{S_2V}^i} - 2\sqrt{\gamma_{S_1V}^d \cdot \gamma_{S_2V}^d} \end{aligned} \quad (39)$$

Obviously,  $W_{S_1S_2}^{adh}$  is as much in doubt as the components of the solid and liquid surface tensions. These are the physical limits of all these concepts.

### 6.3.4 Neumann’s Approach

Neumann et al. (1974) have adopted the stance of considering the *advancing* contact angle to be related to an equation of state. He followed the evolution of  $\gamma_L \cos \theta_a = f(\gamma_L)$  for a series of liquids on eight fluoropolymer surfaces. Thus, Neumann follows the lines of his predecessors. Combining the results of wetting experiments with an arbitrary choice of test liquids on a small number of polymer surfaces, he considers the phenomenological relationships found for that data pool as generally applicable. The treatment ignores the fact that all wetting pairs represent independent thermodynamic systems.

Neglecting spreading pressure,  $\pi_e$ , he observed a linear variation of  $\phi$  of the Girifalco–Good equation (20a). Combining this linearity with Girifalco and Good’s relation, he arrived at the following expression for Eq. 13:

$$\gamma_{SL} = \frac{[\sqrt{\gamma_S} - \sqrt{\gamma_L}]^2}{1 - A \cdot \sqrt{\gamma_S \gamma_L}} \text{ with } A = 15 \text{ m} \times \text{N}^{-1} \quad (40)$$

This relation is purely empiric and thus valid for the cases where it has been established. In another attempt, Li and Neumann (1990) used arguments based on the theory of intermolecular physical interactions along the lines of Eqs. 3, 4, 5, 6, and 7. Following Fowkes’ concept, they derived the expression

$$\gamma_{SL} = \gamma_{LV} + \gamma_{SV} - 2\sqrt{\gamma_{LV}\gamma_{SV}} \cdot e^{-\beta(\gamma_{LV}-\gamma_{SV})^2} \quad (41)$$

as an alternative version for the equation of state (13). Here, the model parameter  $\beta$  is the newly introduced unknown. From a pool of wetting data,  $\beta$  was derived to be equal to  $124.7 \text{ m}^2 \cdot \text{N}^{-2}$  (Li and Neumann 1992). Hence, this relation is purely empirical, too.

## 6.4 Conclusions

All thermodynamic adhesion models start with the idea that wetting experiments with suitably chosen test liquids could provide the surface tension,  $\gamma_{SV}$ , of the wetted solid.

As shown in the previous sections of this chapter, numerous approximations are made in each of these evaluations of the wetting data. Let us mention three of the more important simplifications: (a) the thermodynamic adhesion models blur the physical distinction between interfacial tension and thermodynamic excess energy of an interface; (b) they neglect the contribution of the interphase composition (i.e., the role of the absolute adsorptions  $\Gamma_i$ ); and (c) they ignore the fact that an interfacial tension belongs to *two* contacting phases in the framework of thermodynamics. In many published papers, the problem of how the thermodynamic contact angle is derived from measured advancing or receding angles is overlooked. These and more approximations are needed to handle the key problem of the overall situation: How should an explicit form for a general equation of state be constructed that is only implicitly given by theory  $-\gamma_{SV} = f(\gamma_{SL}, \gamma_{LV})$ ? The models vary considerably as can be seen by comparing Eqs. 17, 20, 31, 32, 33, 35, 40, and 41. Moreover, it is not presently possible to assess the accuracy of any of these approximate equations. Nevertheless, thermodynamic adhesion models are widely used in the literature.

In conclusion, it must be emphasized that wetting experiments do not provide enough information on interphases for deducing the interfacial tensions,  $\gamma_{SV}$ ,  $\gamma_{SL}$  of a solid, or, even worse, for the reversible work of adhesion,  $W_{S_1S_2}^{adh}$ . As far as future work is concerned, it would be a challenging goal to find an experiment enabling direct measurement of the specific excess free Helmholtz energy of adhesion  $\Delta f^{adh}$ .

## Abstract

The use of surface treatments to optimize adhesion has been well established. In this chapter, the main treatment methods for metals and polymers will be considered in terms of how such processes are carried out and their influence on surface physical and chemical properties. Consideration has been given to a range of treatments from simple degrease options to the more highly complex multistage

processes. An attempt has been made to relate the changes in physicochemical properties to adhesion performance, and, where relevant durability.

## 7.1 Introduction

It is usually recommended that some degree of modification or treatment is applied to all surfaces prior to adhesive bonding. This is particularly important if structural or semi-structural bonding is to be carried out. Some examples of specific surface treatments and their influence on initial adhesion and durability are given later in this section and, more extensively, in ► [Chap. 8, “Surface Treatments of Selected Materials.”](#) The particular surface treatment applied in any given situation will depend upon the requirements of the bond and the service conditions that it will experience and will generally be chosen on a “fit-for-purpose” basis. Additional factors such as the adherend type and geometry and production constraints, including cost considerations, may also be relevant factors when selecting a treatment process.

In simple terms, treatments are required to make the surface receptive to the applied adhesive. A treatment may also be required to provide a mechanically sound surface to be bonded and one which will also minimize the potentially damaging influence of external factors such as environmental ageing, corrosion, or applied loading. From the relevant literature, it is clear that the main function of any treatment on any surface is to provide desirable physical and chemical properties to that surface which will achieve the above-mentioned objectives. To do this, a particular treatment will facilitate one or more of the following functions:

- To remove, or prevent the formation of, any weak boundary layer on the adherend surface. Examples of weak boundary layers include machine oils, weak oxides or hydroxides, and airborne contamination on metals, or, internal segregants from within polymers. A simple degrease may fulfill this requirement. Alternatively, mechanical or deoxidizing treatments may be required if friable, inorganic layers are present.
- To maximize the degree of intimate molecular contact between the adhesive or primer and the adherend during the bonding and curing processes. This usually involves the creation of a high-surface free energy and the introduction of specific functional groups.
- To generate a specific structure or texture on the adherend surface. Even though mechanical interlocking may not be responsible for primary bonding, the complex structures present on, for example, conversion-coated or anodized surfaces may help increase joint fracture energies by redistributing the stresses away from any interphasial polymer. These structures also create an extended surface area, which may be utilized if the adhesive is able to flow into, for example, the pores on anodic oxides.
- To passivate the surface of the adherend prior to adhesive bonding. This is paramount for high-energy adherends as these are not only receptive toward the adhesive but also to all forms of contamination. This contamination may be

organic or inorganic and can influence the adherend in a number of ways, including by a reduction in its surface free energy, gross contamination, or corrosion. Passivating processes offer protection of the surface after bonding by providing electrochemical and barrier corrosion resistance to the substrate material.

The minimum preparation which is usually carried out on adherend surfaces might include a simple degrease to remove processing aids and contaminants. There does, however, exist a hierarchy of treatments. It is generally thought that mechanical processes such as abrasion or grit-blasting offer improved bonding surfaces compared with degreasing-only and, in some cases, offer adequate levels of adhesion either alone or with coupling agents applied. Further information on the role of coupling agents is given in ► [Chap. 11, “Organosilanes: Adhesion Promoters and Primers.”](#) Similarly, simple chemical treatments such as acid etching tend to offer further enhanced bond performance compared with mechanical treatments. However, it is recognized that the current state-of-the-art processes, particularly those for structural or semi-structural metal bonding and which are highly complex, multistage treatments, including chemical conversion coating and anodic oxidation of metals perform best of all. The more advanced processes provide the adherend surface with all of the required physical and chemical properties mentioned above to obtain optimized initial adhesion and, importantly, durability.

This chapter will firstly consider the problems associated with bonding as-received surfaces and the problems caused by the presence of contamination. Following this, details will be given of different surface treatment methods in terms of how they modify the above-mentioned surface physical and chemical properties, and how these changes impact upon the measured adhesion levels. In some cases, consideration has been given to alternative environmentally friendly surface treatments which might be considered as drop-in replacements for the current industrial standards. Many of the currently used processes are detailed further in ► [Chap. 8, “Surface Treatments of Selected Materials.”](#) This chapter will focus on the modification or treatment of metallic and polymeric adherends. It is, however, recognized that adhesion to other materials such as wood, ceramics, and glasses are industrially significant, and mention of relevant treatments for these materials are given in ► [Chap. 8, “Surface Treatments of Selected Materials.”](#)

---

## 7.2 The Problem with Surface Contamination

The removal of preexisting contamination, which often comprises low energy and friable material, to facilitate bonding to a mechanically sound surface is a fundamental requirement in establishing good adhesion. The requirement to remove such material is often overlooked, but it is, in fact, an essential stage in the more complex processes such as anodizing also.

It is important at this stage to note that when considering polymers, it is possible that internal migration of low-molecular-weight materials or processing aids can

occur to create a highly modified surface layer. This layer might be considered as comprising internal contaminants. A simple illustration of this has been given by Ansanfar et al. (2009) in their consideration of natural rubber (NR) and NR-sytrene-butadiene rubber blends. In this study, internal migration of paraffin wax, a processing aid, was directly observed, which led to poor self-adhesion between these polymers. In addition to influencing the surface thermodynamics, such internal contaminants may also form weak boundary layers; this topic has been extensively discussed following the early studies by Brewis (1982). The removal of such internal contaminants will be considered later in this section.

Following is a consideration of external contaminants on adhesive joints. There are many possible forms of external contamination; a reasonably comprehensive list is given by Averill et al. (1998).

For simplicity, surface contaminants can be considered to fall within two broad groups: organic and inorganic materials. The removal of the organic compounds can, generally, be achieved using simple degrease processes, whereas the inorganic compounds might require a combination of degrease, desmut and, in extreme cases, deoxidizing solutions.

As previously mentioned, substrate contamination can have a major effect upon the resultant quality of the bond due to the influence of the contaminant reducing the surface free energy. Naturally, in any conscientious facility that undertakes adhesive bonding, contamination will be reduced to an absolute minimum. In one study, Smith and Crane (1980) looked at the influence of controlled levels of contamination from various sources and determined their effects upon adhesive bond strength using aluminum alloy adherends. Ellipsometry and water contact angle measurements were used to study a range of process variables and contaminants. Aluminum panels treated by phosphoric or chromic acid anodizing (PAA or CAA) were contaminated with materials likely to be introduced by human error, including finger prints, cigarette smoke, and mucous, along with drink residues. Contaminants originating from a factory environment were also considered, including lubricating oils and silicone grease. In all cases, ellipsometry and water contact angles were able to detect the presence of these materials. In this study, it was noted that the presence of a level of 10 nm, and above, of lubricating oils had no effect upon the lap shear strength of joints made with a single part epoxide adhesive, even though an increase in the water contact angle was observed. Increasing the levels of oil did result in an increase in water contact angle toward 100°. Silicone grease was also introduced and evaluated; in this case, a more dramatic effect was noted in that a significant decrease in lap shear strength was observed. In an assessment of the sensitivity of the two types of surface treatment, small amounts of silicone grease, from 3.5 to 20 nm, were found to increase the water contact angle value and, using lap-shear testing, this was accompanied by a significant reduction in the failure load. Almost total apparent interfacial failure was noted for the silicone-contaminated joints.

Significant work carried out to evaluate the effects of contamination has also been conducted in the area of automotive bonding, where adhesion to lubricated surfaces is desirable. Research carried out principally on behalf of the automotive industry has studied the ability of adhesives to absorb or displace contaminants to facilitate

the formation of bonds with the underlying substrate. In one study carried out on electrogalvanized steel adherends, Hong and Boeno (1995) showed that the adhesive formulation can play a key role in successfully accommodating oils on such surfaces. In a related study, Minford (1981) looked at the effects of lubricants as contaminants on bonded and spot-welded aluminum substrates. For the substrates, he used 2036 T4 aluminum lap-shear joints bonded with a single part hot-curing epoxide. Surface contamination was controlled by immersing the substrates to be bonded in varying concentrations of an emulsified forming lubricant. Durability was tested by exposing joints to 52 °C and 100% relative humidity and measuring residual failure loads. Joints were also subjected to a 3.5% salt fog for 16 h in a 24-h cycle. Both simulated service conditions were assessed against freshly prepared joints. Other than the joints that were deliberately contaminated, all adherends received no other treatment. It was found that the adhesive was able to accommodate up to 0.82 mg/cm<sup>2</sup> of oil before any loss of strength was noticeable. At the 0.95 mg/cm<sup>2</sup> level, there was a significant loss in strength from 10 to 6 MPa and a shift in the locus of failure dropping from over 90% cohesive to demonstrate a mixture of 60% cohesive and 40% apparent interfacial failure. For the environmental ageing of joints, specimens were exposed to either humidity or salt-spray conditions for up to 180 days. Joints were periodically removed and loaded to 50% of their original bond strength and then finally tested to destruction after 280 days of exposure. Joints retained their original strengths with up to 0.62 mg/cm<sup>2</sup> level of contamination. At 0.71 mg/cm<sup>2</sup>, a reduction to 45% of the original joint strengths was observed and at 0.82 mg/cm<sup>2</sup>, the results became variable. Paradoxically, contaminated joints exposed to salt-spray conditions seem to perform better than the as-milled substrates which failed at 2% of their original joint strength after only 90 days exposure. The only contaminated joints that performed worse than this were the ones prepared at the 1.05 mg/cm<sup>2</sup> level. Overall, it was this latter level of contamination that caused the most detrimental effect upon the fresh and aged specimens.

Debski et al. (1986) have tried to explain the mechanisms by which the adhesive is able to function even through oily layers by investigating the ability of an epoxide adhesive to either displace or absorb such contamination. They determined the surface free energies for a diglycidyl ether of bisphenol A (DGEBA) based epoxide resin on ASTM 3 grade oil, plain steel, and a zinc-coated steel. Utilizing these surface free energy values, they investigated the thermodynamic possibility of the epoxide adhesive displacing a layer of an apolar oil on a steel surface. The model was that of a drop of resin spread over a layer of oil upon a metal substrate. Assuming that the resin remained geometrically constant they concluded that, theoretically, the oil could be displaced if the substrate was flat and determined that no oil could become entrapped within surface crevices. To deal with this entrapped oil, they assumed that any oil trapped beneath the adhesive was absorbed into the epoxide matrix. Using differential scanning calorimetry (DSC), they monitored the cross-linking kinetics of an adhesive containing 6% dicyandiamide and of the adhesive with the same formulation but with the addition of a CaCO<sub>3</sub> filler. They found that the effect of the increase in oil content was to lower the glass transition temperature ( $T_g$ ) during the cross-linking process. However, the  $T_g$  of the fully cross-

linked adhesive was unaffected even at the highest levels of oil contamination. Similar trends were also noted for the unfilled epoxide adhesive. Thermal gravimetric analysis (TGA) was also conducted to evaluate the levels of oil that were lost due to evaporation from the free surfaces of the adhesive samples. The filled and unfilled adhesives both containing 10% oil were monitored at 210 °C for weight loss alongside control samples containing no oil. After 1 h of heating, no loss of weight was recorded for either control sample; however, the unfilled sample with oil lost approximately 3% the filled version lost 1% and a pure oil sample lost 36% of its original weight. This study demonstrated the capacity of an epoxide adhesive to accommodate oil from substrates in one of three ways; the displacement, absorption, and “digestion” by the filler and absorption followed by evaporation at free surfaces. However, the latter would be a second-order mechanism in real joints as the free surface to volume ratio would be significantly lower than that present in the experiments conducted.

Anderson (1993) also discovered that contaminated bondlines can behave differently under different loading conditions. He studied the effects of HD-2 grease upon steel butt joints and tapered double cantilever beam test specimens that were bonded together with either Hysol EA946 or EA 913 epoxide adhesives. The substrates were prepared by vapor degreasing, grit-blasting, and a final vapor degrease prior to bonding. For the contaminated joints, varying solutions ranging from 0.5% to 2% of HD-2 grease were prepared by thinning down in 1,1,1 trichloroethane, which was then sprayed onto one of the substrates from a bonded pair. The test results from the tensile butt joints showed that there was a change of failure mode from that of cohesive to one of near interfacial even for the lowest levels of contamination. Joints prepared with the EA 913 adhesive lost approximately 50% of their overall tensile strength at a contamination level of 400 mg/m<sup>2</sup>, while EA946 was hardly affected. The results for the tapered double cantilever beam trials were somewhat different, and significant effects were noted for both adhesives. The EA946 results were significantly reduced from approximately 1,200 N/m to around 600 N/m at the 100 mg/m<sup>2</sup> level. The EA913 results were also similarly affected and were significantly reduced from an initial value of 400 N/m for the uncontaminated specimens to approximately 20 N/m at the lowest levels of contamination, 50 mg/m<sup>2</sup>. Trials were repeated for the EA 946 adhesive but with the addition of a silane primer to the bondline. The silane was applied by spraying a solution of 5% A187 in 40% toluene, 40% absolute ethanol, 5% butoxy ethanol, 5% deionized water, and 5% n-butanol. The results of both the tensile butt joint and cantilever beam trial showed improvements in the resistance to contaminant levels. For the butt joint trials, only a small loss of strength was observed up to the 200 mg/m<sup>2</sup> contaminant level. There was also a notable improvement in the fracture toughness values from a value of 1,200 to 4,000 N/m for the uncontaminated test specimens. Losses were again noted at the 100 mg/m<sup>2</sup> level of contamination.

In the above studies, the influence of various deliberately introduced chemical contaminants on the prebond condition of the adherends has been studied. Also of significance is the influence of prebond handling and the ability of some surface treatments to accommodate physical damage as well as contamination; this aspect has been investigated by McNamara et al. (1979).

It is clear that the role of surface contamination and its effects upon the resultant joint strength is complex; this point has been further highlighted in the work of Olsson-Jacques et al. (1996) who studied the influence of adsorbed aviation fuel on various differently treated surfaces. It is, however, important to note that the degree of degradation is a function of the specific adhesive-primer-treatment-adherend combination used. Therefore, to ensure good adhesion, in the general case, it is recommended that contamination is removed prior to adhesive application. Some methods to achieve this for metallic and polymeric adherends are discussed in the following sections.

## 7.3 Removal of Surface Contamination

### 7.3.1 Degreasing Metallic Adherends

For metals, an atomically clean surface will have a positive spreading coefficient, so wetting by a subsequently applied adhesive will occur; this topic has been dealt with elsewhere in this book and previously by Shanahan (2005). A large spreading coefficient is particularly important if complete wetting of highly textured surfaces is to be achieved. Note that the texture produced by various treatments may vary from the macro- or microscale created by grit-blasting to the nanoscale porosity present on anodized surfaces. Surface cleanliness, surface free energy, and wettability are intimately linked as has also been discussed, for example, by Rance (1985). Degreasing is the simplest possible method of achieving a clean surface and thereby increasing its surface free energy and spreading coefficient.

The simplest form of degreasing, involving the use of organic solvents, is used as a stand-alone treatment and as the first stage in a wide variety of multistage processes. Degreasing methods can range from simple immersion or wiping techniques to vapor degreasing or ultrasonic cleaning. The solvents industrially employed include isopropyl alcohol, acetone, methyl ethyl ketone, perchloroethylene, trichloroethylene, or 1,1,1 trichloroethane. However, environmental as well as health and safety legislation is rapidly reducing the range of solvents that can be used for this method (Averill et al. 1998). Furthermore, some standards agencies no longer advocate the use of solvents for the degreasing and cleaning of substrates to be bonded, preferring instead detergent degreasing or alkaline cleaning. For example, Lesley and Davies screened a range of approximately 150 solvents and degreasing agents in the search for a cleaner to replace the preexisting chlorinated vapor degreasing of aluminum and steel components for adhesive bonding. They concluded that substrates treated with aqueous cleaners resulted in surfaces with less residual organic matter than with any of the organic solvents they reviewed. Extensive studies have been carried out by Thiokol on replacements for methyl chloroform (TCA) for the cleaning of large-scale parts with great success achieved by various aqueous-based cleaners.

Alternatives to the commonly used degreasing processes are sought for many reasons, for example: established processes may not be adequate for difficult-to-

**Table 1** A summary of cleaners studied code to treatments

	2% NMR Sea Power 100 solution +1% sodium hydrogen orthophosphate solution followed by a 4% sulfuric acid solution

remove materials or the processes may use undesirable volatile organic compounds (VOCs); alternatively, they can be carcinogenic or ozone depleting. In a study by Smith et al. (2000), a range of aqueous-based cleaners was evaluated in terms of their effectiveness on stainless steel. The usefulness of contact angle analysis was also demonstrated in this work. It is recognized that a monolayer of organic material present on metal surfaces will, typically, give a water contact angle between 55° and 95°. If the organic layer is effectively removed, the contact angle will be reduced to zero. Contact angle measurements can provide a simple method to assess the effectiveness of various cleaning agents. Smith et al. considered a range of cleaners on as-received stainless steel; the cleaners are detailed in Table 1. It was shown that the detergents were moderately effective in removing organic material from the stainless steel as can be seen from the much reduced contact angles in Table 2, compared with the untreated control. However, they were not as effective as the proprietary metal cleaner. Of particular interest, a natural detergent based on seaweed proved very effective in removing organic material as was confirmed using Auger electron spectroscopy (AES), particularly when used in combination with sodium hydrogen orthophosphate. As would be expected, the degree of cleaning increased with treatment time. Ultrasonics also significantly increased the effectiveness of the proprietary cleaner and the rate of cleaning. The alkaline and acid-based cleaners were also shown by AES to modify the surface oxide by enrichment of chromium, and the thickness of the oxide layer was reduced by both the alkaline and the acidic etches. The latter point may be relevant in terms of the durability of subsequently produced bonds.

For the removal of strongly adsorbed or chemisorbed contamination, simple solvent cleaning may not be effective. Litchfield et al. (2006) have detailed a

312 range of processes for the removal of cross-linked epoxide resins from both metal  
313 and composite surfaces. Methods such as sodium hydride immersion, CO<sub>2</sub>-  
314 cryoblasting, and laser ablation all proved highly effective. In a further study, the  
315 efficacy of CO<sub>2</sub>-laser ablation was also demonstrated in terms of its ability to  
316 produce atomically clean surfaces with a resultant increase in surface energy and  
317 observed initial single lap shear (SLS) joint strength and durability, as measured  
318 using statically stressed SLS joints (Critchlow et al. 1997) with metallic adherends.  
319 In a related study by Bedwell et al. (1998), CO<sub>2</sub>-laser ablation was studied to  
320 establish the effectiveness of simply removing adventitious organic contamination  
321 from industrially sourced hot dipped galvanized (HDG) mild steel. This laser-based  
322 process was demonstrated to be more effective than double-degreasing combined  
323 with ultrasonic immersion in acetone for the removal of organic contamination from  
324 a previously oil-contaminated surface. In addition, the TEA CO<sub>2</sub>-laser was shown to  
325 modify both the near surface chemistry and the topography; the precise modifica-  
326 tions being dependent upon the degree of treatment used. Importantly, in bond  
327 durability trials, the changes introduced to the laser-treated HDG surface were  
328 shown to provide equivalent or better adhesion levels compared with degreased-  
329 only adherends; see Table 3. Furthermore, in durability trials, using statically  
330 stressed SLS joints immersed in hot water, a commercially available phosphate-  
331 based, chemical conversion coating was shown to provide bond durability signifi-  
332 cantly inferior to the TEA CO<sub>2</sub>-laser treatment. It should be noted though that a  
333 chromate-based process gave markedly superior bond durability in these trials; see  
334 Table 4. Lu and Aoyage (1994) also confirmed the effectiveness of laser cleaning on  
335 various substrates using a KrF excimer source.

336 Another process which is gaining popularity is the use of CO<sub>2</sub>-cryoblasting as  
337 discussed by Brewis et al. (1999). The combined thermomechanical action of solid  
338 CO<sub>2</sub> particles impacting upon surfaces combined with the effective solvent action

339 means that highly contaminated surfaces can be readily cleaned very quickly and  
340 over large areas. This process was shown by Brewis to effectively leave an atomi-  
341 cally clean surface on previously contaminated aluminum and to introduce some  
342 surface texture. SLS joint testing was carried out using aluminum 5251 alloy  
343 adherends and, in terms of creating initial adhesion, this treatment proved better  
344 than simple ultrasonic degreasing and as effective as grit-blasting. A further devel-  
345 opment by Deffeyes et al. (1997) is the use of cryoblasting followed by ultraviolet-  
346 light irradiation which proved to be highly effective at removing oils and waxes from  
347 aluminum surfaces. This combination process was shown to produce a zero-degree  
348 water contact angle on the treated surface, indicating complete removal of the  
349 preexisting contaminants.

350 In summary, although externally sourced surface contamination can be accom-  
351 modated by some adhesive-substrate combinations, it is generally regarded as good  
352 practice to remove such material prior to adhesive application. There are many  
353 treatments which will achieve this outcome; the preferred one will depend upon a

number of factors, including the chemical nature of the contaminant and adherends. Some degrease options can be considered as reasonably effective stand-alone treatments. In general terms though, mechanical, chemical, electrochemical, and some alternative treatments tend to give improved levels of adhesion and durability compared with simply degreasing.

### 7.3.2 Polymer Treatment: Removal of Contamination and Surface Functionalization

As previously mentioned, the surface of polymers can comprise contaminant from both internal and external sources. The aim of many polymer pretreatments is often to remove such material and to introduce or to expose desirable chemical functionality. This topic has been extensively covered by Brewis (1982) and Brewis and Briggs (1985); note that many of the treatments considered in Brewis' early work are now favored by industry and so are relevant to this book.

For some polymers, a solvent wipe will suffice to remove, for example, plasticizers, which have migrated to the air interface. However, not all solvents are compatible with all polymers, so care must be taken to select the most appropriate solvent.

Polymers which are difficult to bond such as polyolefins and elastomers may require the removal of such weak boundary layers and also the introduction of relevant functional groups; these are often oxygen-containing. The most favored methods to achieve this result include: flame treatment, corona discharge treatment, and plasma treatment. These are all dry processes which can oxidize a range of polymers by using excited gases, ions, neutrals, electrons, or free radicals. An illustration of the usefulness of plasma treatment to treat fluoropolymers, namely poly (vinyl fluoride) (PVF) and polytetrafluoroethylene (PTFE), has been given by Brewis et al. (1995). In this example, argon, oxygen, air, and nitrogen plasmas were used. In the case of PTFE, there was no significant change in surface chemistry observed by XPS; however, SLS joint strengths increased from 420 to 1,860 N following argon plasma treatment for 30 s. This result was explained as due to the removal of a preexisting weak boundary layer. In contrast, with PVF, XPS showed the various plasma types to increase oxygen levels in the surface from 0.8 up to 12.4 atom %, in the case of the oxygen plasma. The introduction of this level of oxygen functionality resulted in an approximate tenfold increase in initial adhesion. Similar large increases in adhesion are observed in many studies of polymer–polymer adhesion, these are explained in terms of the removal of weak boundary layers, an increase in surface functionality or free energy, or enhanced roughening of the polymeric substrate using these methods. A recent study by Stewart et al. (2005) has demonstrated the effectiveness of air plasma treatment of polypropylene as applied to complex shapes; in this case, a car bumper, which, with an optimized treatment condition, demonstrated good adhesion post treatment.

As an alternative to the above-mentioned treatments, Charbonnier et al. (2001) discussed the use of excimer laser and ammonia gas treatment for the

functionalization of polycarbonate and polyimide. In their study, a large increase was observed using X-ray photoelectron spectroscopy (XPS) in the levels of nitrogen, from 6.4 to 17.6 atom%, with no great change in the levels of oxygen as a result of a 3 min treatment. The improved adhesion of a subsequently applied palladium complex was attributed to this increased level of nitrogen, given the affinity of palladium to form “N-Pd” bonds.

Note that a consideration of plasma polymerized coatings, which is a related technology, is outside of the scope of this contribution; attention is drawn, however, to the relevant book by Strobel et al. (1994).

## 7.4 Mechanical Treatments and the Role of the Interphase

Mechanical treatments generally remove friable surface layers and generate macro-rough surface texture on metallic surfaces. They are generally combined, before and after, with a simple degrease process.

The penetration of polymers into the asperities on, or within, surfaces has been well discussed in the literature; an early study was carried out by Packham et al. (1974a) who investigated the keying of polyethylene into the pores present on anodized aluminum. The effect of such polymer penetration and the importance of mechanical interlocking with such highly textured surfaces which will facilitate energy dissipation within bondlines was further discussed by Packham et al. (1974b) and, amongst others, Rider and Arnott (2001). One important conclusion from such studies is that the stresses applied to joints containing highly rough adherends are potentially no longer concentrated at the surfaces, but are then distributed more widely within the bondline, enabling more plastic energy dissipation to occur and increased observed levels of adhesion. Photoelastic (Packham 2010) and Moiré interferometry (Asundi 1987; Sargent and Ashbee 1985) studies have directly observed the nonuniform stress distributions within bondlines and in the region of surface asperities. One advantage of creating such asperities is that stresses are then potentially dispersed into and away from the “interphasial” region.

It has been acknowledged for some years now that there is a zone between the substrate and adhesive within the bondline that is different to that of the bulk adhesive. In an early study, Allen et al. (1972) noted thin glassy layers remaining on titanium alloy lap joints after testing, free from the filler and pigmentation associated with the bulk of the adhesive. Similarly, Sharpe (1972) in 1972 commented upon the fact that, at that time, the components within a bonded system were treated as discrete entities, when, in fact there are many more layers present in a bonded joint. Since this pioneering work, many other workers have begun to study the interphasial chemistry. For example, Fondeur and Koenig (1993) conducted Fourier transform infrared (FTIR) microscopy studies on aluminum substrates coated with a dicyandimide cured epoxide adhesive. They found that there was a variation of the dicyandiamide concentration with thickness through the adhesive layer. Using both the nitrile and carbonyl peaks, they found that for untreated aluminum substrates, there was a comparatively high level of dicyandimide near

to the substrate surface that coincided with a high level of carbonyl material. The opposite was observed for chromic acid anodized adherends, where the dicyandimide content was at a minimum close to the substrate.

Similarly, Nigro and Ishider (1989) conducted FTIR reflectance absorption spectroscopy on an epoxide resin with a BF<sub>3</sub>-monoethylamine catalyst system applied to polished 1008 Drawing Quality steel substrates. They studied the degree of conversion of the oxirane (epoxide) ring as a function of depth and found that epoxy conversion rates were higher closest to the steel substrate. The epoxy prepolymer was also applied onto the steel surface without hardener and the same phenomenon was still observed. They suggested that the steel might, in some way, interact with the epoxide adhesive causing homopolymerization of the epoxide resin at the surface of the substrate.

Likewise, Roche et al. (2002) studied the resultant interphase of a DGEBA epoxide when combined with either an aliphatic, aromatic, or cyclic diamine curing agent and then applied onto aluminum or titanium surfaces. They found differences through the thickness of the adhesive layer: the  $T_g$  was lower at the interphase for both substrates and the stoichiometric ratio was higher nearer to the substrate, with an amine to epoxy ratio of 1.2 as opposed to 1 within the bulk region. Placing the DGEBA and IPDA individually in direct contact with the aluminum and titanium substrates, they found that dissolution of the metal oxides occurred in the basic IPDA liquid. Taking samples of the reacted IPDA liquor and combining them with DGEBA, they measured the  $T_g$ , Young's modulus, and the epoxide amine ratio. They compared this with the properties of the interphasial regions and bulk polymer regions. What they found was that the modified IPDA system had the same properties as the thin layer samples with reduced  $T_g$  and differing Young's moduli.

Safavi-Ardebili et al. (1997) conducted experiments upon acid etched A1100 aluminum substrates bonded with an epoxide adhesive, Hysol EA-9346. Sectioning the joints at varying angles, they examined the bondline with EDS, they measured the interphasial region, and found that this layer was irregular in thickness ranging from  $2 \times 10^{-6}$  to  $6 \times 10^{-6}$  m. Nano indentation revealed that there was a gradient of the Young's modulus, which increased by approximately 13% in the interphasial region when compared to the values obtained within the bulk of the bondline.

Likewise, Kollek (1985) used FTIR diffuse reflectance analysis to study the absorption chemistry of epoxide and phenolic resins on aluminum substrates. He observed that both the curing agent and the epoxy resin monomer were adsorbed on the aluminum oxide surface. They found that the dicyandiamide monomer was adsorbed by the oxide layers of the substrate and was attributed to the acid proton of the aluminum oxide reacting with and reducing the observed nitrile peaks. For the epoxide monomer, less adsorption was observed, and it was suggested that this occurred by the opening of the epoxide ring.

More recent studies have further added to the understanding of polymer-metal interactions and confirm the highly variable chemical nature of the polymer-metal interphase (Gaillard et al. 1994; Bistac et al. 1997; Roche et al. 2006); particular attention is drawn to the work of Possart in this area (Possart 2005). Of critical importance, the interphase comprises a region whose chemical composition might be

very different from the bulk polymer. The mechanical properties of the interphase might, as a consequence, be different as observed by many of the workers in this area mentioned above. The extent of the polymer-metal interphase is also the subject of some discussion with some researchers focusing attention on the polymer up to a few nanometres from the metal surface, whereas others maintain that the region of modified chemistry and properties extends up to many micrometres. What is clear is that the chemistry and resultant mechanical properties of the interphasial polymer are very different from the known bulk polymer properties; hence, the ability of this material to sustain loads and resist the initiation of damage and its reaction to moisture, all factors which might influence failure in the interphasial region, are more difficult to predict than the bulk polymer. Other complications arise when, for example, water interacts with the interphasial polymer and accelerated corrosion can be initiated.

In summary, the creation of rough surfaces provides the possibility of redistribution of stresses away from the interphasial polymer and into the bulk adhesive. This, in addition to the fact that rough surface have much higher specific surface areas for adhesive interaction and texture for mechanical attachment, means that the creation of such surfaces is highly desirable.

The simplest form of mechanical treatment is to hand abrade using dedicated abrasive pads or papers, followed by a solvent, or similar, wipe to help remove residues. This process may be effective but can also introduce contamination and may be nonuniform in application (Bishopp et al. 1988). On an atomic scale, the surface can retain contaminating residues from the pads or papers which cannot easily be removed. In terms of resultant texture, on the macroscale, the hand-abraded surface tends to comprise broad flat areas of unaltered surface in between the grooves created by the treatment. The ratio of the surface area exhibiting these features is clearly dependant on the degree of treatment applied.

A more controlled method of surface treatment is by grit-blasting or slurry-blasting followed by degreasing. Frequently, coupling agents are also applied post grit-blasting. This topic will be covered in greater detail in ► [Chap. 11, “Organosilanes: Adhesion Promoters and Primers.”](#) During grit-blasting, the abrasive media, which usually comprises alumina, chilled iron, or silica, is propelled to the surface under pressurized air, while in slurry-blasting alumina is usually used, which is transported via high pressure water jets. Clearly, treatment parameters such as pressure, times, and blast media can be optimized to produce the desired surface texture. In one study of the grit-blasting treatment, Critchlow and Brewis (1995a) quantified the degree of enhanced roughness created using various grades of alumina from 40/60 to 320, using profilometry, and changes to the surface chemistry, using AES. With 5251 grade aluminum alloy, grit-blasting did improve adhesion, but the importance of post cleaning to remove embedded grit and to create a subsequently wettable surface was emphasized. In general, the enhanced surface features created by grit-blasting provide reasonable levels of initial adhesion, Critchlow and Brewis (1996) in a review article identified a number of studies where this was the case. However, it should be noted that the very thin oxide-remaining post grit-blasting leaves metals susceptible to corrosion, and durability in hot-wet environments can

be poor. Bishopp illustrated this point by immersion of aluminum 2024-T3 clad alloy joints in 85% RH at 70 °C and measuring the fall-off in peel strengths with time (Bishopp et al. 1988). Under these conditions, joints incorporating grit-blasted adherends retained only 20 N/25.4 mm compared with anodizing which retained up to ~180 N/25.4 mm after 10 days exposure. Bishopp suggested that in some cases, surfaces can be “too rough,” allowing air to be trapped at the adhesive-metal oxide interface, i.e., there is incomplete wetting with poor durability resulting.

The possibility of using power beams for surface texturing has been originally discussed by Tavakoli (1994). In this sense, the term “power beams” includes the use of laser and electron beams for the texturing of surfaces. Significant work has been carried out in this area with the establishment of the Surfi-sculpt® and Comeld® processes. Some details of the structures generated by electron beam bombardment have been discussed by Tu et al. (2010). Such processes look highly promising for the generation of highly complex structures up to millimeters in scale on metallic, polymeric, and composite surfaces.

In summary, good initial levels of adhesion can be observed using metallic adherends post-mechanical treatment due to the ability of such surfaces to partially negate any adverse influence of the interphase and to provide desirable texture. However, the thin oxides present after such treatments tends to cause mechanically treated joints to perform badly, particularly in durability tests carried out under hot-wet conditions. The application of primers and coupling agents is usually carried out to obviate this poor performance. Also, the use of chemical treatments can be carried out if enhanced durability is required, as discussed in the following section.

The use of such mechanical methods on polymers is, to some extent, limited. Mechanical treatments such as grit-blasting can introduce high stress and damage into the substrate which metals can accommodate, but some polymers cannot. However, this is not always the case and grit-blasting is routinely used to treat carbon fiber-reinforced polymer (CFRP) composites. Attention is drawn to work of Belcher at NASA who reported that grit-blasting of CFRP performed similarly to the use of peel ply or laser ablation. The importance of using optimized mechanical methods though has been highlighted by Stone (1981) in his study on the influence of abrasion on CFRP adherends.

---

## 7.5 Chemical Treatments

### 7.5.1 Chemical Treatments for Metallic Adherends

These are invariably aqueous-based processes which may be applied from spray or full immersion. Importantly, surfaces are generally degreased prior to chemical treatment. In practical terms, this is to reduce drag-out contamination passing from stage-to-stage and so obviating the possibility of contamination present in the final solution. Chemical treatments can be considered as etchants or, alternatively, used to produce chemical conversion coatings.

Etch solutions invariably utilize strong single or mixed acids, although, in some rare instances, strong alkaline solutions can be used. The purpose of such etchants is to remove friable organic or inorganic layers, including loosely bound oxides, hydrated oxides, or other corrosion products, and to leave an enhanced surface topography. In principle, with metallic adherends, after rinse operations, the surfaces should also be of a high surface energy being atomically clean. Depending upon the treatment conditions used, i.e., solution type, time, and temperature along with substrate characteristics such as the alloy type and thermal history, the resultant topography can vary from macro- to nano-rough. The nanoscale features being regarded as particularly useful to enable the creation of a “micro-composite interphase.” The benefits of such topography have been discussed above and an illustration of the commonly used Forest Products Laboratory (FPL)–etched aluminum surface is given in ► [Chap. 8, “Surface Treatments of Selected Materials.”](#) Many of the common acids used for the prebond treatment of metallic adherends have been reviewed by Minford (1993) in the case of aluminum alloys and Critchlow and Brewis (1995b) for titanium alloys. The aforementioned works by Minford and Critchlow indicate that, as with mechanical treatments, acid etching can produce excellent initial levels of adhesion but, again, a relatively thin oxide is present after such treatments so that durability can be compromised. Chemical conversion coating is the simplest method of producing thicker, passivating films on metal surfaces.

Chemical conversion coatings develop a passivating film by means of a complex growth and deposition mechanism. The degree of roughness introduced by such conversion coatings on surfaces can be highly variable. For example, on medium carbon steel, this variability was illustrated in the work of Critchlow et al. (2000). In this study, a range of chromate-free conversion coatings were compared with chromate-containing processes. The best-performing process, Bonderite 901-Pyrene 8–90, provided a thick, mixed oxide extending to approximately 150 nm, which was highly nodular on the nanometre scale and which contained polymeric functionality in its outer layers. It was concluded that these physicochemical properties were responsible for the excellent adhesion performance: with the nodular surface capable of interphase formation, some epoxide component possibly present to react with the adhesive and good barrier corrosion protection afforded by the oxide. With this treatment combined with a single part epoxide mean initial SLS strengths of 57.9, MPa were measured. Significantly, after 8 weeks of immersion in water at 60 °C, these joints retained approximately 80% of their initial joint strength. Due to the complex nature of the conversion coating process, it should be noted that although the aforementioned Bonderite 901-Pyrene 8–90 process worked well for medium carbon steel, it will not necessarily be applicable to other adherends. There are, however, many available conversion coatings some of which are detailed below.

Phosphate coatings are widely used in the automotive industry due to their ability to treat both aluminum and steel. These coatings offer good levels of adhesion and, although the corrosion resistance is generally regarded as marginally lower than that of chromate-containing coatings, joints produced offer good environmental stability. A study of chromate-phosphate-based conversion coatings has been carried out by Maddison and Critchlow (1996). This study showed that the preexisting oxide

on aluminum 5251 alloy was removed within the first few seconds of treatment followed by a controlled film formation up to a thickness of approximately 1,000 nm with extended treatment times up to 60 s. The resultant film composition was highly complex comprising Al, O, P, and Cr. Importantly, with reasonable treatment times, the chromate-phosphate treatment demonstrated excellent durability with a single part epoxide in impact testing carried out on SLS joints which had been immersed in water at 75 °C prior to testing. In this experiment, the chromate-phosphate-treated joints absorbed over five times more energy than alkaline-cleaned controls.

Underhill and Rider (2005) propose an interesting alternative: a simple hot-water conversion coating. They have shown this method to have understandably low processing costs as well as suggesting successful adhesive performance. The same group has also demonstrated the effectiveness of boiling water treatment-applied post grit-blasting and subsequently followed by epoxide-functional silane application (gamma-GPS).

Molybdenum-based coatings have been considered as alternatives due to molybdenum having an electronic structure similar to that of chromium. Molybdates are known to be corrosion inhibitors. When incorporated within aluminum oxide films, the molybdate ( $\text{MoO}_4^{2-}$ ) is regarded as providing excellent corrosion resistance to pitting. The high cost of molybdenum conversion coatings is a possible explanation for their lack of popularity.

Of particular note are the titanium-zirconium-based solutions which are the basis of many commercial conversion coating systems due to their ease of application. These coatings, for example, are widely used to help attain good lacquer adhesion in the canning industry. Titanium-zirconium coatings produce thin films in very short application times, in the order of a few seconds, and good adhesion and corrosion performance is reported for a range of aluminum alloys. On some aluminum alloys, namely 6060, preferential deposition has been found to cause localized variations in film thickness which, when coupled with the fact that these processes produce colorless films, makes quality control assessments very difficult, however. For example, Schram et al. (1995) showed such conversion coatings to extend to about 10 nm in thickness independent of treatment time. Using AES, the same workers identified a duplex structure to the coating with a simple oxide present adjacent to the aluminum 1050 alloy substrate, but a more complex aluminum oxide-zirconium fluoride plus polymer present in the outer nanometres of the film. Critchlow and Brewis (1997) also studied such films on aluminum and confirmed the highly complex, duplex nature of the resultant films. These workers demonstrated that static-stressed SLS joints immersed in water at 60 °C had much greater times to failure compared with degreased-only or grit-blasted controls. Subsequent studies have shown the best-performing conversion coatings, on aluminum alloys, at least match the durability performance of the best acid etches, such as the FPL. However, the use of hot-water immersed static SLS joints has demonstrated that titanium-zirconium conversion coatings to be less durable than the phosphoric acid anodizing (PAA) treatment.

Cerium-based conversion coating processes are thought to precipitate Ce (III) hydroxide at regions of high pH. This precipitation gives the coating corrosion inhibiting properties similar to that of titanium-zirconium-based coatings. The

inhibition is believed to decrease the rate of cathodic oxygen reduction. A multistage process combining chemical and electrochemical treatments based on cerium and molybdenum has been studied and is shown to enhance the corrosion protection in the high-copper-content aluminum alloys, for example, the aerospace 2024 and 7075 alloys. The combined process offers good levels of adhesion on the 2xxx series alloys but mixed results are obtained on other alloys. One disadvantage of this process is the extended time taken to produce the coating, which increases production costs.

In summary, the chemical treatments when applied to metals do remove preexisting friable oxides or hydrated oxides in the early stages of the treatment followed by controlled film formation. The films can offer the advantages of increased surface free energy or, in the case of conversion coatings, the possibility of polymeric functionality introduced. The conversion coating processes, in particular, can provide corrosion protection via a number of mechanisms; the result of which is the observed increase in durability of such treated adhesive joints exposed to hot-wet conditions. A range of surface morphologies can be generated by both etch and conversion coating processes, and techniques such as electron and atomic force microscopy (AFM) can be used to monitor these treatments to provide optimized surface texture which will facilitate interpenetration of the polymer into the asperities of the treated surface. Whilst, chemically treated surfaces do offer a range of physicochemical properties which enhance adhesion, the electrochemical processes generally provide the best bonding surfaces for aluminum and titanium; these are discussed in the following section. Note that anodizing of steels is not possible.

## 7.5.2 Chemical Treatments for Polymeric Adherends

In addition to the dry processes detailed previously, wet chemical processes can also be used to modify polymeric surfaces to introduce desirable physicochemical properties. For example, chromic acid has been used as an oxidizing agent to this end for some time (Brewis and Mathieson 2001). Given the concerns over the usage of hexavalent chromium in this field, there are ongoing efforts to find suitable replacements. In one study by Brewis et al. (1995), a proprietary etchant, Tetra-Etch, was used to treat two fluorinated polymers, PTFE and PVF. The results of this treatment are given in Table 5. XPS showed Tetra-Etch caused the PTFE surface to lose almost all of its surface fluorine with a short treatment time of 10 s. This was accompanied by a large increase in the surface oxygen levels from zero to 11.6 atom%. This increase in useful oxygen-containing functional groups enabled a tenfold increase in measured adhesion in the SLS configuration. The PVF, however, required longer treatment times with the best results observed after 60 min immersion in Tetra-Etch. Again, a large increase in adhesion was observed from 360 to 3,020 N, but in this case, there was relatively little surface modification observed by XPS. This result was attributed to the removal of a potential weak boundary layer by the Tetra-Etch treatment.

Similarly, Dahm et al. (2005) studied a range of wet chemical treatments, including various oxidizing and halogenating agents on both additive-free and fully formulated

t.1 **Table 5** To show surface compositions and SLS joint strength of PTFE and PVF polymers following Tetra-Etch treatment for various times (Brewis et al. 1995)

t.3	Polymer/treatment	XPS (atom%)			Failure load (N)

700 elastomers. Of particular interest were styrene butadiene (SBS) and ethylene-  
701 propylene-dimer terpolymers (EPDM). In this study, extensive use was again made  
702 of XPS to relate changes in surface chemistry to SLS strength determined using a  
703 composite SLS joint. As with polyolefins, elastomers proved highly receptive to  
704 oxidizing agents, showing a large increase in surface oxygen content with, for  
705 example, potassium permanganate, potassium dichromate, Fenton’s reagent, and  
706 other such treatments. In general, however, the oxidizing agents provided only a slight  
707 increase in observed adhesion; this being attributed to the production of a layer of low  
708 cohesive strength at the surface of the elastomers. In particular, static secondary ion  
709 mass spectrometry (SSIMS) was used to study the SBS surface following potassium  
710 permanganate treatment, and it could be inferred that this treatment did cause some  
711 chain scission of the elastomer surface. In contrast, a number of chlorinating agents,  
712 including sodium hypochlorite solution, Chloramine-T, and trichloroisocyanuric acid  
713 (TCICA) were studied, and these also created highly modified SBS and EPDM  
714 surfaces. With these treatments, however, a large increase in adhesion was observed,  
715 by a factor of approximately x4 to x20, depending upon the specific treatment on SBS.  
716 The mechanisms by which this was achieved have been discussed by Dahm et al.  
717 (2005). In summary, wet chemical treatments can be highly effective on a range of  
718 polymers by the removal of weak layers and the introduction of desirable chemistry.  
719 As with dry processing of polymers, there is always the potential for over-treatment,  
720 causing chain scission and a net reduction in adhesion levels. For this reason, such  
721 treatments should always be optimized for a specific application.

722 **7.6 Electrochemical Treatments**

723 **7.6.1 Introduction to Anodizing**

724 Regarding the higher treatments, and the anodizing processes in particular, these can  
725 be applied to a number of metals but are mostly carried out on aluminum and  
726 titanium and their alloys. These treatments are in the main complex, time consuming,  
727 and costly to carry out. There are also legislative drivers which make the use of some

processes, especially those which utilize hexavalent chromium, highly undesirable. Other factors such as energy and chemical disposal costs also deserve consideration. However, for structural metal bonding, these treatments are highly recommended as they impart all of the fundamental physicochemical properties required to provide the best initial levels of adhesion and durability of any treatments, namely, wettability, micro- and nano-roughness, mechanical stability, and passivation. Note that to take full advantage of the porosity present on anodic oxides, it is often recommended that primers are used in combination.

There exists extensive literature on this topic and attention is drawn to the highly relevant book by Minford (1993) and to ► Chap. 8, “Surface Treatments of Selected Materials” of this handbook. It is widely reported, and further discussed in ► Chap. 8, “Surface Treatments of Selected Materials,” that the most successful treatments for aluminum and titanium include direct current (DC) anodic oxidation in chromic, phosphoric, or sulfuric acid electrolytes (CAA, PAA or SAA). It is, of course, recognized that other electrolytes are used, some of which will be discussed later in this section. The Bengough–Stuart 40/50 V CAA process is currently the preferred pretreatment of European aerospace manufacturers, and on clad aluminum alloy produces a porous surface oxide typically 2–3  $\mu\text{m}$  thick with a pore diameter of approximately 25–35 nm. This oxide offers possibly the best levels of adhesion and environmental resistance. PAA, as a prebond process, is preferred by Boeing Commercial Airplane Company. Boeing claim good in-service durability performance with adherends using this pretreatment. The oxide produced is described as being 400–800 nm thick incorporating 100 nm of small outwardly protruding fibrils. The phosphate content of the oxide improves stability toward water and therefore improves the hydration resistance as discussed in the following section. PAA is considered to be very tolerant to variations in processing parameters compared to CAA. PAA is claimed by Boeing to provide the most durable joints but, in some studies, it is shown to be comparable to or even worse than CAA.

Sulfuric acid anodizing (SAA) has also been widely compared to CAA, PAA, and FPL etches in the review by Critchlow and Brewis (1996). As indicated by Critchlow and Brewis, SAA prepared joints usually demonstrate moderate initial joint strength and relatively poor long-term joint durability. In general, SAA-treated adherends are significantly out-performed by CAA and PAA but perform similarly to FPL etched adherends. The oxide thickness associated with SAA is of the order of 10  $\mu\text{m}$  and is significantly thicker than oxides produced during other anodizing processes. For this reason, it is ideally suited to corrosion protection applications. SAA followed by a phosphoric acid dip has been shown to improve joint performance by the opening up of the otherwise highly dense porous oxide.

Alternating current (AC) anodizing produces a similar but thinner surface oxide structure to the aforementioned direct current (DC) treatments, but with the advantage of the adherend being electrolytically deoxidized on the negative half of the applied voltage cycle. This reduces the importance of the preceding degrease and alkaline cleaning usually associated with conventional DC anodization. This, however, comes at a cost. The solution–adherend resistance is much less on the cathodic half of the cycle than it is on the anodic half. Consequently, the current density is

much larger and can potentially cause an undesirable effect known as “burning” or “powdering” on the surface. A compromise must be struck between treatment time, temperature, and applied voltage in order to minimize this effect. The thinner resultant surface oxide and limited applications are consequences of this. The two main electrolytes, indicated in the literature as being used for AC anodizing, are phosphoric acid and sulfuric acid. A number of workers have investigated both electrolytes and found promising results indicating that AC anodizing was suitable as a prebond process. Further details of this treatment, including a consideration of the mechanisms of anodic film formation, follow.

## 7.6.2 Structure and Composition of Anodic Films

It has been accepted for some time that an anodic oxide formed on the surface of an aluminum alloy typically consists of an inner, thin, compact oxide layer, called the barrier layer, and a porous outer oxide displaying a honeycomb-like hexagonal close-packed structure, as illustrated in Fig. 1. The thickness of the barrier layer is approximately 0.1–2.0% of the overall film thickness and is dependent upon the electrolyte concentration and the applied anodic voltage. Several authors propose the dependency to be close to 0.01 nm/V. It is suggested that the idealized honeycomb arrangement is due to repulsive interactions between the pores during anodic film growth, and that a mechanical stress resulting from the volume expansion of the forming oxide causes these repulsive forces. In doing so, the formation of a hexagonal arrangement during nucleation occurs. Production rates of between 1 and 5  $\mu\text{m/h}$  are typical. Factors such as the alloy type, the thermal history of the metal, deoxidizing process used, and electrolyte agitation can be a very important factor in the formation of ordered pore arrays.

When an anodic voltage is applied to aluminum in an electrolyte, a current will flow through the electrolyte to the anode and aluminum oxide or hydrated aluminum oxide will be produced on the surface. If this oxide is soluble or partially soluble in the electrolyte, then dissolution will occur creating the porous oxide layer. The porosity of the oxide will therefore be a function of the solubility of the oxide in the electrolyte, and the film will only grow if this rate of dissolution is less than the rate of oxide production. An important realization is that the oxide grows from the bottom of the film rather than being deposited on the outer surface as in electrodeposition. For this reason, it is pivotal in the understanding of porous oxides that the outer surface, being formed first, has been in contact with the electrolyte for the longest time and may have been notably modified.

The growth of the oxide film is reported to be made possible by the solid-state migration of the  $\text{Al}^{3+}$  and  $\text{O}^{2-}$  ions which move outward and inward, respectively, through the film. This movement is driven by the electric field created during anodization. The development of the new material at the metal/film interface is due to oxidation of aluminum atoms to form  $\text{Al}^{3+}$  combining with the  $\text{O}^{2-}$  ions present in the electrolyte. This migration results in new material being formed in two places, the metal/film and the film/electrolyte interfaces. The second phase elements

**Fig. 1** To show the idealized cell structure of a porous aluminum oxide grown post chromic acid anodization

present on the alloy surface are either removed or oxidized along with the aluminum. A further mechanism, field-assisted dissolution, may occur due to the of the electric field concentration across the barrier layer which is thermally enhanced due to localized Joule heating and the aforementioned ionic mobility. This effect causes the aluminum to oxygen bonds in the oxide lattice to weaken, resulting in a dissolution at the oxide/electrolyte interface. The chemical and field-assisted dissolution take place with widely differing rates, with the field-assisted being reportedly up to 3,000 times greater. Note that the electrolytically driven growth competes with these dissolution mechanisms to produce the final anodic film under steady-state conditions. The resultant surface features associated with the anodizing are further detailed in ► [Chap. 8, “Surface Treatments of Selected Materials.”](#) It is, however, sufficient to state that the microscopically rough features produced can increase the specific surface area of an anodized adherend by a factor of several hundred. It is widely accepted that wetting by an adhesive, or primer, into a porous anodized structure such as the PAA oxide or the CAA oxide is possible and is necessary for the formation of a strong bond via the formation of a “micro-composite” region due to this penetration of adhesive into the oxide. The microstructure generated by the CAA process on both bare and clad aluminum alloy is illustrated in Fig. 2. Note the non-idealized structure which is typical of that on the higher aluminum alloys.

### 7.6.3 Physical Factors Affecting Anodic Oxides

Physical properties such as the temperature of the electrolyte and the anodizing voltage have been shown to have a marked effect on the anodic oxide film formation. For example, an increase in local temperature due to convection heat transfer enhances the field-assisted dissolution at the pore bases and results in an increase in current density. The anodizing voltage has been shown to affect most of the overall film properties such as the barrier layer thickness, cell wall thickness, pore diameter, and the overall thickness of the oxide layer. The electrolyte temperature also has an effect on these properties due to its influence over the dissolution power of the solution. Increasing the temperature produces thinner porous and barrier layers, larger pore diameters, and thinner cell walls. Reducing the temperature has the opposite effects. The alloy used also affects the oxide composition. The copper rich 2xxx series alloys adversely affect the film morphology and integrity. The oxidation of copper and the inclusion of  $\text{Cu}^{2+}$  in the anodized alumina is associated with  $\text{O}_2$  evolution which causes localized film cracking and can lead to nonuniform current flow through the film.

### 7.6.4 Alternatives to Phosphoric and Chromic Acid Anodizing

As detailed above, anodizing of aluminum and titanium alloys provides a surface that is corrosion resistant and which may be receptive to applied organic layers. Such

functionality is achieved by engineering a hydrated oxide film with controlled nanometre-scale porosity within an adherent coating measuring typically 2–3.5  $\mu\text{m}$  in thickness. The 20–30 nm diameter ( $\Phi$ ) pores created during chromic acid anodizing (CAA), for example, enable interphase formation with the organic layer giving excellent adhesion, while the oxide present provides barrier corrosion protection. There is, however, a conflict between the requirement for good corrosion resistance, which dictates a compact pore structure with thick cell walls and small diameters, and adhesion, which requires good interlocking and a large pore diameter. The former case is satisfied by the sulfuric acid anodizing (SAA)–based processes with  $\Phi \sim 5$  nm, and the latter by phosphoric acid–based processes, where  $\Phi \geq 50$  nm. The CAA process, in some respects, provides a compromise; it is, however, very widely used but for a number of reasons drop-in replacements are being sought (Critchlow et al. 2006).

One option is the use of a more benign electrolyte, such as boric-sulfuric acid. In one study on boric-sulfuric acid anodizing (BSAA), Critchlow et al. (2006) modified a standard process by varying the deoxidizing stage prior to anodizing, and introduced a post-treatment stage in order to optimize structural adhesion between a range of aluminum alloys and a single part epoxide. It was shown that BSAA could provide all of the physicochemical parameters required for excellent adhesion being capable of replacing CAA for adhesively bonded components. The conclusions from the study by Critchlow et al. (2006) were that increasing the temperature of the electrolyte from room temperature to 35 °C increased the pore diameter of the BSAA oxide film, which allowed more complete surface wetting by the adhesive/primer and maximized the pore penetration depth of the primer. This resulted in joints which replicated CAA for environmental durability and adhesion performance.

Importantly, however, duplex structures offer the advantages of a large pore diameter in the outer layers of the anodic oxide and very small pores in the inner layer close to the metal to give the optimum adhesion and corrosion performance. There are a number of methodologies which might be used to achieve a resultant duplex structure. Yendall (unpublished work) has investigated the use of an electrolytic deoxidizing process (EPAD) followed by a conventional SAA. Figure 3 shows

**Fig. 3** (a) Low-magnification FEGSEM image to show the through thickness duplex structure of the EPAD plus SAA oxide on clad 2024-T3 aluminum, and (b) the surface region at high magnification

the structure formed using an optimized EPAD plus SAA process. A number of process variables, for example, immersion times and temperatures plus acid electrolyte types and concentrations were considered to achieve this optimized structure. 2024-T3 clad aluminum alloy bonded with the BR127/FM73 primer/adhesive system (Cytec) exposed to 60 °C and tested using the standard wedge test configuration showed comparable results, with optimized processes, to CAA-treated controls. In contrast, the SAA only treated aluminum alloy performed very unfavorably in this test due to the lack of primer penetration; see Fig. 4. Other electrolytes have also attracted much recent attention such as the tartaric-sulfuric-based process. Although DC anodizing does provide many of the desirable features required for optimized bonding, alternating current (AC) or combined AC then DC combination processes do offer some further advantages and will be discussed in the following sections.

### 7.6.5 Alternating (AC) Current Anodizing

Apart from the obvious use of alternating current, the main difference between AC and DC anodizing is the increased porosity and ductility of AC films. The formation of the oxide is essentially the same as for direct current anodizing with the exception of the extra time during the cathodic half-cycle when extra field-assisted dissolution can take place, this being the cause of the increased porosity. Fortunately, this dissolution reaction is not as efficient as the anodic production reaction and dissipates much of the energy input by means of hydrogen evolution and heat. This results in an overall film thickening during AC anodizing. The proposed reactions for AC anodizing in a sulfuric acid electrolyte are given below [1] and [2]:

**Fig. 4** To show the results of wedge testing with clad 2024-T3 aluminum exposed to deionized water at 60 °C

• Anodic reactions [1]:

• Cathodic reactions [2]:

There is a tendency during AC anodizing for compounds from the electrolyte to be deposited within the anodic film, this can be an advantage if, for example, phosphates ions are incorporated, for reasons discussed in the following section. The oxide morphology of an AC anodized surface does not differ widely from the oxide produced using a DC counterpart when using either sulfuric or phosphoric acid electrolytes. The oxide retains the columnar porous structure with the only differences being the reduced thickness and increased pore diameter due to the extra dissolution time allowed on the cathodic part of the voltage cycle.

The overall thickness of the oxide is dependent on the electrolyte composition, but more importantly on the electrolyte temperature as this has, by far, the greatest effect in increasing the dissolution rate of the oxide. Specifically, with electrolytes comprising of sulfuric acid, there are two main processing difficulties; the discoloration of the oxide due to the deposition of sulfur compounds and the difficulty in growing a thick oxide layer without burning the surface.

AC anodizing in hot sulfuric and hot phosphoric acids gives clear advantages compared with conventional DC treatments. During the cathodic half-cycle, hydrogen evolution produces a cleaning effect of the surface of the substrates, possibly reducing or even eliminating the need for multistage degreasing and deoxidizing steps. The resultant anodic films are produced in treatment times typically in the order of 10 to 60 s. Hot AC SAA is typically conducted in an electrolyte of 15% sulfuric acid at a temperature of around 80 °C, whereas hot AC PAA has parameters of 10% acid concentration and 50 °C. The current densities for both these processes are held at 10<sup>3</sup> A/m<sup>2</sup> rms. Work by Johnsen et al. (2004) has shown AC anodizing to be comparable in mechanical performance to DC anodizing in equivalent electrolytes.

### 7.6.6 Alternating Current–Direct Current Anodizing (ACDC Anodizing)

The duplex structure created by first AC anodizing aluminum followed by a DC anodize was optimized by Cartwright (2005). Figure 5 shows the evolution of

**Fig. 5 (a–d)** FEGSEM micrographs showing the development the AC anodized 2024-T3 clad aluminum alloy surface with application periods ranging from 5 to 240 s in the phosphoric/sulfuric acid electrolyte

the honeycomb-like porous oxide created by the AC phase. Figure 6 shows the fully formed optimized ACDC structure in cross-section at various magnifications. A range of tests have been conducted using 2xxx (clad and bare), 5xxx, 6xxx, and 7xxx (clad and bare) aluminum alloys. These tests include measurement of both adhesion and corrosion performance. In all cases, with all alloys, the ACDC process performed favorably compared with either SAA or CAA controls. Examples of wedge test data are presented by Cartwright (2005); see Table 6 which compares wedge test data for various ACDC parameters against the 40/450 V Bengough–Stuart CAA process. Note, however, that peel, butt, lap-shear (static exposed and fatigue) tests have also been carried out. All tests indicating comparable levels of adhesion between ACDC and CAA treated alloys (Shenoy 2009). Similarly, linear polarization and other corrosion studies have shown that the ACDC process gives comparable corrosion resistance to the CAA. Importantly, the ACDC process is carried out in a weak acid electrolyte with only a 5% total acid content and containing no hexavalent chromium. Furthermore, the total processing time for ACDC is approximately one tenth of that required to anodize to the standard CAA specification. These advantages make the ACDC anodizing process of industrial interest (Cartwright 2005).

965 **7.7 Conclusions**

966 A large range of processes exist which might be used to modify the surface of  
967 adherends prior to the application of an adhesive. All such treatments modify the  
968 surface physical and chemical properties to one degree or another. Important surface  
969 properties which might be modified include: wettability, roughness, mechanical, and  
970 electrochemical stability. The last point is particularly significant if joints are to  
971 experience environmental ageing under corrosive conditions.

972 The requirements of a particular treatment depends upon the demands put upon  
973 the joint; a simple degrease operation may suffice, and, alternatively, a more  
974 complex process may be required with well-defined surface topography and chem-  
975 istry to meet the demands of structural bonding.

976 Importantly, legislative drivers intended to reduce operator health and safety risks  
977 or environmental impact are currently in place which promote the need for more  
978 acceptable surface treatments such that the range of options available today may be  
979 reduced in the near future. Extensive efforts are, of course, ongoing to help develop

drop-in replacements particularly for the high-performance chromate-containing treatments. A number of drop-in replacements do, however, exist today which provide all of the functionality of the chromate-containing treatments and are likely to see further industrial usage.

## Abstract

Proper treatment of an adherend surface is one of the most important factors in assuring high initial strength and extended durability of high-performance adhesive joints. There are several requirements for a good surface preparation: (1) The surface must be cleaned of any contamination or loosely bound material that would interfere with the adhesive bond. (2) The adhesive or primer must wet the adherend surface. (3) The surface preparation must enable and promote the formation of chemical and/or physical bonds across the adherend/primer–adhesive interface. (4) The interface/interphase must be stable under the service conditions for the lifetime of the bonded structure. (5) The surface formed by the treatment must be reproducible.

In this chapter, high-performance surface treatments for several metals and other materials are discussed. Surface treatments of aluminum and other metals are used to illustrate how proper surface preparations meet these requirements.

## 8.1 Introduction: Requirements of Surface Treatments

Proper treatment of an adherend surface is one of the most important factors in assuring high initial strength and extended durability of high-performance adhesive joints (Landrock 1985; Kinloch 1987; Clearfield et al. 1990; Minford 1993; Pocius 1997; Chaudhury and Pocius 2002; Davis 2003). Surface general principles, treatments, and assessments are treated in ► Chaps. 7, “General Introduction to Surface Treatments,” ► 9, “Surface Characterization and Its Role in Adhesion Science and Technology,” and ► 10, “Use of Surface Analysis Methods to Probe the Interfacial Chemistry of Adhesion” respectively. In the present chapter, surface treatments of selected materials are given.

In the case of a structural bond, a strong adhesive is of little value unless the stresses can be transferred via the adhesive from one adherend to the other. The interface or interphase (a three-dimensional interfacial region with properties different from those of either material) between the adhesive and the adherend is critical to this stress transfer. The goal of a surface treatment is to form a strong and stable interface or interphase that is stronger and more durable than the adhesive being used so that joint failure is cohesive within the adhesive, both initially and throughout the joint’s service lifetime.

There are several requirements for a good surface preparation: (1) The surface must be cleaned of any contamination or loosely bound material that would interfere with the adhesive bond. (2) The adhesive or primer must wet the adherend surface. (3) The surface preparation must enable and promote the formation of bonds across the adherend/primer–adhesive interface. These bonds may be chemical (covalent, acid–base, van der Waals, hydrogen, etc.) or physical (mechanical interlocking) in nature. (4) The interface/interphase must be stable under the service conditions for the lifetime of the bonded structure. A stable interface/interphase is critical for structures expected to be in service for a long time, e.g., aircraft, but is less critical for structures whose lifetime is expected to be short, e.g., some packaging, or if the bond will be protected from the environment over its lifetime. (5) The surface formed by the treatment must be reproducible. Reproducibility requires that the prepared surface be independent of material variables, such as surface contamination, mill scale, and, ideally, even alloy or heat treatment. Reproducibility is facilitated if the treatment has wide processing windows so that processing variables, such as pH, solution contamination, solution chemistry, temperature, and time, do not have to be narrowly controlled. The robustness provided by the wide processing windows increases reliability and decreases costs associated with stringent process controls and parts scrapped due to out-of-specification processing.

Different industries assign different roles to surface preparation. The aerospace industry, with relatively low throughput, but long expected lifetime (several decades), carefully prepares the surface prior to bonding during original manufacture

and repair to assure the best practical durability. The automotive industry, with high throughput, prefers almost no surface preparation and uses contamination-tolerant adhesives and overdesign of joints. The construction industry follows a similar approach. The packaging industry, with very high throughput but relatively low requirements for stress and durability, also minimizes surface preparation by using relatively pure aluminum that reportedly can be more easily wetted and bonded by adhesives. This chapter will focus on surface treatments used for high-performance bonds, primarily in the aerospace industry.

### 8.1.1 Surface Pretreatment Steps

Cleaning the surface of undesirable organic and inorganic material is the first step in preparing an adherend for bonding. The organic contamination originates from rolling oils at the mill, oils and greases applied for corrosion protection, machining oils and release agents used during fabrication, and contamination from the atmosphere. Unless the adhesive is specifically designed to absorb this material, such contamination will prevent wetting and formation of strong bonds across the interface and the joint will perform poorly.

The amount of acceptable contamination varies and can be very small. Silicones and other mold-release agents are designed to be very effective at preventing adhesives and primers from wetting the surface. Even small amounts can cause bond failure. Aluminum surfaces with one third to one molecular layer of silicone will not bond well. Unfortunately, silicones are very mobile and can readily migrate during solvent cleaning, transfer from tooling or handling, or diffuse during curing operations at elevated temperatures. Silicones and silicone-containing materials, such as certain pressure-sensitive adhesive tapes and mold-release agents, need to be carefully marked and kept away from bonding operations.

The sensitivity of a system to contamination depends on many factors. Rubbers are more tolerant of contamination than epoxies. Rougher surfaces can be more tolerant than smoother surfaces. In general, waterborne or high-solid adhesives and primers are more sensitive to organic surface contamination than solvent-borne materials. Thus, contamination may become a greater issue as environmentally acceptable adhesives and coatings are introduced. This is illustrated in Fig. 1, which shows the solvent-borne system to be very tolerant of grease, while the aqueous system is more sensitive. The type of contamination is also important as illustrated in Fig. 2, which shows that some contamination will cause the rubber-steel peel strength to decrease by 50% at levels less than  $1 \mu\text{g}/\text{cm}^2$  while others require more than  $100 \mu\text{g}/\text{cm}^2$  or even enhance the bond strength. Because one must always assume the contamination to be detrimental, the first step in an adherend preparation process is usually a degreasing step. Traditionally this was done with chlorinated solvents, but regulations have required substitution of more environmentally acceptable cleaners.

In addition to organic contamination, most as-received metal alloys have a thick oxide/hydroxide film formed during heat treatment, fabrication, and other processing.

**Fig. 1** Peel strength of nitrile butadiene rubber (NBR) as a function of grease contamination level on grit-blasted steel using a solvent-borne primer/adhesive and an aqueous primer/adhesive

**Fig. 2** The effect of surface contamination on the peel strength of rubber-steel bonds (Adapted from Davis 1993)

The coating's composition, morphology, thickness, and mechanical properties will vary from fabricator to fabricator and from lot to lot. In the case of aluminum alloys containing magnesium, such as the 5000, 6000, and 7000 series alloys, the mill scale can be all or mostly MgO because of the high mobility of Mg in the alloy and its preferential oxidation when exposed to the atmosphere at high temperatures. In copper-containing alloys, such as the 2000 and 7000 series, there often is a buildup

of copper at the oxide/metal interface as aluminum is preferentially oxidized. This copper can serve to promote corrosion via galvanic coupling with the aluminum and reduce bond durability. The effect of magnesium is less clear and differences in surface morphology and other variables may have played a role in conflicting results. To assure reproducible bonding surfaces, the second step in treatment process is generally a deoxidizing step so that oxidizing or coating process begins with bare metal (or a thin native oxide).

The final step in providing an acceptable bonding surface is to grow or deposit an oxide or other surface film designed to promote good, stable bonds with the primer or adhesive. As mentioned earlier, the bonding can be either chemical or physical. Durable covalent chemical bonding across the interface can be achieved with phenolic adhesives, but not the more common epoxy adhesive without the use of coupling agents or sol-gel films. In the other cases, suitable surface morphology to promote physical bonding (mechanical interlocking) is critical. This is discussed below.

### 8.1.2 Degradation Processes

For most structural joints using epoxy adhesives and metallic adherends, secondary or dispersive bonds are the only ones formed across the interface. Because metal oxide surfaces are polar, they attract water molecules that can disrupt these dispersive bonds across the interface. This disruption can be seen thermodynamically by the work of adhesion in an inert medium,  $W_A$ , which can be represented as (Kinloch 1987)

$$W_A = \gamma_a + \gamma_s - \gamma_{as} \quad (1)$$

where  $\gamma_a$  and  $\gamma_s$  are the interfacial free energies of the adhesive and substrate, respectively, and  $\gamma_{as}$  is the surface free energy. In the presence of a liquid such as water, the work of adhesion  $W_{A1}$  becomes

$$W_{A1} = \gamma_{a1} + \gamma_{s1} - \gamma_{as} \quad (2)$$

where  $\gamma_{a1}$  and  $\gamma_{s1}$  are now the interfacial free energies of the adhesive/liquid and substrate/liquid interfaces, respectively. In an inert environment, the work of adhesion for a bonded system will be positive, indicating a stable interface, whereas in the presence of water, the work of adhesion may become negative, indicating an unstable interface that may dissociate. Table 1 shows, in fact, that moisture will displace epoxy adhesives from iron (steel) and aluminum substrates and promote disbonding (Kinloch 1987). In contrast, although moisture weakens epoxy/carbon fibers bonds, these remain thermodynamically stable. Experience with both metal and composite joints confirms these predictions.

The data presented in Table 1 illustrate the potential disastrous results when relying solely on dispersive bonds across the interface between an epoxy adhesive

**Table 1** Work of adhesion for various interfaces (Kinloch 1987)

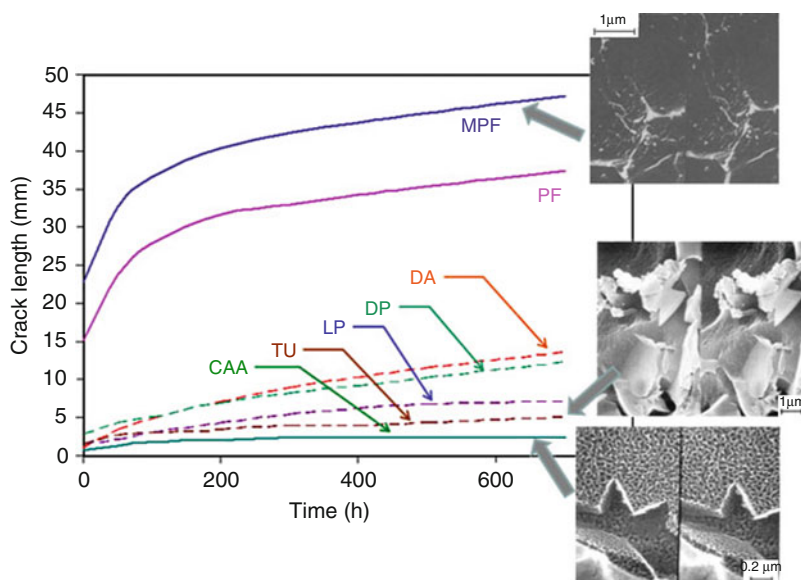

Interface	Work of adhesion (mJ/m <sup>2</sup> )		Interfacial debonding after immersion
	In inert medium	In water	
Epoxy/ferric oxide	291	−255	Yes
Epoxy/alumina	232	−137	Yes
Epoxy/carbon fiber	88–90	22–44	No

and metals or ceramics. Even though good initial bond strengths may be obtained with cohesive failure (within the adhesive), bond durability in the presence of moisture is likely to be poor with interfacial failure. To illustrate this danger, demonstration specimens can be produced that exhibit good initial strength, but fall apart under their own weight when a drop of water is placed at the crack tip.

Because moisture will break the dispersive interfacial bonds, mechanical interlocking on a micro- or nanoscopic scale is needed between the adhesive/primer and adherend for good durability. In these cases, even if moisture disrupts interfacial chemical bonds, a crack cannot follow the convoluted interface between the polymer and oxide and the joint remains intact unless this interface or the polymer itself is destroyed. In addition, the micro- or nanocomposite interphase formed with the polymer and oxide allows a gradient of mechanical properties between the adhesive and the metal so that there is less buildup of interfacial stresses.

The scale of the microscopic surface roughness is important to assure good mechanical interlocking and good durability. Although all roughness serves to increase the effective surface area of the adherend and, therefore, to increase the number of primary and secondary bonds with the adhesive/primer, surfaces with features on the order of tens of nanometers exhibit superior performance to those with features on the order of microns. Several factors contribute to this difference in performance. The larger-scale features are fewer in number for a given area and generally are smoother (even on a relative scale) so that interlocking is less effective. Depending on the particular treatment used, there may also be loosely bound material that prevents bonding to the integral adherend surface. In addition, the larger-scale roughness frequently allows trapped air and surface contaminants to remain in the microscale valleys. These unbonded regions limit joint performance by reducing both chemical and physical bonds and serving as stress concentrators. In contrast, smaller-scale micro- or nanoroughness tends to be more convoluted in morphology and generates strong capillary forces as the primer wets the surface, drawing the polymer into all the “nooks and crannies” of the oxide and displacing trapped air and some contaminants to form a micro- or nanocomposite interphase. Indeed, cross-sectional micrographs show complete filling of the nanopores (Venables 1984; Clearfield et al. 1990).

This dependence on the degree and scale of roughness is illustrated in Fig. 3, which shows wedge test results of titanium bonds with several surface preparations (Brown 1982). Because the titanium surface is stable under these conditions, differences in the joint performance can be attributed solely to differences in the polymer-to-oxide bonds and correlate very well with adherend roughness. The poorest

**Fig. 3** Wedge test results for Ti adherends with several different surface treatments having differing degrees and scales of roughness. Also shown are micrographs of selected specimens showing improved bond performance with increasing micro- or nanoroughness. Specimens were exposed to 100% relative humidity at 60 °C. Treatment key: phosphate fluoride (PF), modified phosphate fluoride (MPF), Dapcotreat (DA), dry hone Pasa Jell (DP), liquid hone Pasa Jell (LP), Turco (TU), and chromic acid anodization (CAA) (Wedge test data are from Brown (1982))

performing group of pretreatments (Class I: phosphate fluoride [PF] and modified phosphate fluoride [MPF]) produced relatively smooth surfaces. The intermediate group (Class II: Dapcotreat [DA], dry hone Pasa Jell [DP], liquid hone Pasa Jell [LP], and Turco [TU]) exhibited macrorough surfaces with little microroughness. They had significant improvements in durability over the smooth adherends, but not as good as the Class III pretreatment (chromic acid anodization [CAA]), which provided a much evolved nanoroughness. Because of the importance of nanoscale roughness, high-quality micrographs with magnifications in the order of 50,000X are critical in evaluating surface morphology.

Once high-quality physical bonds are formed across the interface, the interphase will not fail unless the polymer disengages from oxide or the interphase degrades in some manner to break the interlocking or allow crack growth through the oxide or at the oxide/metal interphase. The mechanism of degradation will depend on the adherend material and the exposure conditions. For aluminum adherends, moisture causes hydration of the surface, i.e., the  $\text{Al}_2\text{O}_3$  that is formed during the surface treatment is transformed into the oxyhydroxide  $\text{AlOOH}$  (boehmite) or trihydroxide  $\text{Al}(\text{OH})_3$  (bayerite) (Davis et al. 1982; Venables 1984). The transformation to the hydroxide leads in an expansion of the interphase (the volume occupied by the hydroxide is larger than that originally occupied by the  $\text{Al}_2\text{O}_3$ ). This expansion and the corresponding change in surface morphology and structure induce high stresses

at the bondline. These stresses coupled with the poor mechanical strength of the hydroxide, promote crack propagation near the hydroxide/metal interface.

The rate of hydration of the aluminum oxide depends on a number of factors, including surface chemistry (treatment), presence of hydration/corrosion inhibitors in the primer or applied to the surface, temperature, and the amount of moisture present at the surface or interface. One surface treatment that provides an oxide coating that is inherently hydration resistant is phosphoric acid anodization (PAA). Its stability is due to a monolayer of phosphate incorporated into the outer  $\text{Al}_2\text{O}_3$  surface during anodization; only when this phosphate layer goes into solution does the underlying  $\text{Al}_2\text{O}_3$  hydrate to  $\text{AlOOH}$ . The hydration process is illustrated in the surface behavior diagram of Fig. 4 (Davis et al. 1982; Davis 1986). It shows hydration to occur in three stages: (1) a reversible adsorption of water, (2) slow dissolution of the phosphate layer followed by rapid hydration of the freshly exposed  $\text{Al}_2\text{O}_3$  to  $\text{AlOOH}$ , and (3) further hydration of  $\text{AlOOH}$  to  $\text{Al}(\text{OH})_3$ .

Although the evolution of surface chemistry depicts the hydration of bare surfaces, the same process occurs for buried interfaces within an adhesive bond. This was first demonstrated by using electrochemical impedance spectroscopy (EIS) on an adhesive-covered Forest Products Laboratory (FPL, a sodium dichromate + sulfuric acid etch) aluminum adherend immersed in hot water for several months (Davis et al. 1995b). EIS, which is commonly used to study paint degradation and substrate corrosion, showed absorption of moisture by the epoxy adhesive and subsequent hydration of the underlying aluminum oxide after 100 days (Fig. 5). At the end of the experiment, aluminum hydroxide had erupted through the adhesive. Later, cross-section micrographs of bonded tapered double-cantilever beam specimens cyclically loaded during immersion in water revealed the very early stages of hydration (prior to substantial changes in the oxide morphology and volume) in advance of the crack tip (Kinloch et al. 2000). Similar early stages of hydration have also been seen using high-frequency dielectric spectroscopy (Affrossman et al. 2000).

Subsequent investigations proved that identical hydration reactions occur on bare aluminum surfaces and bonded surfaces, but at very different rates of hydration

**Fig. 4** Surface behavior diagram showing hydration of the phosphoric acid anodized (PAA) aluminum surface. Hydration occurs in three stages: I. Reversible adsorption of moisture; II. hydration of the  $\text{Al}_2\text{O}_3$  to  $\text{AlOOH}$ ; and III. further hydration to  $\text{Al}(\text{OH})_3$  (Data are from Davis et al. (1982) and Davis (1986))

**Fig. 5** Low-frequency electrochemical impedance of an epoxy-coated Forest Products Laboratory (FPL)-etched aluminum adherend as a function of immersion time in 50 °C water (Adapted from Davis et al. (1995b))

(Davis et al. 2000). An Arrhenius plot of incubation times,  $t_i$ , prior to hydration of bare and buried FPL surfaces, for the equation

$$\frac{1}{t_i} \propto k = Ae^{-E_a/RT}, \quad (3)$$

where  $R$  is the universal gas constant and  $T$  is the absolute temperature in Kelvin, showed that the hydration process exhibits the same energy of activation,  $E_a$ , ( $\sim 82$  kJ/mole) regardless of the bare or covered nature of the surface (Fig. 6). On the other hand, the pre-exponential factor,  $A$ , and the rate of hydration vary dramatically, depending on the concentration of moisture at the oxide interface/surface available to react. The epoxy-covered surfaces have incubation times (and rate constants,  $k$ ) three to four orders of magnitude longer than bare, immersed specimens, reflecting the limited amount of moisture absorbed by the epoxy and free to react with the oxide.

The slow rate of hydration for buried surfaces is good from a service point of view, but makes the study and evaluation of the durability of surface treatments difficult unless wedge tests (ASTM D3762) or similar tests are used to accelerate the degradation. The stress at the crack tip of a wedge test specimen, together with the presence of moisture at the tip, serves to make this test specimen more severe than soaked lap-shear specimens or similar types for which moisture must diffuse from an edge and is only present at the interface in relatively low concentrations. As a result, the wedge test is a better laboratory evaluation of relative durability. Furthermore, from a production perspective, Boeing has correlated the results of wedge tests from

**Fig. 6** Arrhenius plot of incubation times prior to hydration of Forest Products Laboratory (FPL)-etched aluminum under various conditions (Adapted from Davis et al. (2000) with additional data)

actual aircraft components with their in-service durability (Marceau and Thrall 1985). Specimens fabricated from aircraft components that had exhibited service disbonds showed significant crack growth during the first hour of exposure whereas those fabricated from good components showed no crack growth during this time period. In contrast, lap-shear specimens and porta shear specimens all demonstrated high bond strengths regardless of the service conditions. Wedge tests can be used as a quick quality control test in the production facility (crack length after 1 h must be below a given value) or the laboratory to study long-term stability of a surface/interface. In principle, lap shear or similar tests can also be used to obtain the same information. However, the time for moisture to diffuse into these specimens and for the specimens to come into equilibrium with the test environment is so long that most investigators stop the test before useful durability information is obtained.

Unlike aluminum, titanium adherends are stable under conditions of moderately elevated temperatures and humidity. In the wedge test results of Fig. 3, the adherend surfaces underwent no change in morphology. Failure of the CAA specimens remained within the adhesive, with the physical bonds provided by the microscopically rough oxide remaining intact. For moderate conditions, the key requirement for a titanium treatment is a convoluted nanorough surface to promote physical bonding.

At elevated temperatures where titanium alloys would be the adherend of choice, a different failure mechanism becomes important. Because the solubility of oxygen in titanium increases with temperature, the oxygen in a CAA or other oxide dissolves into the metal, leaving voids or microcracks at the metal-oxide interface and embrittles the surface region of the metal. Consequently, stresses are concentrated at small areas at

the interface and the joint fails at low stress levels. Such phenomena have been observed for adherends exposed to 600 °C for as little as 1 h or 300 °C for 710 h prior to bonding (Clearfield et al. 1989) and for bonds using a high-temperature adhesive cured at elevated temperatures. To prevent this failure mode, thick oxides, such as those grown by CAA, should be avoided in high-temperature applications.

### 8.1.3 Processibility Issues

For a surface treatment process to be practical, not only does it have to produce a clean, stable surface suitable for bonding to the primer/adhesive, but it must be able to do this reliably in a production environment. An important aspect of processibility is the acceptable windows for the different process variables. That is, how much can a parameter vary from its nominal value before the performance of the bonded structure is compromised and degraded? The narrower the acceptable window, the tighter the processing controls must be. Tight controls, in turn, are associated with high cost for implementation of the controls, the inspection of the part or processing variable, and the waste from out-of-specification parts that must be reprocessed or discarded. In contrast, a robust process will have wide processing windows so that the prepared surface will still be acceptable despite the inevitable processing discrepancies that occur.

The critical processing parameters (those which must be controlled most closely) will depend on the specific process, the material, and the performance requirements. Typical parameters include solution composition/concentration, pH, temperature, and contamination of cleaning, deoxidizing, etching/anodization/deposition, and rinsing solutions, time of each step and time between each step, anodization voltage and current, ambient temperature and humidity, and airborne contamination.

An example of process controls is the acidification of rinse water baths following FPL or other chromic acid etches (CAE). Due to the nature of the processing, some etch solution drag-out is inevitable as parts are transferred from the etch bath to the rinse bath. In such cases, the pH of the rinse bath in the vicinity of the aluminum surfaces can be quite low. If low pH rinse water is allowed to dry on the oxide, the surface may become sufficiently acidic to react with the amine-curing agents that typically are in epoxy primers, leading to an undercured epoxy at the oxide interface (McNamara et al. 1983). Similar surfaces bonding with a partially cured (b-staged) film adhesive do not suffer bonding problems, presumably because the curing agent in these films is not sufficiently mobile to diffuse to the interface and be neutralized. Because the acidic residue cannot usually be detected on the surface during production, a two-step rinse after etching/anodizing is recommended.

Because of the critical nature of adhesive bonds in the aerospace industry, among others, it is essential to inspect the process to assure quality. This inspection can involve monitoring the critical process parameters, testing of witness specimens prepared at the same time as the structure, or evaluating the surface to be bonded. The best surface to inspect is the actual surface to be bonded, but techniques available for inspection are limited. Witness specimens allow a broad range of

techniques, including those requiring small sizes, vacuum, or highly trained personnel. They also allow bonding and destructive testing.

The most common inspection of actual bonding surfaces is the water-break test. Water, being a polar molecule, will wet a high-energy surface, such as a clean metal oxide, but will not wet a low-energy surface, such as most organic materials and will “bead up.” As a part is removed from a rinse bath or spray, if the water flows uniformly over the entire surface, the surface is clean. However, if the water beads up or does not wet an area, that area likely has an organic contaminant that must be cleaned.

A separate set of processability issues involves health, safety, and environmental concerns. Ozone-depleting compounds (ODCs), such as trichloroethane and trichloroethylene, have been banned. Hexachromium is a carcinogenic toxin and is heavily regulated. Disposal is becoming increasingly difficult and expensive. Other materials are either strong acids or strong bases and require appropriate safety precautions. As a result, considerable research has aimed at developing more environmentally acceptable and less hazardous processes. These will be discussed below along with the more conventional treatments.

---

## 8.2 Specific Metal Treatments

In this section, the most common or promising new treatments for aluminum, titanium, and steel are discussed. For more details, the reader is referred to books such as Wegman (1989), Cagle (1973), and Minford (1993) and review articles such as Crithlow et al. (2006) for comprehensive descriptions of the most relevant processes.

### 8.2.1 Aluminum

Aluminum surfaces are most commonly prepared for adhesive bonding in aerospace applications either by etching or anodization in acid solutions. (For less stringent strength and durability requirements, mechanical abrasion can be adequate.) Common preparations result in nanorough adherend morphologies, which studies have shown yield the best overall bond durability. The two widely used treatments are phosphoric acid anodization (PAA) and chromic acid anodization (CAA). Other treatments include Forest Products Laboratory (FPL) etch, or similar chromic acid etches (CAE), P2 etch, and the boric acid/sulfuric acid anodization (BSAA). These treatments are summarized in Table 2. In addition, sol-gel or grit blasting/silane coupling agent treatments are showing promise as environmentally acceptable processes that can be used for repair.

#### Anodization

Phosphoric acid anodization was developed by Boeing to improve the performance of bonded primary structures. Bonds formed with PAA-treated adherends exhibit

t.1 **Table 2** Selected surface treatments for aluminum adherends

t.2	Process	Solution	Process parameters
t.3	PAA	$\text{H}_3\text{PO}_4$	20–25 °C, 25 min, 10 V
t.4	CAA	$\text{H}_2\text{CrO}_4$	32–38 °C, 8 V/min to 40 V, hold 55 min
t.5	BSAA	$\text{H}_2\text{SO}_4 + \text{B}_2\text{O}_3 + \text{H}_2\text{O}$	25–30 °C, ramp to 15 V, hold 20–25 min
t.6	FPL	$\text{Na}_2\text{CrO}_7 \cdot 2\text{H}_2\text{O} + \text{H}_2\text{SO}_4 + \text{H}_2\text{O}$	68 °C, 15–30 min
t.7	P2	$\text{FeSO}_4 + \text{H}_2\text{SO}_4 + \text{H}_2\text{O}$	60–70 °C, 8–15 min

superior durability during exposure to humid environments compared to those formed with FPL-treated adherends, especially when epoxy adhesives are used. In addition, PAA bonds are less sensitive than FPL bonds to processing variables, such as rinse-water chemistry and time before rinsing. As a result, the PAA procedure has become the treatment of choice in the USA for critical applications.

Chromic acid anodization is widely used to improve the corrosion resistance of aluminum surfaces. The use of the good protective coating on the aluminum protects the metal interface and increases the bond durability of the joint. CAA is widely used for aerospace applications in Europe, although it is not as popular as PAA in the USA.

Boric acid/sulfuric acid anodization also avoids the chromates of the older processes. It provides an oxide similar to the CAA oxide – thick relative to PAA (~0.5  $\mu\text{m}$ ) with thick cell walls and narrow pores. Wedge test results indicate durability similar to CAA and PAA.

Although there are some differences in detail among the anodization processes used commonly for Al adherend preparation, they share many common features: cleaning, deoxidizing, and anodization. The anodization step for PAA is performed at a constant voltage, whereas for CAA, voltage is applied to the adherend in a gradual or stepwise fashion until the maximum voltage is reached, and is then held for roughly 30 min. Both anodization processes are more costly and time-consuming than the FPL process but are justified by the increase in bond durability as shown by the wedge test results of Fig. 7.

The PAA oxide morphology has an open nanorough morphology consisting of narrow-walled pores with whiskers sticking up above the pores, as the isometric drawing (adapted from Venables et al. (1979)) and the high-resolution stereo scanning electron micrograph (SEM) in Fig. 8 show. The total oxide thickness is ~400 nm. This type of nanoroughness can provide more mechanical interlocking than most other treatments for improved bond strength and durability, but this increase occurs in the interlocking only if the polymeric polymer or adhesive completely wets and penetrates the pores of the oxide. The nanoscale pores create capillary forces that help this penetration. Cross-sectional SEM views of PAA coated with typical epoxy primers show such penetration (Venables 1984). In such cases, strictly interfacial bond failure is very unlikely.

Chemically, the PAA film is amorphous  $\text{Al}_2\text{O}_3$  (Venables 1984) with the equivalent of a monolayer of phosphate incorporated onto the surface (Davis et al. 1982). Alloying constituents of the adherend are not generally found in the as-anodized

**Fig. 7** Wedge test results for Forest Products Laboratory (FPL)-etched and phosphoric acid anodized (PAA) adherends (*above*) and PAA, chromic acid anodized (CAA), and boric-sulfuric acid anodized (BSAA) adherends (*below*). The upper wedge test involved FM-123 adhesive; the lower wedge test involved FM-94 adhesive so the crack lengths cannot be compared from one test to the other. Exposures were 50 °C at 95% relative humidity (RH)

oxide. Depending on the storage conditions, some water can adsorb on the surface, but is readily removed by heating or storing in a dehydrating environment.

The morphology of the CAA oxide duplicates the morphology of the surface prior to anodization as oxidation occurs at the interface without dissolution of the existing oxide. The total oxide thickness is 1–2  $\mu\text{m}$ , which is much greater than that provided by PAA. The barrier layer at the bottom of the columns is also relatively thick ( $\sim 40$  nm), due to the high anodization voltages used. The CAA oxide is  $\text{Al}_2\text{O}_3$ ; the upper portion is amorphous but the lower part may be crystalline. In contrast to the phosphate incorporated in the PAA oxide, little Cr is incorporated into the CAA oxide.

Because the morphology of the outer surface of the CAA oxide is strongly dependent on the process steps used just prior to the CAA treatment, the type of pretreatment can be chosen to enhance the bonding. Samples that are FPL-etched and then anodized have a typical FPL shallow cell-and-whisker morphology. Surfaces that are PAA treated before the CAA anodization have a deeper cell structure, typical of PAA. Finally, surfaces that have a smooth tartaric acid-anodized (TAA) oxide before CAA treatment retain a smooth surface which is typical of the TAA treatment.

The morphology of CAA oxides can also be altered by varying the processing conditions, including using higher temperature anodizing solutions and post-anodizing phosphoric acid etches (Arrowsmith and Clifford 1985). One advantage

**Fig. 8** Phosphoric acid anodized (PAA) aluminum morphology. *Above*: Isometric drawing adapted from Venables et al. (1979). *Below*: High-resolution stereo scanning electron micrograph (SEM). Note: viewing this stereo micrograph and others in this chapter with a stereo viewer provides a 3-D image of the surface

to the CAA process is that the oxide is less friable, i.e., less susceptible to mechanical damage, than the PAA oxide.

Bonds made with PAA adherends exhibit excellent inherent durability with failure normally occurring within the adhesive (Venables 1984; Chaudhury and Pocius 2002) due to both the hydration resistance of PAA surfaces and the evolved nanoroughness and subsequent interlocking that occurs between the oxide and the adhesive (Venables 1984). Hydration of PAA surfaces occurs via a three-step process, as discussed above. It is the second step (hydration to boehmite) that causes crack propagation. The initial stability of the PAA surface results from the very thin layer of phosphate ions that is incorporated into the oxide during anodization. FPL oxides with an adsorbed layer of phosphonate-containing hydration inhibitor derive their hydration resistance from a similar mechanism (Davis et al. 1985). In all cases, the bond-degradation processes can be retarded by using moisture-resistant adhesives or primers.

CAA oxides protect the metal surface from hydration because of their inherent thickness; the important factor for bond durability is the stability of the outer oxide

structure when water diffuses through the bondline to the polymer/oxide interface. Because hydration rates are a function, in part, of the thickness of the barrier layer (which is directly proportional to the anodizing voltage), typical CAA processes yield oxides that are more resistant to hydration than FPL surfaces. Direct comparisons of the normal surface treatments based on durability tests show that CAA adherends and PAA adherends perform equally well (Fig. 7).

## Etches

The FPL and other chromic-sulfuric acid etching procedures are the oldest surface pretreatments for aluminum adherends other than simple degreasing or mechanical abrasion. In addition to being used as a complete adherend pretreatment, FPL was used as the first step in other pretreatments, such as PAA and CAA although it has largely been replaced as part of the PAA process for environmental reasons.

The presence of hexavalent chromium in the FPL/CAE and CAA solutions led to alternative treatments, such as P2 and BSAA and, later, sol-gel processing. The P2 etch, avoids the use of toxic chromates, but still provides the complex oxide surface morphology that is crucial to a “mechanically interlocked” interface and strong bonding. Ferric sulfate is used as an oxidizer in place of sodium dichromate (Rodgers 1981). The P2 solution produces an oxide morphology similar to what is seen on chromic-sulfuric acid etch surfaces over a broad range of time-temperature-solution concentration conditions. Mechanical testing indicates that P2-prepared surfaces are equivalent to FPL-prepared specimens.

The FPL oxide morphology is shown in the isometric drawing (adapted from Venables et al. (1979)) and high-resolution SEM stereo micrograph in Fig. 9. The oxide consists of a network of shallow pores and protrusions or whiskers on top of a thin barrier layer. This nanoroughness provides some mechanical interlocking between the adhesive and the oxide surface that is critical for the durability of epoxy-bonded structures, but is not sufficient to avoid interfacial failure if the oxide is stable enough to hydration (Davis et al. 1982). Chemically, the FPL film is amorphous with varying quantities of adsorbed water that can be removed by heating, vacuum exposure, or adsorption with certain organic hydration inhibitors.

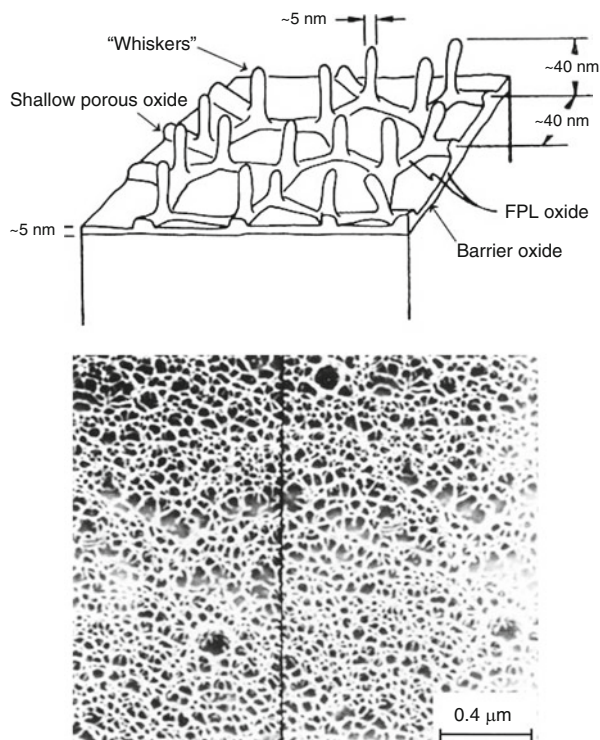

## Other Treatments

### Sol-Gel Processing

Sol-gel or “solution-gelation” is based on hydrolysis and condensation reactions to form inorganic polymer networks. The coating is schematically shown in Fig. 10. The Boegel process involves a dilute aqueous alkoxide solution containing zirconium isopropoxide (tetra-n-propoxyzirconium, TPOZ) and a silane coupling agent (Blohowiak et al. 1996; Park et al. 2000). The silane constituent can be chosen to be compatible with the primer and to form strong, durable chemical bonds. A glycidoxyl group, such as that of glycidoxymethoxysilane (GTMS), is typically used for epoxies. The hydrolyzed aluminum oxide surface promotes the condensation reactions. The part to be treated can be sprayed, drenched, or immersed. No rinsing is required.

**Fig. 9** Forest Products Laboratory (FPL)-etched aluminum morphology. *Top*: Isometric drawing adapted from Venables et al. (1979). *Bottom*: High-resolution stereo scanning electron micrograph (SEM)

A thin film (typically 50–200 nm) serves as a hybrid inorganic/organic interphase between the metal (oxide) surface and the organic primer or adhesive. The surface is silane-rich and the interface near the metal substrate is zirconia-rich with Zr-O-metal substrate chemical bonds formed with the substrate. The graded coating allows covalent bonding throughout the deposited interphase film. In this way, the sol-gel treatment differs from the traditional oxide treatments discussed above in that chemical bonding and not physical bonding governs joint strength and durability. Sol-gel films deposited on a grit-blasted aluminum surface give performance close to PAA bonds with little crack growth (Fig. 11). Failure is generally cohesive.

### Silane/Grit-Blast Treatment

The grit-blast/silane (GBS) treatment was developed in Australia for use with bonded repair patches. One example is the repair of outer wing fatigue cracks, in which over 1,000 bonded doublers have been applied to primary structure with no crack growth or patch failures for 20 years. The US Air Force has extended the technology and optimized a grit-blast/silane surface treatment for patching other aircraft.

In contrast with the oxide treatments discussed above where mechanical interlocking is the key to obtaining good bond strength and durability, the GBS treatment utilizes the functionality of the silane to form chemical bonds with both

**Fig. 10** Schematic of sol-gel surface (Adapted from Blohowiak et al. (1996))

**Fig. 11** Wedge test results for Phosphoric acid anodized (PAA) and grit-blasted sol-gel treated aluminum adherends. Note the expanded crack-length scale (Data are from Blohowiak et al. (1998))

the surface and the adhesive/primer to couple the two materials (Plueddemann 1982; Bascom 1990). Silane coupling agents have the form  $R-SiX_3$ , where R is an organic function group and X is a hydrolysable group. The GBS treatment uses  $\gamma$ -glycidoxypopyltrimethoxy silane ( $\gamma$ -GPS), in which R is an epoxy group connected to the Si by a propylene chain and X is a methoxy. In an aqueous solution, the methoxies hydrolyze to form the trisilanol ( $R-Si(OH)_3$ ). For this application, the

epoxy group reacts with epoxy adhesive while the silanols react with the metal oxide surface. These bonds are stable against moisture attack and can provide excellent bond durability.

One issue with silane-coupling treatments is that the performance can be highly dependent on processing conditions, especially hydrolysis and drying conditions. Nonetheless, process controls suitable for field application of bonded repair patches are possible. With such controls, Optimized grit-blast/silane treatments can provide wedge test durability as good as PAA with failure entirely cohesive within the adhesive.

8.2.2 Titanium

Titanium alloys are particularly attractive for aerospace structures due to their high strength-to-weight ratio. In addition, they retain their mechanical properties at high temperatures, so that they can be used as components in structures where operating temperatures up to 370 °C (700 °F) are expected for short times or up to 177 °C (320 °F) for extended times. The desire to use adhesively bonded titanium structures at elevated temperatures has been a driving force in the development of high-temperature adhesives (those curing at temperatures up to 400 °C). In this section, surface preparations for titanium and the durability of the subsequent adhesive bonds are described. Selected treatments are shown in Table 3.

Like Al, durable surface preparations for titanium can be achieved by forming oxides in anodizing and/or etching solutions. Typically, anodization results in the best bond durability for Ti alloys, primarily due to the nanorough surface morphology that results from the treatment. The most commonly used anodization process is CAA (but in a different form than for aluminum adherends) (Venables 1984; Clearfield et al. 1990). The Pasa Jell 107 and Turco 5578 etches are also commonly used.

In early studies, the durability of Ti-6Al-4V adherends was determined as a function of surface preparation for ten adherend preparations (Brown 1982) and was discussed above (Fig. 3). The general result was that surface preparations that produce oxides with no roughness (macro- or micro-) yield the poorest bond durability; those that produce a large degree of macroroughness, with little or no micro- or nanoroughness, fall into an intermediate class of moderate-to-good durability; and those preparations that produce oxides with significant nanoroughness

Table 3 Selected surface treatments for titanium adherends

Process	Solution	Process parameters
CAA	CrO <sub>3</sub> + NH <sub>4</sub> HF <sub>2</sub> + H <sub>2</sub> O	20–25 °C, 10 V for 20 min
AP	NaOH + H <sub>2</sub> O <sub>2</sub>	65 °C for 20 min
Turco 5578	Proprietary, includes NaOH	80–95 °C for 15 min
Pasa-Jell 107	Proprietary	<38 °C, for 15–20 min

lead to the best durability. The morphology and bond durability of the most common treatments are described below.

The general steps used to provide an anodized surface on titanium adherends are similar to those used for aluminum adherends. Initially, the adherend must be degreased to remove organic contaminants. Degreasing is followed by an acid etch to remove the oxide scale. The anodization (if used) is done at constant voltage and the adherend is rinsed and dried.

The oxide formed by the CAA process is shown as an insert in Fig. 3. A two-level large-scale morphology is evident. This is typical of CAA-treated Ti-6Al-4V and is due to the two-phase nature of the alloy – large grains of the aluminum-rich alpha phase with an intergranular, vanadium-rich beta phase. At high magnifications, a honeycomb-like structure consisting of amorphous  $\text{TiO}_2$  is evident (Venables 1984; Clearfield et al. 1990). The cell diameters are on the order of 30–40 nm, with wall thicknesses about 5–10 nm. The thickness of the oxide depends on the concentration of the solution and the anodization voltage used. Typically, a 5%  $\text{CrO}_3$  solution (10 V, 20 min at room temperature) is used. This results in an oxide that is 120–130 nm thick. Cross-sectional transmission electron micrographs reveal that the honeycomb structure is on top of a thin, dense barrier layer (20–30 nm).

Turco 5578 (shown in insert of Fig. 3) and Pasa Jel 107 surfaces exhibit a roughness on the order of microns. At smaller scales (down to ~20 nm), the Pasa Jel surface is largely featureless while the Turco surface exhibits shallow oxide protrusions.

Surface preparations for Ti-6Al-4V that result in thick oxide films are limited to moderate temperatures over long times because the oxide is dissolved into the alloy at high temperatures. For instance, the failure mode in CAA lap-shear specimens (bonded with a thermoplastic polyimide) changed from cohesive to adhesive after 5,000 h of aging at 232 °C (Progar and St. Clair 1986). Oxide failure in CAA adherends that were exposed to high temperatures prior to bonding with epoxy was also observed. Although dry, high-temperature environments have little or no effect on CAA morphology, bonds formed after such exposures to high temperatures failed under minimal force. In these cases, the failures occurred at the oxide–metal interface, caused by the dissolution of the oxide into the base metal at the exposure temperature. Any stress applied to the adherend after exposure would then be concentrated at the weakened interface. Under these conditions, very little tensile force would be needed to pull the oxide away from the metal. This phenomenon has been observed for an adherend exposed in vacuum at 400 °C for as little as 1 h prior to bonding. Testing of bonded structures at lower temperatures, e.g., 177 °C, requires longer testing times for the same processes to occur. Such times reduce the feedback needed to optimize a surface treatment and make development slower, but are necessary to obtain valid testing.

Thus, for high-temperature applications, alternative surface treatments are necessary. Sol–gel processes similar to those for aluminum appear the most promising. Several different sol–gel chemistries have been described: the TPOZ/GTMS chemistry used for aluminum, an aromatic silane (m- and p-aminophenyltriethoxysilane), an aliphatic silane (3-aminopropyltriethoxysilane), and polyimide-silica hybrids (pendent

phenylethynyl imide oligomeric disilanes/tetraethoxysilane or PPEIDS/TEOS and phenylethynyl terminated imide oligomer/aromatic phenylethynyl imide silane/TEOS or PETI-5/APEIS/TEOS) (Blohowiak et al. 1996; Park et al. 2000). The later chemistries include high-temperature-stable components similar to those used in high-temperature adhesives. The surface morphology has not been investigated and reported in as much detail as CAA and the other oxide surfaces. However, Cobb et al. describe it as being similar to that of Turco 5578 provided that the Turco process is used as a precursor to the sol-gel process (Cobb et al. 1999). Because it relies on chemical bonding between the adhesive and the hybrid organic/inorganic structure, it does not require the fine microscopic features to form physical bonding that the anodized surface does. Exposure to 177 °C for up to 2,000 h has little effect on the lap-shear strength and locus of failure of PPEIDS/TEOS sol-gel treated bonds (Fig. 12). Other studies show that bonds prepared with the sol-gel treatments retain significantly more fracture toughness than bonds treated with Turco 5578 or Pasa-Jell 107 (Cobb et al. 1999).

Another high-temperature-compatible surface treatment is a microrough titanium coating deposited by plasma spraying. In plasma spraying, an electric arc is struck between a cathode and an anode (nozzle). A working gas, typically a mixture of argon and hydrogen (or nitrogen and hydrogen), is forced through the arc, creating a plasma. A powder of the material to be deposited is injected into the plasma either within or downstream from the nozzle, and the plasma softens or melts the powder in flight. The molten particles, traveling at supersonic velocities, strike the substrate and splat cool. The result is a microrough, metallic coating.

At high magnification, the microroughness of the plasma-sprayed surface is more random than that produced by any chemical process. The pores are quite deep, and many knob-like protrusions can be seen. These protrusions result from the splat

**Fig. 12** Normalized lap-shear strengths as a function of exposure to 177 °C for pendent phenylethynyl imide oligomeric disilanes/tetraethoxysilane (PPEIDS/TEOS) sol-gel treated titanium bonds. Also shown is the percentage of cohesive failure (Data are from Park et al. (1999))

cooling and rapid solidification of the Ti-6Al-4V droplets as they strike the substrate. At lower magnifications, some macroscopic inclusions are evident.

Plasma-sprayed adherends were exposed in vacuum at temperatures up to 800 °C for 1 h. No changes were observed at temperatures of 650 °C and below. Above 650 °C, changes in the bulk microstructure, and hence the surface morphology, were observed. At all temperatures, the coating remained adhered in tensile-button tests when the stubs were bonded following the high temperature exposure.

### 8.2.3 Steel

Although there is significant commercial interest in the adhesive bonding of steel structures, no general-purpose pretreatments for steel substrates have been developed (McNamara and Ahearn 1987; Clearfield et al. 1990). There are several reasons for this.

- For industries like the automotive industry, the focus has been on developing adhesives and processes that require minimal surface preparation.
- Unlike aluminum and titanium, iron does not form coherent, adherent oxides, so that it is difficult to grow a stable film with the fine micro- or nanoroughness needed for good adhesion.
- Different alloys can require different pretreatments so that a process that may give good performance for one alloy may give very different results for other alloys.

Grit blasting is commonly used as a pretreatment. Although it is adequate in many applications, it may not be suitable for cases where the bonded structure is exposed to severe environments.

The variety and complexity of steel microstructures greatly complicate the task of developing a universal surface treatment. Although several cleaning treatments and chemical etchants have been used for low-carbon and stainless steels, none has been widely adopted or shown to be superior to grit blasting. There have been encouraging results for stainless steels, but an effective etch or anodization process for low-carbon steels has not been developed. The best approach for preparing low-carbon steels appears to be the deposition of a more durable and bondable coating, such as a conversion-coating treatment.

As with aluminum and titanium, the most critical test for bonded steel joints is durability in hostile (i.e., humid) environments. Pocius et al. illustrated the difficulty of forming durable bonds on steels (Pocius et al. 1984b). They compared solvent-cleaned (smooth) 1,010 cold-rolled steel surfaces with FPL aluminum (nanorough) substrates. Although the dry lap-shear strengths were not markedly different, stressed lap-shear joints of steel adherends that were exposed to a humid environment failed in less than 30 days, whereas the aluminum joints lasted for more than 3,000 days.

Virgin alumina grit-blasted steel surfaces showed poor durability, as well, in wedge tests where specimens exhibited rapid crack growth (Trawinski et al. 1984).

Electron micrographs of opposing failure surfaces taken in the crack-growth region showed purely interfacial failure. The metal surface had not been corroded, nor was there visual evidence of moisture attack on the polymer during the relatively short test period. Gledhill and Kinloch investigated joints immersed in water and found a similar displacement of adhesive-to-metal bonds and concluded that thermodynamics considerations, such as those given in Table 1, indicate that water will virtually always displace an organic adhesive from a smooth metal oxide surface (Gledhill and Kinloch 1974). This suggests that simply cleaning the adherend surface is not an adequate treatment for structural bonding applications.

Other mechanical cleaning operations are no better and often worse than grit blasting. The best results were obtained when the grit size was matched to the size of the filler material in the adhesive.

Although chemical treatments for cleaning steel surfaces have been widely used for many years, there are no general chemical treatments designed to prepare steels for adhesive bonding. One of the main problems with chemical-etch treatments of low-carbon steels is the formation of a loosely adhering layer of iron oxide “smut” on the adherend surface. The oxide is difficult to remove before bonding even with vigorous rinsing, but easily pulls away with the adhesive when the joint is stressed. The formation of the smut can be suppressed by using acid etches in alcohol solutions. Although such solutions were reasonably effective, the treatments were no better than grit blasting in stressed durability testing. In many applications, a treatment that is “as good as grit blasting” is still acceptable.

Another major problem with chemical etches is that the resulting morphology is a function of the metallurgy of the substrate. Even though ASTM A606 and A514 substrates are chemically similar high-strength, low-alloy steels, their phosphoric-acid etched surfaces offer different bonding/interlocking potentials because different heat treatments are used to purposely change their microstructure (McNamara and Ahearn 1987). In both, the acid primarily attacks grain boundaries, etching out surface grains. However, the A606 surface has smooth-sided, dimpled morphological features, similar to grit-blasted surfaces, whereas the A514 surface has small crevices that can allow adhesive penetration. Etched A514 performs much better than either grit-blasted A514 or etched A606 surfaces in wedge tests.

The adherend metallurgy also indirectly determines the degree of smut buildup because the rate of smut formation is proportional to the etch rate (McNamara and Ahearn 1987). For instance, the etch rate of A606 is four times greater than that of A514, due to differences in grain size, etc. As a result, a different etch treatment is required for each. In general, the roles of alloy and heat-treatment differences have not been widely investigated in bonding research on steel; details of the substrate metallurgy are usually not reported.

Although chemical surface treatments can improve the substrate bondability of stainless steels, there is no general agreement on which is the best. One etchant commonly used with stainless steels is an  $\text{HNO}_3$ -HF mixture (Bottrell 1965; David 1974); another is chromic acid. Various solutions based on sulfuric acid have also been beneficial (Allen 1977), and several researchers investigated a wide variety of solutions based on acids with dichromates added, with and without anodization

(Haak and Smith 1983; Pocius et al. 1984a). They all used highly concentrated, very active solutions that attacked grain boundaries and the chromium-poor regions around chromium carbide particles. However, a treatment judged to be the best by one researcher did not receive the same ranking from another and the differences were probably related to the precise metallurgy of the samples investigated, which varied from one group to another. One common finding was that surface roughness correlated with peel test performance. Pocius et al. (1984a), for example, noted that peel performance could be correlated to the microscopic surface roughness.

A better approach to forming durable bonded joints with steels is to use a conversion-coating process to deposit a rough, corrosion-resistant layer on the adherend (Crithlow et al. 2000). To achieve such a coating, zinc and iron phosphate solutions are used to precipitate crystallites onto the steels. This can provide good bonding morphology if the process forms small crystallites (McNamara and Ahearn 1987). Large crystallites, on the other hand, can allow crack propagation within the conversion coating. Trawinski and coworkers demonstrated that lap-shear strengths using carefully controlled zinc-phosphate treatments were equivalent to those on grit-blasted steel substrates, but wedge test performances were greatly improved (Fig. 13) (Trawinski et al. 1984). To achieve this performance, the crystallites in the coating must be small. If the grain size is not controlled, the coating becomes too thick with phosphate crystallites precipitating on others, and a weak interface is introduced. As with chemical etches, optimum conversion coatings depend on the microstructure of the steel.

An alternative means of depositing a bondable coating onto steel that is largely independent of substrate metallurgy is thermal spray, such as plasma spray. The

**Fig. 13** Wedge test results for ASTM A606 steel for grit-blasted and conventional and microcrystalline zinc phosphate conversion coatings. Failure of the microcrystalline zinc phosphate was 100% cohesive; that for the grit blast and conventional zinc phosphate was 100% adhesive (Data are from Trawinski et al. (1984))

chemistry and morphology of such coatings can be engineered for given applications. Plasma spray coatings of Ni-Cr, Ni-Cr-Al, and Ni-Cr-Zn exhibit excellent corrosion protection of the substrate and bondability to epoxy and rubber (Davis et al. 1995a, 1997). Additions of small amount of Zn provide cathodic protection of the substrate, much like galvanized coatings, and prevented substrate corrosion under a variety of aggressive conditions. Although the Zn component undergoes corrosion to protect the steel surface, the Ni-Cr or Ni-Cr-Al component provides a stable coating structure or framework so that adhesive bonds made after the corrosion tests using epoxy adhesive tensile buttons failed within the adhesive.

These plasma sprayed coatings also exhibit significant tolerance to oil and grease contamination of rubber bonds. In investigations using contamination-tolerant rubber materials, the plasma-sprayed surfaces retain high peel strengths and cohesive failure for more than double the grease level at which the grit-blasted surface begins to show degraded performance (Fig. 14). This increased tolerance is likely a result of a greater roughness and complexity of the plasma-sprayed surface compared to the grit-blasted surface.

In many high-volume production applications (i.e., the automotive and appliance industries), elaborate surface preparation of steel adherends is undesirable or impossible. Thus, there has been widespread interest in bonding directly to steel coil surfaces that contain various protective oils (Charnock 1985; Debski et al. 1986). Adhesives, particularly those curing at high temperatures, can form suitable bonds to oily steel surfaces by one of two mechanisms: (1) thermodynamic displacement of the oil from the steel surface and (2) absorption of the oil into the bulk adhesives (Debski et al. 1986). The relative importance of these two mechanisms depends on

**Fig. 14** Peel strength of rubber–steel bonds contaminated with grease. Two different surface treatments were used: plasma spray and grit blast. Also shown are the loci of failure

the polarity of the oil and the surface area/volume ratio of the adhesive (which can be affected by adherend surface roughness).

Lap-shear bond strengths of joints made from steel substrates coated with a variety of oils and waxes ( $\sim 6 \text{ mg/cm}^2$ ) and joined with room-temperature curing acrylic adhesive have been reported to be up to 15 MPa (Charnock 1985). Very little degradation was seen after 1,000 h of exposure at 40 °C and 95% relative humidity. However, the shear strength dropped by roughly half when the joints were subjected to a 30 min bake at 200 °C. Although the bond strengths do not approach those reported for Al or Ti adherends, they were adequate for the intended application.

---

## 8.3 Other Materials

### 8.3.1 Composites

Bonding high-performance composite structures, such as those in aerospace, are very different than bonding metal structures in that the matrix polymer, such as epoxy, bismaleimide, or polyimide, can be used as the adhesive as well so that there is excellent chemical compatibility and good adhesion between the substrate and the adhesive (Pate 2002). Therefore, there is much less reliance on mechanical or physical bonding.

Often the adhesive and the adherends are cured simultaneously. This procedure reduces the cost of multiple curing cycles and promotes extensive chemical bonding and interdiffusion of polymeric chains during the curing process when the chains are mobile and the interface is under compressive forces.

Co-bonding (bonding cured parts to uncured parts) and secondary bonding (bonding fully cured parts) are also performed, especially for complex or large structures. In these cases, surface preparation of the composite surface is necessary to chemically reactivate surface and remove any surface contamination that might have occurred. One particular class of contamination of concern is mold-release agents. These agents are applied to the mold or tool surfaces to prevent the composite from bonding to the mold and to facilitate removal of the composite. By necessity, these agents are designed to prevent chemical bonding and must be removed prior to any subsequent bonding operation.

Peel plies are generally the preferred means of achieving a suitable surface. A peel ply is a sacrificial layer of dry or resin-impregnated tightly woven fabric that is added to the composite's surface during initial part fabrication. It is designed to form a weakened bond to the composite. The peel ply is peeled off just before the secondary bonding operation to expose a clean, active surface for bonding.

The alternative approach is surface abrasion or grit blasting to remove the outermost layer of matrix resin. However, this can be labor-intensive for large structures and exhibits two areas of concern: nonuniformity and the inherent balance of removing enough material to eliminate surface contamination while not damaging the fibers in the composite. There is also the possibility of abrasion of merely smearing contamination from one area to another.

A special example of secondary bonding is the repair of an existing structure. Once the damaged material has been removed, the structure’s surface area to be bonded is clean (if proper precautions are taken), activation is desired to promote chemical bonds. Silane coupling agents (discussed above) are one successful means to form interfacial chemical bonds.

Composites can also be treated with the same processes described below for plastics. This would be especially helpful when the composite resin is not compatible with the adhesive used.

8.3.2 Plastics

Unlike composites, most plastics have chemistries that are not suitable as adhesives. They typically have low surface energy while adhesive materials have high surface energy. Consequently, the high-surface energy adhesives do not wet and bond to the plastic surface. Furthermore, most plastic surfaces contain low-molecular weight material and contaminants, such as lubricants or mold-release agents, from the fabrication process. Thus, surface preparation is needed to prepare a reproducible clean and activated surface that is suitable for forming chemical bonds with the adhesive (Pocius 1997). An example of the need to change the surface chemistry is illustrated in Table 4 from Chew et al. (1986). Very little adhesion is observed between the epoxy adhesive and the unmodified polyethylene adhesive. However, surface carboxyl or ketone groups significantly increase the adhesion.

There are two classes of surface treatments for plastics: physical and chemical (Pocius 1997). Both classes alter the surface chemistry of the plastic but the distinction is that the physical methods involve some form of high-energy radiation while the chemical ones involve wet chemistry.

Perhaps the most common surface treatment for plastic films is Corona Discharge Treatment (CDT). In CDT, a high-frequency, high-voltage electrode serves to ionize the gas, normally air, above a plastic film. In air, a blue glow or corona appears

**Table 4** Effect of surface chemical functionalization of the adhesion of an epoxy to modified polyethylene surfaces<sup>a</sup>

Surface chemical functionality	Butt tensile strength (MPa)
–CH <sub>2</sub> –	1.4
–CH <sub>x</sub> CBr <sub>y</sub> –	6.7
–CH=CH–	3.7
–CH <sub>2</sub> –HC–OH	4.6
–CH <sub>2</sub> –C–CH <sub>2</sub>    O	11.3
–CH <sub>2</sub> –C–OH    O	15.7

<sup>a</sup>From Chew et al. (1986)

around the powered electrode. The ionized air oxidizes the plastic surface giving it a higher surface energy suitable for bonding. For polyethylene and polypropylene, the principal oxidation product is carbonyl (Cooper and Prober 1960; Carlsson and Wilson 1970). Because the treatment is at atmospheric pressure and film can advance rapidly on rollers, the CDT process can treat large areas of plastic very effectively.

Flame Treatment is the second most common surface treatment for plastics based on area treated (Pocius 1997). As with CDT, the plastic film passes over a roller or drum in air. Instead of a high-voltage electrode creating a corona or plasma, flame from a series of gas burners treats the plastic surface. The gas/air ratio, the distance of the burners from the film, and film speed are all important factors that govern the oxidization and activation of the film surface.

Plasma treatment is the third form of physical surface treatment. Here a radio-frequency (RF) or microwave generator ionizes a reduced-pressure gas to generate a plasma. Several different gases can be used to generate different chemistries on the surface. A principal disadvantage of most plasma processes is the partial vacuum required and the need for batch processing. This significantly increases the costs for high-volume operation. However, for low-volume specialty production, increased flexibility in surface chemistry with the use of different gases may warrant this approach.

Wet chemical treatments involve applying a solution to the plastic surface. Solvent cleaning is the simplest approach, but it alone is not usually effective in improving adhesive bonding. One of the oldest wet chemical surface treatments of polyethylene is exposure to oxidizing acids, such as chromic acid. A solution of sodium naphthalenide in tetrahydrofuran is useful in treating polytetrafluoroethylene (PTFE) (Benderley 1962). The very low surface energy of PTFE creates many uses for the polymer, but makes adhesive bonding problematic. For bonding, the surface energy can be increased by defluorination and subsequent oxidization of the surface. Roughening of the surface also occurs. As a result of this treatment, the bond strength can be up to seven times greater than that of the untreated PTFE.

### 8.3.3 Ceramics

Bonding to ceramics commonly relies on mechanical interlocking if the surface is porous or can be made porous, although chemical bonding can also contribute. Examples of ceramic bonds include dentistry, tiles on the Space Shuttle Orbiter, and ceramic armor for military vehicles.

In dentistry, bonding includes orthodontic or restorative dentistry to teeth (Barnes and Newsome 1996). The desired bonding can be temporary in the case of brackets for braces or permanent in the case of crowns, veneers, or bridges. The tooth enamel comprises many interlocking fine prisms of hydroxyapatite (calcium phosphate). Although temperature extremes are limited, the constant moisture in the mouth is a bonding challenge as is the need to achieve a good bond in a short time.

To accomplish adhesive bonding, the enamel is commonly etched by one or more acids, such as phosphoric, maleic acid, nitric acid, tartaric acid, sulfosalicylic acid, polyacrylic acid, citric acid, oxalic acid, and lactic acid, in various commercial formulations. The acids dissolve some of the hydroxyapatite crystals and remove 5–60  $\mu\text{m}$  of enamel surface and create a 5–50  $\mu\text{m}$  deep porous layer (Paradella and Fava 2007; Shinya et al. 2008). Generally, a higher acid concentration or a longer etch time produces deeper porosity. The dental adhesive then can flow into these pores for retentive tags or mechanical bonding. In some cases, the etching and bonding processes are combined as self-etching adhesives to simplify the process and make it quicker.

Other applications generally follow similar approaches. A clean, porous or rough surface, provided by either inherent porosity, etching, or grit blasting, is highly desired, but silane coupling agents or sol–gel treatments can provide chemical bonds to augment or replace physical bonding. They can also help “cure” surface-flaw damage caused by grit blasting (Bujanda et al. 2008).

Depending on temperature variations or extremes, differences in expansion due to differences in the coefficient of thermal expansion (CTE) may need to be considered with graded or intermediate interlayers being used as necessary. This is also true if the ceramic is being bonded to a structure subject to load deformation or other strain. For the Space Shuttle Orbiter, the thermal protection tiles are isolated from the aluminum frame with Nomex felt pads.

In the case of high operating temperatures where ceramics can be the material of choice, inorganic adhesives must be used and the surface preparation suitable to them is needed.

### 8.3.4 Wood

Wood is different from the materials discussed above in that it is a natural, heterogeneous material that exhibits variability of properties according to wood species, according to the cut of the wood, and according to specific wood specimen. Adhesion to wood most often relies on both physical (mechanical interlocking) and chemical bonds. Being inherently porous, the adhesive will normally penetrate into the wood several cells deep for excellent mechanical interlocking, but the most durable bonds to wood occurs when the adhesive diffuses into cell walls to make chemical bonds with the hemicellulosics and celluloses of the wood (Vick 2007). Adhesive penetration into sound wood can form an interphase that is stronger than the wood itself. To achieve such properties, the liquid adhesive must wet the wood surface with good capillary action to penetrate the sound wood structure, while displacing and absorbing air, water, and contaminants at the surface. Normally pressure is applied to facilitate this bonding process.

Surface treatment of the wood is intended to promote this bonding. Wood surfaces should be macroscopically smooth, flat, and free of surface irregularities, including planer skips and crushed, torn, and chipped grain. The surface should be free of burnishes, exudates, oils, dirt, and other contamination (Vick 2007). The best

surface treatment for wood is normally a smooth knife cut that avoids crushing or burnishing the surface and reduces adhesive wetting and penetration. This cut should be performed no earlier than 24 h before bonding. However, other surfacing procedures have been used successfully for certain types of adhesive joints, including sawing for furniture and millwork, knife-cutting for veneer, and abrasive-planning for panels.

Overdrying should be avoided as it can force hydrophobic extractives that can interfere with bonding to the surface (especially for resinous species) or can close some of the natural pores. Preservatives and fire retardants can also serve to fill natural pores and reduce the opportunities for good bond formation.

The density and, hence, the porosity of wood varies from species to species. As density increases, the ease of successful adhesive bonding decreases as opportunities for adhesive penetration decreases. Examples of easily bonding wood include basswood, fir, and pine. Examples of difficult to bond wood include persimmon, rosewood, and teak (Vick 2007).

As with metals, moisture is a major limiting factor in the durability of wood adhesive bonds. Dimensional changes (swelling or shrinking) of the wood adherend create significant changes vary with the orientation, type of wood specimen, and difference in moisture levels, but it can be up to 5–10% (Frihart 2009). Different adhesives handle this dimensional change in different ways. Frihart classifies the adhesives into two groups based on how swelling or shrinking affects the bond: in situ polymerized adhesives (phenolics, amino resins, isocyanates, and epoxies) have a rigid backbone and are usually highly cross-linked when cured, while prepolymerized adhesives (poly(vinyl acetate), polyurethane, emulsion polymer isocyanate, and proteins) have some backbone flexibility and a lower degree of cross-linking. In the first group, the adhesive achieves a durable bond by distributing the swelling strain across the wood interphase region (i.e., the region of the interphase in the wood where the adhesive has penetrated to lower interfacial stress). The flexibility of the second group of adhesives allows them to distribute strain in the adhesive interphase (i.e., the region of the adhesive near the wood). Both approaches decrease interfacial stress and allow dimensional changes to be handled.

---

## 8.4 Conclusions

High-performance, durable adhesive bonds to metal adherends require suitable surface preparation prior to bonding. The surface treatment cleans the surface of contamination that could prevent the adhesive or primer from bonding to the metal (oxide) surface. It also removes mill scale or other uncontrolled oxides that may be unsuitable for bonding or may represent a weak boundary layer. Finally, the treatment forms a new oxide or other film that provides physical (mechanical interlocking) or chemical bonding to the adhesive or primer. This oxide or film needs to be stable in the service environment for the life of the bond. It often forms a graded interphase between the polymer and the metal, thus minimizing stress concentrations at the boundary. This interphase can consist of a nanocomposite of

a porous oxide with the polymer penetrating into the pores or “nooks and crannies” of the oxide or a graded composition film.

The conventional surface treatments of aluminum, titanium, and steel were described. Environmentally benign treatments that are still being developed or are less common were also described. It is expected that these new treatments will see increasing use as environmental and health/safety regulations become stricter.

Similar approaches to preparing the adherend surface of other materials are also used although the details vary. The key aspects are to prepare a stable interface/interphase with either chemical or physical bonds that is stable under service conditions and able to handle stresses that arise from structural loading or from difference in material properties.

## Abstract

This chapter reviews a variety of methods of surface characterization that have been found to be useful in the study of adhesion. The methods considered can be conveniently classified in three groups: those that provide information regarding surface topography (scanning electron microscopy and atomic force microscopy [AFM]); those that probe the surface-free energy of a material (measurement of contact angles and inverse gas chromatography, in addition to simple test methods such as the water break test and dyne inks); and those that provide a surface-specific chemical analysis (X-ray photoelectron spectroscopy, Auger

electron spectroscopy, and time-of-flight secondary ion mass spectrometry). All provide surface-specific information and this is essential for adhesion investigations as the forces responsible for adhesion operate over very short length scales and for any analysis to be meaningful the analysis technique must probe depths of a similar order of magnitude. These methods are used in all types of adhesion investigations, which, in general, can be considered in one of three areas of endeavor. The analysis of the unbonded surface and the relationship of surface characteristics to performance such as strength or durability, the forensic analysis of failed joints with a view to defining the exact locus of failure and any interfacial phenomena that may have exacerbated failure, fundamental studies of adhesion carried out with a view to gaining a fuller understanding of the interfacial chemistry of adhesion.

---

## 9.1 Introduction

The last three decades have seen many advances in our understanding of fundamental aspects of adhesion. This has led to a large body of data in the open literature that relates the surface characteristics of substrates and polymeric overlayers to the interfacial chemistry of adhesion, which, in turn, is used to establish structure/property relationships based on measurements of a performance parameter, at the fundamental level (such as the thermodynamic work of adhesion, see ► [Chap. 6, “Thermodynamics of Adhesion”](#)). For applied investigations, surface data will be related to more pragmatic quantities such as the performance of an organic coating in a salt spray test or the strength and more importantly the durability of a structural adhesive joint. One thing is clear, however, and that is the surface characteristics of the two phases have a profound influence on the formation of the interface, which in turn governs performance. Adhesion relies on the establishment of intermolecular forces between a substrate and the polymeric adhesive itself. To this end it is invariably necessary to pretreat the solid substrate in some manner to confer the required surface properties; this may be a simple abrasion treatment or a more sophisticated method such as acid anodizing. In a similar vein, chemical methods such as a corona discharge treatment and flame treatment used on polyolefins or the application of a primer solution based on an organosilane adhesion promoter may be used to ensure the required durability of an adhesive joint. In all cases the performance of the adhesive joint is directly related to the successful application of such a pretreatment, and an important part of the development of a new pretreatment procedure or the quality assurance of an established process is the assessment of the surface characteristics, both in terms of topography and chemistry.

The characterization that is necessary in order to begin to appreciate the complexities that exist at the polymer/metal oxide junction relates to both surface chemistry and topography. The aim of this chapter is to introduce methods that are now well established in the adhesion field; although it is not possible to provide a complete description of these techniques, the aim is to provide a general background of what can be achieved and indicate why such methods have become widely used in

adhesion investigations. At this juncture it is worth reflecting on what exactly one hopes to achieve by carrying out such investigations, a review of the literature establishes quite clearly that adhesion studies that involve surface characterization techniques essentially break down into three clear areas:

- The investigation of surface characteristics prior to bonding and correlation with some form of performance parameter
- The forensic investigation of failed adhesive joints and once again correlation of failure characteristics with a chosen performance parameter (see ► Chap. 43, “Techniques for Post-fracture Analysis”)
- The use of sophisticated specimen preparation or modeling approaches to investigate the interfacial chemistry of adhesion

Such a list reflects the timeline along which adhesion science has developed in terms of surface characterization with the examination of the unbonded substrate being achieved first, then forensic analysis of failures and the determination of the interfacial chemistry of adhesion still being a significant challenge for many systems. Indeed the attainment of such a goal is in some ways the holy grail of adhesion science as it opens up the possibility of engineering the interface to provide a specific set of properties in terms of strength, toughness, and durability. Much headway has been made in this area in recent years but it is still a topic in which results are hard won and thus by definition very resource intensive.

The techniques by which such surface characteristics can be explored will be described in this chapter and a further chapter in this book will review the manner in which these methodologies are used in adhesion science (► Chap. 10, “Use of Surface Analysis Methods to Probe the Interfacial Chemistry of Adhesion”). The methods discussed will provide information regarding surface topography (SEM and AFM) as well as surface chemistry (XPS, ToF-SIMS, and AES). Surface thermodynamics is important at both a fundamental and an applied level and the use of wetting (see ► Chap. 4, “Wetting of Solids”) and spreading (see ► Chap. 5, “Spreading of Liquids on Substrates”) concepts such as contact angle and surface-free energy and inverse gas chromatography will also be considered.

---

## 9.2 Surface Topography

### 9.2.1 Scanning Electron Microscopy

Most laboratories engaged in adhesive bonding research and/or development will have ready access to scanning electron microscopy, and it is widely used to investigate both substrate surfaces prior to bonding and the characteristics of interfacial failure surfaces from adhesive bonds following a mechanical test. Optical or light microscopy is not really sufficient, not because it lacks the range of magnification of an SEM, although this is an important feature, but because of its poor depth of field and depth of focus. In optical microscopy features not in the image plane appear either under- or over-

focused (i.e., blurred) whereas an SEM is able to accommodate very large depths of field as exemplified by SEM images of small insects that often appear in the popular press. Having said that, the rigor of using digital photography to record all failure surfaces after test cannot be overemphasized to provide archival data that may provide important evidence once a program of testing has been concluded. As the general operating principles of an SEM are generally well appreciated, they will not be repeated here but the reader who needs a brief overview of operating principles is referred to standard texts such as Goodhew et al. (2001). The importance of surface topography is illustrated in Fig. 1. This shows a hot-dipped galvanized steel surface that has been temper-rolled (skin-passed) in readiness for a coil coating process. The surface rugosity is clearly observed at a scale of several tens of micrometers. As will be shown later in this chapter, the temptation to assume a homogeneous surface, although very natural, should be avoided as such mechanical treatment can lead to a well-defined heterogeneous surface.

It is very often convenient to use SEM to examine failure surfaces of joints as indicated above. The micrograph of Fig. 2 is the failure surface of an aluminum substrate bonded with a structural adhesive. Although on the basis of the microscopy one would tend to classify this as an interfacial failure, there are a few small islands of adhesive left on the metal side of the failure that vary in size from a few micrometers up to around 100  $\mu\text{m}$ . As the polymer is an insulating material, it will generally charge during electron microscopy and this is evident in the micrograph of Fig. 2 as darker contrast around the adhesive residue. As ► Chap. 10, “Use of Surface Analysis Methods to Probe the Interfacial Chemistry of Adhesion” will indicate, the definition of the locus of failure is a rather complex task and depends on the level of sophistication of the assessment methods available, but for the time being the example of Fig. 2 will be considered an interfacial failure. Some pre-treatments lead to characteristic morphologies on a very fine length scale that can only be clearly defined by high-resolution SEM. The most widely cited example of this type of surface is the classic work of Venables (1984) on the morphology of acid anodized aluminum. The approach taken by these authors was to record stereo pair

**Fig. 1** Scanning electron micrograph of a hot-dipped galvanized steel surface

**Fig. 2** The interfacial metal failure surface from an adhesively bonded aluminum test piece. The substrate has been grit blasted with 50  $\mu\text{m}$  alumina grit prior to bond fabrication

SEM micrographs and present these along with an isometric drawing of the supposed morphology. These micrographs are, quite rightly, regarded as classics in the adhesion bonding literature and interested readers are referred to the above review of this work for further information.

In the case of polymeric substrates SEM is not quite so useful. The modifications brought about are quite subtle and the need to coat the insulating surface with carbon, gold, gold palladium, or a similar material to prevent electrostatic charging can add another level of complexity to sample preparation. Although useful for identifying debris at a surface or delamination in the case of composite materials, atomic force microscopy is generally preferred to SEM for the examination of polymer surfaces. SEM used in conjunction with energy dispersive X-ray analysis (EDX) will, however, always have a place in adhesion investigations as a result of the ready bulk analysis that can be undertaken, which will identify, for example, pigmentation in a coating or adhesive.

### 9.2.2 Atomic Force Microscopy

AFM is one of a family of techniques referred to by the generic name of scanning probe microscopy (SPM). These all have their genesis with the scanning tunneling microscope first developed by Binnig et al. (1982).

A schematic of an AFM is shown in Fig. 3, and although closely related to the STM the basic principle relies on the attraction between a sharp tip (often of silicon nitride) and the surface under examination. The tip is located at the free end of a cantilever of low spring constant (ca.  $1 \text{ Nm}^{-1}$ ). The force between the tip and the sample cause the cantilever to deflect. A detector arrangement, based on a laser reflecting from the cantilever and a quadrant array photodetector, records the deflection of the cantilever as the tip is scanned relative to the sample. The extent of deflection of the cantilever can then be used to produce an image of surface

**Fig. 3** Schematic of an atomic force microscope

**Fig. 4** Force curve showing interatomic force, between tip and specimen, as a function of distance

topography. The forces involved are repulsive at very close proximity (ca. 0.1 nm) but as the cantilever is withdrawn they become attractive as shown in Fig. 4. This leads to the definition of two forms of AFM operation, contact (ca. 0.2 nm distance on Fig. 4) and noncontact AFM (0.4–0.6 nm). In contact AFM, the tip makes gentle contact with the sample and, in the case of very soft or delicate samples (e.g., pressure sensitive adhesive tape) may indent the surface giving erroneous results, if any at all. To overcome this problem the tip may be vibrated near the surface

**Fig. 5** Tapping mode AFM image of a commercial PVC extrudate: (a) before treatment and (b) after flame treatment

(1–10 nm); however, the force between tip and sample may be very small (10–12 nN) making it more difficult to measure than the force in the contact mode, which is several orders of magnitude higher. There is also the possibility of the tip being pulled into the sample so stiffer cantilevers are required. A compromise between these two modes of operation is tapping mode AFM (TM-AFM) in which a sinusoidal vibration is applied to the tip and it gently taps against the surface; as shear and lateral forces are reduced, sample damage is, in most cases, negligible. An example of TM-AFM is shown in Fig. 5, which illustrates the topography of a poly (vinyl chloride) (PVC) surface before and after energetic surface treatment.

AFM has a wide range of magnifications from close to atomic resolution to a magnification of approximately 500 times; so in many ways it competes with the SEM as a method of assessment of surface topography. The complementarity of AFM and SEM have been discussed at some length by Castle and Zhdan (1997). Instruments are now available in portable format, low cost versions, geometries to accommodate very large specimens, and a plethora of different versions handle difficult samples such as cells and wet surfaces, making it a very versatile technique indeed. As far as those involved in adhesive bonding are concerned, the advantages of an AFM over other forms of surface characterization are threefold: Firstly, all samples, metal, polymer, ceramic, viscoelastic adhesives, and so on, can be handled successfully without the need for further sample processing. Secondly, by processing the image data as a line scan it is possible to carry out a “sectional analysis” that is essentially stylus profilometry, as described in BSI (2010) at the nanometric scale. The third is rather more specialized but if one measures forces directly one can use the AFM to monitor forces and thus use it as a localized surface forces apparatus, probing the adhesion properties of a polymer blend, for instance. In a similar manner force modulation can be used to probe localized elastic properties in the cross section of a polymer composite, or adhesive joint, and in this manner an interphase zone can be identified mechanically. Such modes of operation complement the traditional ways of probing surface-free energy, which are discussed in the following section.

### 9.2.3 White Light Interferometry

Although AFM has much to recommend itself as a technique for surface characterization, its primary role in most areas of research is, as its name suggests, that of a sophisticated microscope for the elucidation of surface topography. As a means of the determination of surface roughness it remains something of “an overkill,” but in addition it has two significant disadvantages for roughness measurement. Firstly, AFM is still some way off becoming a routine tool for quality assurance with a high level of operator skill being required, in addition the speed with which data is produced is not high and given the choice of an SEM or AFM for initial assessment of a surface many operators would resort to the rapidity of the former. The upper bounds of measurement achievable may also be a problem with samples exhibiting coarse features, as for AFM the scan area in the x and y directions is limited to tens or at best hundreds of micrometers and in the z direction only a few micrometers. The solution to the need to acquire statistically meaningful measures of surface roughness over relatively large areas has been driven by the microelectronics industry, which has the need to assess large wafers at roughnesses of much less than 1 nm. The solution to this need has been the development of the well-established technique of white light interferometry (WLI) into a routine quality assurance procedure, with large ranges available in all axes and superb height resolution (0.01 nm are quoted for the latest instruments). The area where AFM outperforms WLI is in lateral resolution, although for many measurements of relevance to adhesive bonding this will not present a problem.

The background to optical interferometry is well known and is based around the spitting of a beam from a single light source into two separate beams using a beam splitter: one of the beams acts as a reference and follows a well-defined path and the other is reflected from the sample surface. At some point in the optical path, the two beams recombine to form an interference pattern of light and dark fringes. This is then magnified by the detector optics and finally imaged using a suitable device such as a CCD (charge-coupled device) camera. If at the same time the objective lens is moved vertically (to change path length between sample and beam splitter), with a high-resolution device such as a piezoelectric drive system, a series of dynamic interference fringes will be observed. Constructive interference will lead to a brightening of the image and, provided the movement of the objective lens is known accurately, this can be mapped back to a position on the sample surface via the establishment of the brightest point on each element of the CCD array. In this way it is possible to create a three-dimensional image of the sample surface by recording the position of the objective that gives the brightest image at each point on the CCD. Data from WLI is often presented in the form of a color-coded topographic plot or a pseudo three-dimensional plot, forms that are familiar to many as a result of their popularity with AFM manufacturers. Roughness values will be reported usually as an average over the entire field of view rather than the one-dimensional line familiar from stylus profilometry or sectional analysis in the AFM.

## 9.3 Surface Energetics

### 9.3.1 Simple Test Methods

Surface energetics is the behavior of gas and liquid molecules on solid surface and the relationship to the surface-free energy of the solid and liquid phases. The three-dimensional equilibrium packing of solids and liquids cannot be maintained at the surface and this less-than-satisfactory situation gives atoms at the surface a greater free energy than those in the bulk. This excess energy is known as the surface-free energy and has the units of energy per unit area, and using the SI notation surface-free energy, represented by the symbol  $\gamma$ , is always reported in  $\text{mJm}^{-2}$ . In liquids the surface-free energy gives rise to the well-known phenomenon of surface tension and, indeed, the values of surface-free energy and surface tension are numerically equal, although surface tension has the units of force per unit length, in the SI notation  $\text{mNm}^{-1}$ . It is incorrect to refer to the surface tension of a solid and terms such as wetting tension, interfacial tension, and so forth are now regarded as deprecated. The value of surface-free energy can vary widely: solid polymers represent the lowest class of solid materials with values in the range of  $20\text{--}50 \text{ mJm}^{-2}$ , inorganic solids have values in the range of  $100\text{--}200 \text{ mJm}^{-2}$ , while clean metal surface (which are not achieved in practice except for the noble metals) are in the range of  $1000\text{--}2000 \text{ mJm}^{-2}$ . Liquid water, as a result of the hydrogen bonding present, has an unusually high-value surface-free energy for a liquid at  $72 \text{ mJm}^{-2}$  (or a surface tension of  $72 \text{ mNm}^{-1}$ ). Solid polymers on the other hand are characterized by very low values of surface-free energy as the surface of polymers generally do not contain broken bonds (or unsatisfied valencies) but merely loops resulting from the folding of the macromolecules making up the polymer structure. Thus the energy difference between bulk and surface is relatively small leading to a small value of surface-free energy.

As with bulk surface thermodynamics there is a driving force to reduce the surface-free energy of a material. For a solid such as a metal oxide this is readily achieved by the adsorption of a monolayer of organic vapor from the ambient. As surface practitioners are only too aware, any high-energy surface will adsorb such a monolayer spontaneously and all samples of this type analysed by X-ray photoelectron spectroscopy (or other methods for surface chemical analysis) will show tell-tale signs of the adsorption of adventitious carbon in the spectrum. The reduction of surface-free energy is the driving force for the deposition of a well-defined hierarchy of layers as discussed in detail by Castle (2008).

Any technique that probes explicitly, or at least gives an indication of the value of surface-free energy, has the potential to provide information regarding the behavior when a solid surface is coated with a liquid such as an adhesive or organic coating. Such measurements will be extremely surface sensitive, mostly providing information about the outer one or two atomic layers. Such methods can be used in a very pragmatic manner for quality assurance and also in a much more sophisticated manner using well-established protocols to evaluate surface-free energy and deduce the contribution to the parameter from various bonding types.

In the category of simple quality assurance methods, there are two widely used tests that provide straightforward information about the fitness of a solid surface (inevitably after treatment) for further processing: dyne pens and the water break test. Dyne pens are used for the assessment of polymeric surfaces where pretreatment has been carried out to increase the surface-free energy of the material by the incorporation of more polar functional groups. The concept of dyne markers is extremely simple (the term dyne is the cgs unit of force, surface tension having the units of  $\text{dyne cm}^{-1} = \text{mNm}^{-1}$ ;  $1 \text{ N} = 10^5 \text{ dyne}$ ; this system of units is based on centimeter-gram-second units and was the predecessor of the SI or mks system based on meter-kilogram-second units). They are usually supplied as a kit containing pens with “inks” of well-defined surface tensions, usually between 30 and  $60 \text{ mNm}^{-1}$ . In order to assess the surface under test, and they are used almost exclusively to establish the printability of polymer surfaces following surface treatment, the marker pen is applied to the substrate, and if it marks (i.e., the liquid wets) the surface then the substrate has been treated to a level required for wetting to take place. These markers will always have a dye included in the liquid so they can be used in the conventional sense as marker pens for product identification. In general these markers will be used as a go/no-go during processing or to identify the treated side of a polymer film. By using a range of dyne pens, it is possible to estimate the surface tension of a liquid that will just wet the surface and thus gain an indication of the level of treatment of the polymer surface. The advantage of this system is that it is quick, cheap ( $<£10$  per pen), easy to use, and, if the pen is new, can provide quite accurate results. The drawbacks are the short shelf life of pens, easy contamination of the liquid, and the lack of a numerical value relating directly to substrate properties – only a relative ranking order can be deduced. Notwithstanding such shortcomings, dyne markers will continue to play an important role in the surface treatment industry.

The other widely used simple test method is the water break test as described in ASTM (2002). The purpose of this test is to assess the efficacy of a cleaning process of a metal substrate. Here the requirement is exactly the opposite to that for the assessment of polymers in that an oxidized metal surface will have a high surface-free energy that may be compromised by the adsorption, or indeed a deliberate application of organic vapors or liquids. Cleaning is required to remove such extraneous material, which leads to a higher surface energy, and the successful removal of contamination is easily recognized by this test. Such carbonaceous films will be hydrophobic (non-wetting) in nature and the test involves withdrawing the metal panel under test from a container full to the brim with distilled water. On withdrawing a clean substrate, the water will drain uniformly over the surface. In the presence of residual contamination the draining water film will break up into a discontinuous layer around the contaminated regions. Although this is a very subjective test it is quick to carry out and lends itself to process control purposes. One form of the test is embodied in an international standard.

However, it is the measurement of contact angle that provides the most sensitive method and one that can be adapted to provide a quantitative measure of surface-free energy.

### 9.3.2 Contact Angle

The observation of contact angle ( $\theta$ ) can be related to the surface-free energies of solid substrate ( $\gamma_{\text{solid}}$ ) and wetting liquid ( $\gamma_{\text{liquid}}$ ), along with the interface free energy ( $\gamma_{\text{interface}}$ ) by the well-known Young Equation:

$$\gamma_{\text{solid}} = \gamma_{\text{liquid}} \cos \theta + \gamma_{\text{interface}} \quad (1)$$

which by the simple expedient of resolution of forces about the triple point relates the surface and interface free energy terms to the observed contact angle as shown in Fig. 6. This observation of a sessile drop is frequently used as a quality assurance measure as a very low water contact angle indicates a hydrophilic surface (i.e., one with a relatively high surface-free energy) and a high contact angle indicates a hydrophobic surface (low surface-free energy). The observed contact angle is simply a measure of the propensity of the liquid (generally water in a simple test) to bond with itself compared with the solid substrate. For a hydrophobic substrate the hydrogen bonding between water molecules is much greater than the association between water and the substrate; in the case of a hydrophilic substrate, the association between water molecules and substrate is sufficient to overcome the hydrogen bonding responsible for the self association between water molecules. The direct observation of a large sessile drop (several millimeters in diameter) is readily accomplished in a production environment but the results obtained are only representative of the actual surface-free energy of the substrate if the substrate is homogeneous; heterogeneities in either topography or composition may prevent equilibrium being attained as required by the Young Equation. This may lead to the periphery of the drop departing from the circular and such behavior also manifests itself as contact angle hysteresis. This is often the case and the use of a sessile drop deposited by syringe or pipette has limited the use of contact angle measurement in such environments. Recently, however, the concept of ballistic sessile drop deposition, in which a stream of nanoliter volume drops are deposited on the surface and then coalesce into a single drop with a volume of several microliters, has been investigated and developed to the point that such a device is now available commercially under the name Surface Analyst<sup>TM</sup> from Brighton Technologies Group Inc. (2010). The output from the device is the diameter of the drop deposited in this manner, typically of the order of several millimeters. Initial results are extremely promising and show that such a device is able to separate

**Fig. 6** The equilibrium that exists between a sessile drop and a solid surface, indicating the contact angle

composite panels prepared for adhesive bonding and then contaminated with a range of typical liquids found in a production plant (Dillingham et al. 2010).

As discussed above the surface-free energy of the probe liquid will influence the extent of solid–liquid interactions which will be observed as the contact angle. By the simple expedient of using a range of liquids with different surface-free energies and bonding types, it is possible to use such an approach to determine the surface-free energy of the solid. Many commercial instruments are available and all will be supplied with a dedicated computer that will contain the necessary software to make calculations of surface-free energy and related parameters, although all software should be supplied with a health warning for the inexperienced user! It is possible to assess the surface-free energy by extending the Young Equation, above, and recognizing that the surface-free energy can be subdivided into components that represent the degree bonding attributable to dispersion forces ( $\gamma^D$ ), polar forces ( $\gamma^P$ ), hydrogen bonding ( $\gamma^H$ ), and so forth, such that:

$$\gamma = \gamma^D + \gamma^P + \gamma^H + \dots \quad (2)$$

where the exact number of components depends on the material type and thus the bonding types involved. It is possible to arrive at the following relationship, the derivation of which is given by Packham (2005):

$$1 + \cos \theta = 2 \frac{(\gamma_L^D \gamma_S^D)^{1/2}}{(\gamma_L)} + 2 \frac{(\gamma_L^P \gamma_S^P)^{1/2}}{(\gamma_L)} \quad (3)$$

where the subscripts S and L represent the solid substrate and wetting liquid, respectively. The approach involves the use of a series of liquids of known values of the dispersive and polar contributions to surface-free energy, to measure the contact angles on the solid substrate of interest. This then yields a number of simultaneous equations of the type shown above. As they contain only two unknowns, the dispersive and polar contributions of the surface-free energy of the substrate, these can be readily evaluated. An alternative approach is to rearrange the equation in the form:

$$\frac{\gamma_L(1 + \cos \theta)}{2(\gamma_L^D)^{1/2}} = (\gamma_S^D)^{1/2} \left[ \frac{(\gamma_L^P)^{1/2}}{(\gamma_L^D)^{1/2}} \right] + (\gamma_S^P)^{1/2} \quad (4)$$

The equation is now in the form of  $y = mx + c$ , and a graph of  $\gamma_L(1 + \cos \theta)/2(\gamma_L^D)^{1/2}$  plotted versus  $[(\gamma_L^P)^{1/2}/(\gamma_L^D)^{1/2}]$ , the gradient of the best-fit line will be  $(\gamma_S^P)^{1/2}$ , and the line intercept  $(\gamma_S^D)^{1/2}$ . The surface energy of the unknown solid,  $\gamma_S$ , is then the sum of the two terms,  $\gamma_S = \gamma_S^D + \gamma_S^P$ . The form of plot obtained using this approach is illustrated in Fig. 7, which represents data obtained from a poly (dimethyl siloxane) surface using water, di-iodomethane, and hexadecane as probe liquids that gave mean contact angles of 119°, 79°, and 37°, respectively.

**Fig. 7** Wetting data for poly(dimethyl siloxane) (PDMS) probed by water, di-iodomethane, and hexadecane

**Table 1** Surface-free energies of liquids used in the wetting experiment of Fig. 7

Probe liquid	$\gamma^D$ (mJm <sup>-2</sup> )	$\gamma^P$ (mJm <sup>-2</sup> )	$\gamma$ (mJm <sup>-2</sup> )
Water	22	51	73
Di-iodomethane	28	0	28
Hexadecane	2	49	51

The relative contributions of dispersion and polar bonding to these three liquids are shown in Table 1. The value of surface-free energy obtained in this way was 22 mJm<sup>-2</sup> (Choi 2003).

### 9.3.3 Inverse Gas Chromatography

As shown above the use of contact angle measurements provides a relatively straightforward manner in which to assess the surface energetics and wetting characteristics of a solid surface. It is particularly attractive as it can be used on several levels of complexity ranging from a qualitative assessment of surface behavior (hydrophobic or hydrophilic) through to its use for the determination of surface-free energy and relative contributions to that parameter from dispersion and polar bonding. In spite of these obvious advantages it remains a macroscopic measurement and invariably represents the value over a large area, and application to rough surfaces will suffer from excessive amount of contact angle hysteresis unless some form of ballistic drop deposition is employed. An alternative approach to assessment of surface-free energy of solids is the use of inverse gas chromatography (IGC). The term inverse is used in the title to indicate that the material of interest is the stationary phase in the gas chromatography column rather than the volatile species injected into the column. (In the usual mode of operation for gas chromatography the volatile species is the phase under investigation and a standard stationary phase is employed.) The major restriction of IGC is that the solid phase under investigation

**Fig. 8** Schematic diagram of the experimental configuration used for inverse gas chromatography (Reproduced from Abel and Watts 2005a with permission)

must be in a form suitable for incorporation into a column a few millimeters in diameter. This limits the physical form to coarse powders and fibers. As the stationary phase is usually conditioned at elevated temperature (ca. 120 °C) before injection of probes, this provides the driving force to desorb adventitious contamination and water so that adsorption of the probes is carried out on a cleaner surface than contact angle measurements. One advantage of IGC is that the high-energy sites on the surface are probed preferentially and rough surfaces can be investigated; indeed the comparison of results from long chain and branched isomers of the same molecule (usually an alkane) enable roughness to be elucidated.

The form of a typical IGC arrangement is shown in Fig. 8 and is readily carried out using standard GC equipment although specialized IGC equipment is available that allows the control of relative humidity and automated operation (Surface Measurement Systems 2010). A column of stainless steel or poly(tetra fluoroethylene) (PTFE) is packed with the solid of interest and loaded between the injector and the detector. The analytical measurements consist of injecting, sequentially, a series of volatile probes of known properties through the column along with an inert carrier gas. The retention time for each probe is related to the surface properties of the stationary phase. The usual practice is to carry out a series of injections with a homologous series of nonpolar organic probes such as the n-alkanes. This gives information about the interactions between the probes and the stationary phase associated with dispersion forces (sometimes referred to as Lifshitz–van der Waals forces). When a parameter derived from the observed retention time is plotted against probe boiling point, a logarithmic relationship can be observed which can be used to calculate the dispersion

441 bonding contribution to surface-free energy (Abel and Watts 2005a). Alkane probes  
442 are apolar molecules only able to interact with solid surfaces through dispersion  
443 bonding and for this reason they only probe dispersion interactions with the stationary  
444 phase enabling the contribution of this bond type to surface-free energy to be assessed.  
445 In order to assess the contribution of acid–base (or polar) interactions it is necessary to  
446 use polar probes, the magnitude of the deviation from the linear relationship referred to  
447 above being a measure of the magnitude of acid–base interaction between the station-  
448 ary phase and the polar probes (Abel and Watts 2005b). The effect on retention time of  
449 the probe properties is illustrated in Fig. 9, which is an inverse gas chromatogram  
450 achieved by simultaneously injecting five probes (two alkanes and three polar probes)  
451 and methane as a noninteracting marker to define zero time. The substrate is hydrated  
452 alumina. A typical plot achieved in this manner is shown in Fig. 10 for an aromatic  
453 methacrylate resin (the parameter  $V_N$  in the ordinate is the net retention volume which  
454 is calculated from the net retention time, the primary measurement in IGC, illustrated  
455 in Fig. 9). The three polar probes are a combination of acidic and basic types:  
456 trichloromethane is acidic, ethyl acetate amphoteric but predominantly basic, and  
457 tetrahydrofuran is basic. The fact that significant deviations are seen from the reference

**Fig. 9** IGC data recorded for hydrated alumina treated with an organosilane adhesion promoter when five probes are injected simultaneously to illustrate the effect of probe characteristics on retention time (Reproduced from Chehimi et al. 2001 with permission of The Royal Society of Chemistry)

**Fig. 10** Adsorption of apolar and acid base probes on an aromatic methacrylate resin. *TCM* chloroform, *EtAc* ethyl acetate, *THF* tetrahydrofuran (Reproduced from Taylor et al. 1995 with permission)

alkane line indicates that the substrate has both acidic and basic sites. This illustrates one of the strengths of IGC; by the informed choice of polar probes it is possible to probe polar sites on the stationary phase and furthermore estimate the extent of acidic and basic contributions.

## 9.4 Surface Chemical Analysis

As the forces responsible for adhesion between substrate and adhesive or organic coatings operate over very short distances, the requirement for a chemical analysis method that can provide information regarding the nature of interfacial bonding, or indeed the presence of species that will compromise it, along with an exact definition of where failure occurs, needs to have a characteristic sampling depth of similar dimensions. This requirement is met by techniques that fall into the category of those that provide a surface chemical analysis. Although there are a number that can be placed in this category, or other methods that can be modified so as to provide surface-specific information, the term “surface chemical analysis methods” is currently taken to mean three methodologies: X-ray photoelectron spectroscopy (XPS); Auger electron spectroscopy (AES) and its chemical imaging variant scanning Auger microscopy (SAM); and time-of-flight secondary ion mass spectrometry (ToF-SIMS). The methods have all been commercially available for many years and can now be considered as mature analytical techniques that are fairly readily available in universities, corporate research laboratories, and organizations providing contract analysis. XPS and AES are based on the energy analysis of low-energy electrons while SIMS makes use of mass spectrometry of the sputtered surface ions (both positive and negative) to achieve surface mass spectrometry. The analysis depth is of the order of 5 nm for the electron spectroscopies and rather less for SIMS. Their application, particularly of XPS, in adhesion studies has been reviewed by the current author several times in the past (Watts 1988, 2009, 2010) and the current section is intended to provide a very brief overview of these methods and their application in adhesion-related studies. For further details the interested reader is referred to introductory

(Watts and Wolstenholme 2003; Vickerman and Gilmore 2009) or more advanced texts (Briggs and Vickerman 2001; Briggs and Grant 2003) on these topics.

### 9.4.1 X-ray Photoelectron Spectroscopy

XPS has been widely used in many areas of materials science, chemistry, and physics over the 40 years since it first became commercially available. The application of XPS to adhesive bonding studies and adhesion science in general was well established by the late 1970s and by 1980 there were four research groups with a strong presence in this area, two in the USA and two in Europe, interestingly enough three of these were based in corporate research laboratories with only one in academia (Castle's Group at the University of Surrey). The enthusiasm with which XPS has been adopted by the adhesion community springs, to a large extent, from the important role that surface and interfacial phenomena have to play in the adhesion process. The characteristic length scales over which bonds form, or indeed can be compromised or enhanced by the presence of additional molecules (e.g., contamination or adhesion promoters), are consistent with the analysis depth that is probed by XPS, as well as the other surface analysis techniques.

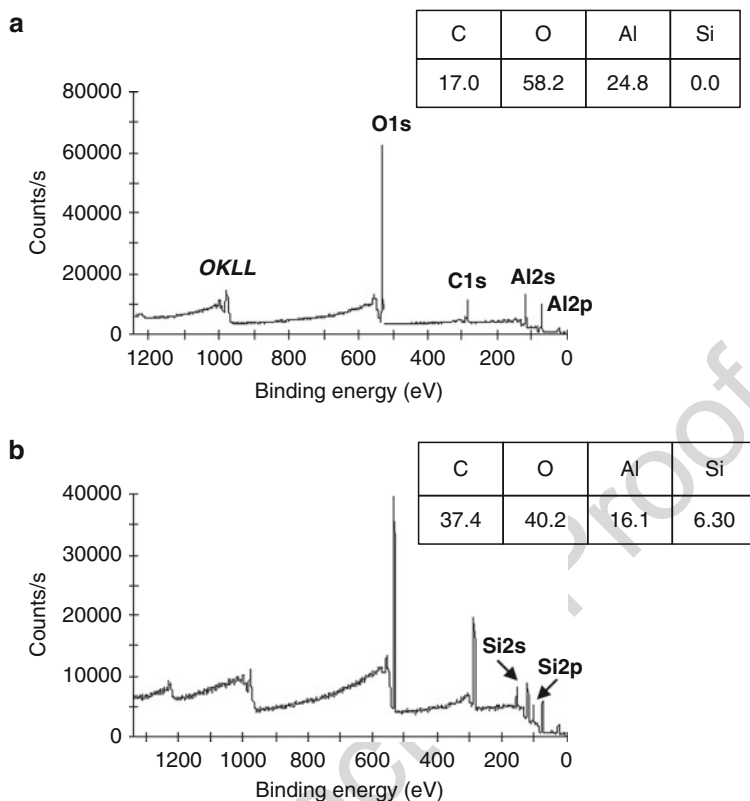

The heart of the XPS experiment is the irradiation of a solid sample with soft X-rays, usually  $\text{AlK}\alpha$  with a photon energy of 1486.7 eV. This leads to the emission of photoelectrons that are then injected into an energy analyzer/detector arrangement that will determine their intensity as a function of energy. The primary measurement made by the spectrometer is the kinetic energy ( $E_k$ ) of the outgoing electrons; this is not a characteristic material property but is a function of the photon energy ( $h\nu$ ) employed in the XPS experiment. The fundamental property is the electron binding energy ( $E_b$ ), in simple terms the energy with which a particular electron is bound into its electronic orbital. This quantity is related to the experimental observable and photon energy by the following equation:

$$E_b = h\nu - E_k - \omega \quad (5)$$

where  $\omega$  is a constant term, the spectrometer work function. The output of an XPS system is the X-ray photoelectron spectrum and Fig. 11 indicates the survey spectra obtained from clean aluminum foil and foil that has been handled prior to analysis. The spectra contain peaks that are assigned to Al (2p and 2s), Si (2p and 2s—contaminated sample only), C (1s), and O (1s); in addition there are Auger transitions associated with the de-excitation of the C1s and O1s core holes. These spectra are readily quantified to provide a surface chemical analysis in atomic percent, the carbon level having doubled on handling and silicon having appeared on the surface at a concentration of 6.3%. The silicon is present as a silicone oil (most likely from a personal care product) and provides an example of the type of adventitious material present on a surface that may compromise the bonding process and the performance of the adhesive joint.

As well as ready quantification XPS can provide chemical state information by inspection of the exact binding energy of the XPS peak. This so-called chemical shift

**Fig. 11** XPS survey spectra of aluminum foil recorded in the (a) as-received condition, and (b) following handling contamination. The quantitative surface chemical analyses (in atomic percent) is given in the inset boxes on each spectrum

is the cornerstone of XPS and provides a powerful means of assessing the valence state of metallic and nonmetallic species and the bonding types in organic and polymeric molecules. Figure 12 illustrates this aspect of XPS with a high-resolution Al2p spectrum showing components assigned to metallic aluminum ( $\text{Al}^0$ ) and the oxide ( $\text{Al}^{3+}$ ). The intensity of electrons ( $I_d$ ) emitted as a function of depth ( $d$ ) is described by the well-known Beer–Lambert Equation:

$$I_d = I_\infty \exp(-d/\lambda \cos \theta) \quad (6)$$

where  $I_\infty$  is the intensity from an infinitely thick sample of the same composition,  $\lambda$  is the electron attenuation length (the effective scattering length of electrons of a particular energy in the solid of interest that will be 1–3 nm), and  $\theta$  is the electron take-off angle relative to the sample surface normal. The variation of the intensity with depth is shown in Fig. 13, which illustrates quite clearly the exponential decay of the signal as a function of depth. This form represents the intensity for a solid with a thin attenuating overlayer (such as an oxide on a metal) and relates to the signal

**Fig. 12** High-resolution Al<sub>2</sub>p spectrum showing metallic and oxidic components of the spectrum

from the substrate. The Beer–Lambert Equation can also be written in terms of a thin overlayer (such as the oxide on a metal) where the signal considered is that from the thin overlayer. The equation then becomes:

$$I_d = I_\infty [1 - \exp(-d/\lambda \cos \theta)] \quad (7)$$

This provides a useful approach for calculating the thickness of thin layers on substrates such as a thin adhesive residues or the thickness of a contaminant layer. In the case of a thin metal oxide, the two equations can be combined to provide a ready means of estimating the oxide thickness from the intensity of the cationic ( $I^{\text{ox}}$ ) and metallic ( $I^{\text{me}}$ ) components of the spectrum:

$$d = \lambda \cos \theta \ln[(I^{\text{ox}}/I^{\text{me}}) + 1] \quad (8)$$

For the spectrum of Fig. 12, an oxide thickness of 4.2 nm is calculated using this method.

The geometric term,  $\theta$ , in Eq. 6 indicates the variation of electron yield with the take-off angle and this provides an important way in which the depth of analysis can be varied by recording spectra at different take-off angles. This is known as angle-resolved XPS (ARXPS) and by combining the ARXPS data set with suitable software it is possible to use this method to produce shallow compositional depth profiles in the range 0–5 nm. This is particularly useful for investigating the surface segregation of minor components to free surfaces or, indeed, interfacial failure surfaces.

Thus, XPS provides a quantitative surface analysis method that is applicable to all solid materials, so long as they are stable within the ultra-high vacuum environment of the spectrometer, and the high-resolution spectra provide chemical information for all elements in the periodic table with the exception of hydrogen. Traditionally XPS is considered to be an area-integrating technique as the photoelectron spectrum is

**Fig. 13** Variation of electron emission as a function of depth for a typical XPS experiment

acquired over a relatively large area of several square millimeters. Modern instruments, however, are able to record complete spectra at high spatial resolution (the best currently available is 10  $\mu\text{m}$ ) or produce elemental or chemical maps similar in appearance to those produced in electron probe microanalysis (EPMA). Such improvements have come about as a result of the development of microfocus X-ray monochromators and analyzers that allow the acquisition, in parallel or serial format, of images at the detector. A current state-of-the-art XPS system will be equipped with a monochromatic  $\text{AlK}\alpha$  X-ray source and imaging facilities by either parallel (at the detector) or sequential (rastering either specimen stage or X-ray spot) acquisition. The two approaches to imaging XPS both have their advantages; parallel imaging is much faster and allows assessment of the specimen to be made as the XPS images develop, but extraction of chemical state information requires a number of sequential energy-selected maps to be acquired. With serial mapping (analogous to the EPMA approach) a full spectrum can be acquired at each pixel point as the position of analysis moves sequentially across the specimen. The data set can then be integrated and spectra at each pixel point peak fitted or used to contribute to a quantitative analysis or overlayer thickness map. The disadvantage of such a method is that it is very time consuming. Figure 14 illustrates the small spot XPS system in the author's laboratory (which uses serial acquisition for imaging) and provides parallel ARXPS data. The XPS images from a failed adhesive joint obtained with this system are shown in Fig. 15.

#### 9.4.2 Auger Electron Spectroscopy and Scanning Auger Microscopy

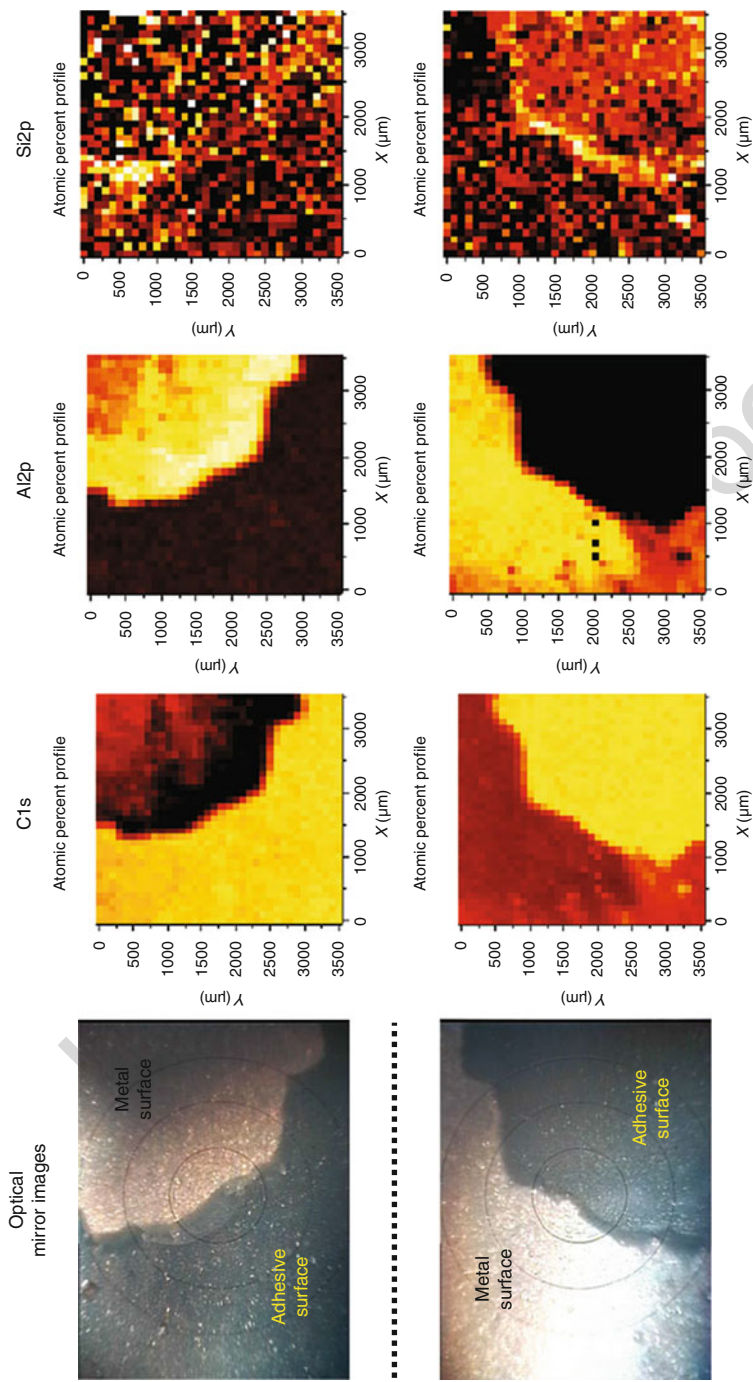

AES and SAM are both based on the use of a finely focused electron beam to provide a surface analysis. The division between the two techniques is largely arbitrary nowadays but the configuration of a scanning Auger microscope will have, in appearance,

**Fig. 14** Modern XPS system with serial imaging and parallel ARXPS capabilities

much in common with a scanning electron microscope and at its heart will be a high-resolution electron gun, typically giving sub 10 nm resolution, and a high transmission electron energy analyzer. Such systems can usefully form the basis of sophisticated multi-technique instruments and Fig. 16 shows the Auger microscope in the author's laboratory that was specified in this way. As well as featuring high-resolution Auger analysis, this instrument also has facilities for energy dispersive X-ray analysis (EDX), XPS, and backscattered electron detection. The provision of AES and EDX without the need to relocate the sample is extremely useful as it provides analysis in surface and bulk regions (5 nm cf. 1  $\mu$ m). In contrast to scanning Auger microscopy, AES is taken to mean the provision of electron-induced Auger spectra, often in the form of an ancillary technique on an XPS system (as the analyzer used is the same) or process systems (where deposition quality may need to be monitored) where the need for the ultimate spatial resolution is not paramount. Electron guns for this application will range in spot size from 5  $\mu$ m down to 100 nm, still much better than the spatial resolution that can be achieved by XPS.

The generation of an Auger electron is a three-electron process involving the removal of a core electron to leave a core hole, the filling of the hole by an electron from outer level and the emission of an electron (often from the same outer level) as an Auger electron. The nomenclature employed for Auger transitions identifies the element and the energy levels involved in the three-electron process, for example, Zn  $L_3 M_{4,5} M_{4,5}$ . The Auger process achieves the same relaxation effect as the emission of an X-ray photon (indeed they can be considered as competitive processes) but

**Fig. 15** XPS images recorded from the interfacial failure surfaces of an adhesively bonded aluminum joint, prepared using an organosilane primer, with an instrument of the type shown in Fig. 14. The optical mirror images are complementary views of the fracture surfaces and are mirrored along the dotted line. Visually the failure appears to be interfacial with the fracture path moving from one interface to the other at the boundary between metal and adhesive interfacial failure surfaces

**Fig. 16** A multi-technique analytical system (AES, SAM, SEM, XPS, EDX, BSE) based around a high-resolution scanning Auger microscope

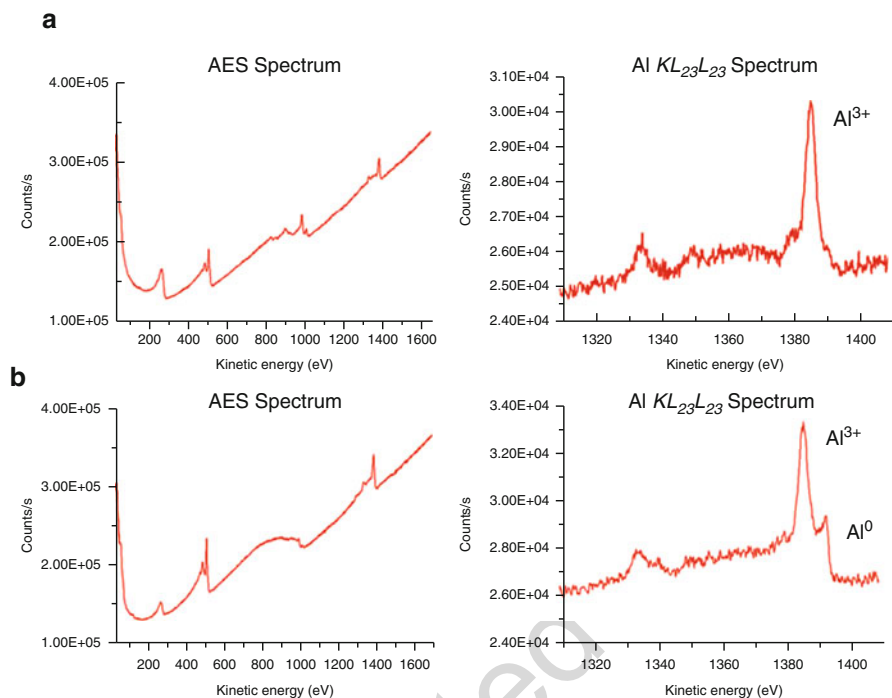

fortuitously Auger cross sections are good where X-ray ones are less favorable and vice versa. The nature of the Auger emission process means that very light elements do not show Auger transitions but elements from beryllium onward all yield Auger spectra. As an example of Auger spectra, Fig. 17 shows Auger spectra taken from the points identified in the SEM image of Fig. 1. The two survey spectra show clear differences in the Zn spectra with the data from Point 1 being much better defined than Point 2. The high-resolution Al KLL spectra provide an example of the chemical shift (seen in all elements in XPS), in AES; Point 2 shows both metallic and oxide contributions but Point 1 only shows evidence of aluminum oxide. The Auger chemical effect is generally only observed for transitions in which all three electrons can be considered to be core electrons. If valence band electrons are observed, the band structure is reflected in the shape of the Auger peak that becomes broad and degenerate and yields little chemical information.

It is usual for XPS and AES/SAM systems to be fitted with an inert gas ion gun which can be used for sputtering the surface layers of metallic and inorganic samples. When such sputtering is interspersed with surface analysis it is straightforward to produce a compositional depth profile. Figure 18 indicates a very high quality Auger sputter depth profile obtained from a multilayer structure provided as a standard reference material. In order to get very good interface definition from these 5-nm thick metallic layers, various parameters were optimized including ion beam energy, and specimen geometry, which was rotated during sputtering to avoid the development of ion beam-induced topography. By combining depth profiling with SAM it is possible to obtain a three-dimensional nanoscale representation of the near-surface region of a specimen.

SAM is a technique that can sample extremely small volumes of material (probably the smallest of any technique without the need for extensive sample preparation) and for this reason the choice of sample and the manner in which the analysis is carried out is extremely important. As with any electron microscopy-based analysis method, the need to acquire data from a representative sample of the specimen must be uppermost in the mind of the analyst. As SAM is an electron beam technique it is really only applicable to conductors or semiconductors, a useful guide being that if the specimen

**Fig. 17** AES point spectra from the regions identified in the SEM image of Fig. 1. **(a)** Point 1 of Fig. 1, **(b)** Point 2 of Fig. 1

**Fig. 18** AES sputter depth profile through an iron/copper/chromium multilayer structure. Each layer is 5 nm thick (Courtesy of Thermo Fisher Scientific)

can be imaged in an SEM without sample charging SAM will be possible. For these reasons the role of AES/SAM in adhesion studies is restricted to the analysis of metallic substrates and pretreatment layers. There are ways in which it is possible to apply the technique to insulators (Baer et al. 2010) but analysis of polymers by AES is not practicable the usual approach being to use XPS or ToF-SIMS.

### 9.4.3 Time-of-Flight Secondary Ion Mass Spectrometry

In recent years SIMS has become a widening field with many types of ion sources and mass spectrometers being used to provide surface mass spectrometry. In ToF-SIMS the solid sample under investigation is bombarded by a beam of primary ions that sputters atomic ions, cluster ions, and neutrals from the surface. The secondary ions (either cations or anions depending on whether a positive or negative ToF-SIMS spectrum is being acquired) are extracted by high voltage extraction optics and injected into a time-of-flight mass spectrometer. The flight time of the ions is proportional to their mass, once energy distribution has been normalized by the use of an ion mirror, and the time taken to reach the detector is then converted to mass to charge ratio. Modern ToF-SIMS systems can operate at extremely high mass resolution and peak positions can be recorded with an accuracy of  $\pm 0.001$  Da, and this together with high transmission and parallel detection of all masses makes this analyzer the one of choice for surface analysis by SIMS. It should be noted that Dalton (Da) is the preferred unit in mass spectrometry indicating unified mass/charge ( $m/z$ ). The unified mass unit is not the same as atomic mass unit as the former is relative to the  $^{12}\text{C}$  isotope while the latter is relative to the  $^{16}\text{O}$  isotope. The difference between the two however is small at 318 ppm. As the SIMS process is a destructive one, in that material is removed from the surface as it is irradiated with the primary ions, by collecting the secondary ion signals as a function of sputter time it is possible to construct a compositional depth profile. This forms the basis of a technique known as dynamic SIMS, used for profiling dopant concentration in semiconductors and the like. For surface analysis by SIMS it is important that the spectrum is recorded from the undisturbed surface and the general rule of thumb is that the surface remains in this state if the total ion dose during the acquisition of the spectrum is  $<10^{13}$  ions  $\text{cm}^{-2}$ . When SIMS is carried out under these conditions it is known as static SIMS and the critical ion dose is referred to as the static limit.

A top end ToF-SIMS instrument, of the type shown in Fig. 19, is a very complex analytical system that provides the analyst with many choices relating to the manner in which the spectrum or image is acquired. Does one optimize spectral resolution or spatial resolution? Which ion source should be employed as the primary beam and, if required, which for sputtering to produce a depth profile? One of the key decisions to be made is in the choice of ion source; this can be monoatomic in nature (e.g.,  $\text{Ga}^+$ ,  $\text{Bi}^+$ ,  $\text{Cs}^+$ ,  $\text{Ar}^+$ ), but a major advance over the last decade has been the routine availability of cluster (i.e., polyatomic) ion sources. These are particularly useful in the ToF-SIMS analysis of polymers as they increase the yield at high masses and there is also increasing evidence that they increase the yield of nitrogen-containing

**Fig. 19** A modern ToF-SIMS instrument featuring multiple ion sources and preparation chamber

fragments (which occur at even masses if there are an odd number of nitrogen atoms in the cluster), which is particularly useful for the analysis of amine-cured epoxy adhesives. The choice of cluster ions available from ToF-SIMS manufacturers is currently based around liquid metal ion sources for high spatial resolution; for example, a bismuth source of this type can provide elemental ion ( $\text{Bi}^+$ ) or  $\text{Bi}_3^+$ ,  $\text{Bi}_5^+$ , or  $\text{Bi}_7^+$  cluster ions. There is a very slight reduction in spatial resolution of bismuth trimers compared with elemental ions, the best available currently being of the order of 100 nm. The other cluster ion source that has gained increasing popularity in the last few years is Buckminster Fullerene,  $\text{C}_{60}$  and while the resolution is of a few micrometers it is widely used as a primary source in biological studies although the mode of operation preferred for polymeric samples is to use the  $\text{C}_{60}$  source for sputtering and the Bi source for analysis. This combination indicates one of the strengths of the  $\text{C}_{60}$  source, which is its ability to sputter profile some polymeric materials without the damaging effects that are normally observed when profiling with inert gas ions such as  $\text{Ar}^+$ . Such profiling can be carried out by XPS as well but is restricted to certain commercial systems, whereas in ToF-SIMS the depth profiling of polymers is becoming a routine undertaking. Figure 20 illustrates such a depth profiling experiment on a poly(vinylidene fluoride) coating to which an acrylic flow aid had been added. The negative ToF-SIMS spectrum (Fig. 20a) was obtained after a short (<500 ms) sputter with 8 kV  $\text{C}_{60}$  ions. The depth profile of Fig. 20b shows how the acrylic specific ions peak at a sputter time of 1 s and then decreases as the PVdF ions reach a maximum at the same time. Angle-resolved XPS indicates that the surface segregated layer is about 1.5 nm thick so the seven second depth profiles represent about 10 nm in depth. The high-resolution spectra of Fig. 20c, recorded from the acrylate-rich subsurface and the PVdF bulk material from deeper in the profile, indicate the ease with which two ions of nominal mass

**Fig. 20** ToF-SIMS depth profile experiment of a PVdF organic coating. **(a)** Negative ToF-SIMS spectrum from a subsurface region of the materials showing the presence of acrylate ions in the spectrum, **(b)** molecular depth profiling showing PVdF and acrylate specific ions, **(c)** high-resolution negative ToF-SIMS in the nominal 31 u region of the spectrum

31 u can be resolved in the high-resolution mode. The exact masses of the two ions are 30.9984 u ( $CF^-$ ) and 31.0184 u ( $CH_3O^-$ ), the separation of 0.02 u quite easily achieved with the experimental conditions used.

ToF-SIMS can also be operated in a mode that provides spatially and mass-resolved chemical images referred to as imaging SIMS. The usual manner of operation is to collect full sets of mass spectra at each pixel point and post-acquisition processing is undertaken to assemble the mass-selected images of interest. A very simple manner in which variations of two mass fragments can be compared is by the use of a scatter ratio diagram, a technique developed many years ago for the processing of scanning Auger microscopy data. In the creation of a scatter ratio diagram, from ToF-SIMS data, two mass-selected images are compared and at each pixel point the intensity of the two ions are plotted on orthogonal axes. This enables the analyst to identify clusters of pixels that have similar compositions. These pixels are then highlighted

on a false color image to enable these regions to be visualized in x:y space. The scatter ratio diagram contains only compositional, but no direct positional, information while the false color image correlates positions of similar compositions. This can be illustrated by data obtained from a galvanized steel sample similar to that illustrated in Fig. 1. ToF-SIMS data was acquired in the usual way from a region  $500 \times 500 \mu\text{m}$  in size. The intensity of the  $^{27}\text{Al}^+$  and  $^{64}\text{Zn}^+$  ions were compared at each pixel point and the scatter ratio diagram of Fig. 21 produced. From this diagram it can be seen that the data falls into two distinct regimes, those with a low  $^{64}\text{Zn}^+$  intensity (outlined in dark grey) and those where the  $^{64}\text{Zn}^+$  intensity is significantly higher (outlined in light grey). If a false color map is now constructed with pixels in the low zinc region coded dark grey and those from the higher zinc region coded light grey, the characteristic topography of the steel sheet is revealed (Fig. 21b), indicating the regions that are low in zinc (dark grey) and those where the surface zinc concentration is higher (light grey).

Of course as with all forms of microscopy there is the trade-off of spatial resolution with intensity, which, in the case of ToF-SIMS, invariably compromises the spectral resolution. Although the ultimate spatial resolution may be of the order of 100 nm, the spectral resolution at this level will only be around unit mass resolution; if one optimizes spatial resolution the mass resolution has to be degraded to several micrometers in order to get adequate counting statistics. Fortuitously for the analyst instrument manufacturers provide a mode of operation that offers middle ground in forms of both spatial and spectral resolution.

The manner in which a ToF-SIMS data set is collected, with complete spectra at each pixel point, means that a single image, from perhaps a  $100 \times 100 \mu\text{m}^2$  or  $500 \times 500 \mu\text{m}^2$  field of view comprising of a  $128 \times 128$  pixel array, will contain

**Fig. 21** ToF-SIMS analysis of a galvanized steel sample. (a) is the scatter ratio diagram constructed from the intensities of the  $^{27}\text{Al}^+$  and  $^{64}\text{Zn}^+$  ions and regions of higher (light grey) and lower (dark grey) zinc concentration are readily identified, (b) grey scale ToF-SIMS image constructed using the dark and light grey regions of Fig. 21a, which now indicates the areas on the sample surface enhanced and deficient in zinc

more than 16,000 individual spectra; added to this is the possibility of depth profiling with 100 analysis points into the sample and the number becomes well over one million in the data set! With so many spectra the examination and interpretation of each individual spectrum becomes impossible; the univariate analysis approach will not work so one must resort to multivariate analysis (MVA) techniques. These are now widely applied in ToF-SIMS as well as many other forms of materials analysis and form part of an area of endeavor known as chemometrics. Commercial ToF-SIMS data systems now have MVA software included, but it is still often necessary for the analyst to buy in specific software suites and adapt for ToF-SIMS use. Popular MVA methods used to process ToF-SIMS data include principal component analysis, multivariate curve resolution, and partial least squares regression. Recent literature in the area has been augmented by an extremely comprehensive review article by Lee and Gilmore (2009) and also a special two-volume issue of the journal *Surface and Interface Analysis* (2009a, b) dealing MVA in surface analysis.

In adhesion research one of the options that has become achievable at last with the latest generation of ToF-SIMS instruments is the ability to track reaction chemistry on surfaces; in this manner it is possible to study how components present in an adhesive formulation may interact with the solid surface, and in this manner it has become possible to start to unravel the interface chemistry of adhesion from very complex multicomponent systems. Other important applications in adhesion include the identification of minor components of an adhesive at fracture surfaces and the ability to visualize such residues at a resolution of significantly less than 1  $\mu\text{m}$ .

---

## 9.5 Conclusions

There are a wide variety of procedures and analytical methods that can be used to assess the surface characteristics of a solid surface relevant to adhesive bonding. These range from the relatively simple and inexpensive such as the water break test through to the extremely complex and expensive such as ToF-SIMS. Some will be required for quality assurance purposes and some belong in a research environment; the surface characteristics that require assessment may be surface topography (AFM or SEM might be used), surface energetics (contact angle measurements or IGC), or surface chemical analysis (XPS, AES/SAM, or ToF-SIMS). It is unlikely that any one laboratory will have access to all such techniques and thus those readily available will be pressed into service. Some laboratories will carry out commercial consultancy activities for all-comers and this is often a cost-effective way to obtain electron microscopy and surface analysis services. This is often a way to gain familiarity with advanced techniques and added value is often obtained from experienced analysts who will be responsible for instrument operation.

In order to obtain a clear, concise, and accurate picture of the surface under investigation, there will almost certainly be the need to resort to more than one of the methods described in this chapter. The choice will be influenced by the nature of the material, the type of investigation, and other variables. In adhesive bonding research one thread that runs through virtually all work, be it quality assurance, development,

or research, is to relate surface characteristics to a performance measure of the bonded structure. This may be joint strength or toughness but more usually, and particularly for structural adhesive bonding, attempts will be made to correlate the surface and interface characteristics with joint durability.

## Abstract

This chapter explores the manner in which the surface analysis methods of X-ray photoelectron spectroscopy (XPS) and time-of-flight secondary ion mass spectrometry (ToF-SIMS) can be used to extract information regarding the interfacial chemistry of adhesion from polymer/metal systems such as adhesive joints. It will be shown that the analysis of a failure interface is an uncertain method to extracting interface chemistry but in certain situations, where a very thin layer of polymer remains on the metal oxide surface, this provides spectra characteristic of the interphase. In most situations, some form of chemical or mechanical sectioning is necessary, and microtomy and dissolution methods are described

J. F. Watts (✉)

e-mail: [j.watts@surrey.ac.uk](mailto:j.watts@surrey.ac.uk)

as ways in which chemical information at high depth resolution can be extracted from the interphase zone.

An alternative manner in which interphase chemistry can be examined is by the use of model specimens consisting of thin layers of polymer deposited on the metal substrate. The construction of an adsorption isotherm from the liquid phase is a useful precursor to such studies as it provides an indication of the solution concentration at which monolayer coverage occurs. The shape of the isotherm can provide invaluable information regarding the adsorption of various components from a formulation on the substrate, indicating which component(s) has(have) the greatest affinity with the metal oxide. Specimens from the plateau region of the isotherm will have a monolayer of polymer deposited on them, and XPS and ToF-SIMS can be used to probe the interphase region through this very thin layer. This provides a powerful method for the elucidation of the specific interactions, such as covalent bonds, that are responsible for the forces of adhesion. Examples are given in this chapter of a range of systems featuring iron, zinc, aluminum, and ceramic substrates and polymeric systems as diverse as radiation-cured coatings and adhesives, through structural adhesives to an isocyanate-based systems turning finally to the fracture and analysis of a polyester-based nanocomposite.

---

## 10.1 Introduction

The surface chemical analysis methods of X-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES), and time-of-flight secondary ion mass spectrometry (ToF-SIMS) are introduced in ► [Chap. 9, “Surface Characterization and Its Role in Adhesion Science and Technology.”](#) The aim of the current chapter is to review the use of these techniques in adhesion science research paying particular attention to the contribution that they have to make toward unraveling the interfacial chemistry of adhesion. Surface analysis has been applied to adhesion investigations for more than three decades with a great deal of success, and their application in this field can be divided into three distinct areas:

- The investigation of surface characteristics prior to bonding and correlation with some form of performance parameter.
- The forensic investigation of failed adhesive joints and once again correlation of failure characteristics with chosen performance parameters.
- The use of sophisticated specimen preparation or modelling approaches to investigate the interfacial chemistry of adhesion.

This hierarchy also follows the chronology in which surface analysis has been applied with the three levels representing increasingly difficult situations for the analyst. As with most areas of science, however, the development of procedures and methodologies that provide a greater level of information occurs in parallel with advances in instrument design, operation, and data interpretation. XPS, AES, and ToF-SIMS are now mature analytical techniques but experience and specialist

knowledge are needed to get the best from them in adhesion research. The aim of this chapter is to illustrate the manner in which this can be achieved.

Adhesion science research covers adhesion between a number of polymeric and inorganic phases and has direct relevance in the areas of adhesive bonding, sealant chemistry, organic coatings, and composites manufacture. The work described in this chapter has developed from initial work on coatings and adhesives into the interface chemistry of fiber-reinforced composites.

The format of this chapter will follow the areas identified above with sections devoted to the analysis of substrate surfaces, the forensic analysis of failed adhesive joints and organic coatings, and a final section that will look at the methods in which the interfacial chemistry can be probed directly. Specimen preparation is an important part of this last section, and the particular methods relevant to adhesion research will be considered in some detail. The tenor of this chapter is to provide the adhesion scientist with an overview of the different hierarchies of information that can be obtained using surface analysis methods, throughout which there will be illustrations of work from the author's laboratory.

---

## 10.2 Substrate Characterization

### 10.2.1 Metallic Substrates

The use of XPS, and particularly AES, to assess the surface cleanliness of sheet steel in the automobile industry was one of the first applications of surface analysis in adhesion research. Forty years ago, the traditional manner to assess the level of carbonaceous contamination on steel stock, generally residues from processing aids or temporary corrosion protectives, was to use a glass fiber pad to remove as much of the residue as possible and then analyze for carbon by combustion methods. The level of carbon was then reported in units of mass per unit area (often  $\text{mg cm}^{-2}$ ), and correlations made with performance of the painted steel in a standard test. Once variations in steel performance were investigated in this rather crude manner it became clear that there was a strong correlation between the concentration of surface carbon and poor performance of the painted steel. Although a combustion test is perfectly adequate when it comes to assessing very high levels of carbon concentration (panels that feel greasy to the touch), at low levels where performance in a salt spray test is seen to be very variable for low concentrations of carbon, this approach is rather insensitive, as seen in Fig. 1. This changed in the mid-1970s when XPS and AES were applied to the assessment of surface cleanliness. The story that emerged was that adventitious carbon had the potential to interfere with the formation of the chemical conversion coating, an inorganic coating based on zinc phosphate, that is routinely applied to steel stock in the automobile and other industries prior to the application of the organic coatings system. The study undertaken by Iezzi and Leidheiser (1981) illustrates the strength of scanning Auger microscopy for the characterization, at high spatial resolution, of metal substrates prior to coating. A useful postscript to this is the recognition by Smith (2005) that the surface

**Fig. 1** Correlation of steel surface cleanliness (determined by a combustion method) with time to failure in a salt spray environment. Although the general trend is clear, there is not sufficient discrimination at low carbon concentrations

concentration as measured by XPS can be converted directly to an overlayer thickness,  $d$ , in nanometers, by the use of a modified form of the Beer–Lambert Equation:

$$d = -\lambda \cos \theta \ln(1 - 0.01x) \quad (1)$$

where  $\lambda$  is the electron attenuation length,  $\theta$  is the electron takeoff angle relative to the sample normal, and  $x$  is the surface concentration of carbon in atomic percent determined by the usual method included in the software provided by the manufacturer of the data system.

An example of the manner in which XPS can be used to differentiate between surfaces that are notionally clean is provided in Fig. 2, which illustrates the XPS survey spectra from two steel surfaces prepared by different methods. Using Smith's approximation (above) the thickness of the adventitious carbon layer is 0.92 nm for the sample with the lower surface concentration (31 at%) and 2.46 nm for the other (63 at%).

Some alloys have minor components that show a propensity to segregate to the surface under certain process conditions which, in turn, can compromise the adhesion of a coating or adhesive. In the case of aluminum alloys, even very low levels of magnesium in the alloy may segregate to the surface during closed coil annealing to form a friable layer of MgO at the surface. This is readily identified by XPS or AES but if not removed prior to bonding will lead to poor performance. The

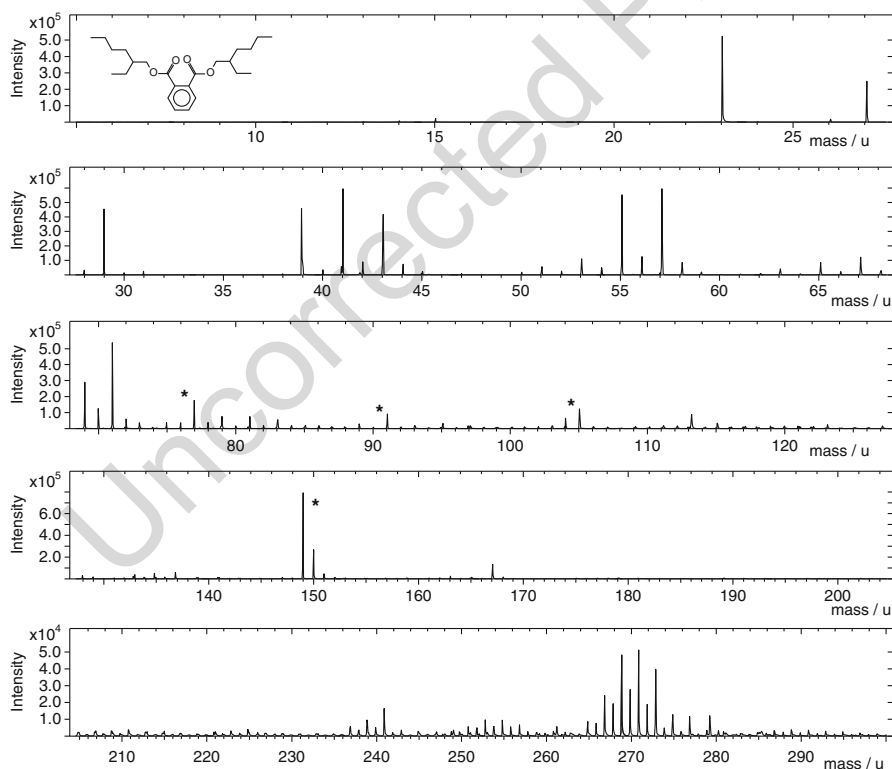

**Fig. 2** XPS survey spectra of low carbon steel sheet following (a) alkali cleaning and (b) energy abrasion. Note that the abrasion process, which removes the near-surface material, results in a much cleaner surface

128 detection of magnesium by surface analysis is not always a cause for concern as  
129 if the element is immobilized, in an anodic oxide layer, for example, satisfactory  
130 performance may result.

### 131 10.2.2 Polymer Substrates

132 In the case of metallic substrates the problem that is encountered which will  
133 compromise bond performance is often the presence of hydrocarbon contamination  
134 which as well as having the potential to act as a weak boundary layer will also reduce  
135 the surface free energy of the substrate from a high value (many hundreds of  $\text{mJm}^{-2}$ )  
136 to a value lower than  $100 \text{ mJm}^{-2}$ . In the case of polymers the surface energy is  
137 intrinsically low, of the order of  $20\text{--}50 \text{ mJm}^{-2}$ , as a result of chain folding rather  
138 than unsatisfied valencies at the material surface observed in metals and inorganic

materials. As a result, many pretreatments of polymers rely on increasing the surface functionality, and thus the surface free energy of the substrate by using methodologies that incorporate oxygen into the polymer surface, such as corona discharge and flame treatments, see ► Chap. 8, “Surface Treatments of Selected Materials.” There are, however, two process-related phenomena observed in polymers that have the potential to compromise bond performance. One is the segregation to the free surface of low molecular weight species (such as oligomers of the bulk polymer) that lack sufficient mechanical integrity with the bulk and lead to premature failure. The other is the segregation of minor components such as processing aids to the surface during production. A classic example is the surface segregation of the familiar plasticizer di-iso octyl phthalate to the surface of poly(vinyl chloride) (PVC). This can readily be identified by ToF-SIMS and is a familiar, along with poly(dimethyl siloxane), as a contamination to all ToF-SIMS users. The spectrum of the external surface of a PVC tube, widely used for many laboratory applications, is shown in Fig. 3 with the peaks assigned to the plasticizer labeled, which indicates the high concentration of material that can exist at a polymer surface. The presence of such additives at the surface of

**Fig. 3** The positive ToF-SIMS spectrum of the external surface of laboratory PVC tubing. The peaks marked with an asterisk are those attributed to the plasticizer di-iso octyl phthalate. The structure of this molecule is shown in the inset, and the dominate ion at  $m/z = 149$  u is C<sub>8</sub>H<sub>5</sub>O<sub>3</sub><sup>+</sup>

mass-produced polymers is a familiar observation, and additives are readily detected and identified by ToF-SIMS. They can, however, be a source of a weak boundary layer when attempting to print or bond such substrates, and the application of some pretreatments to polymers may merely remove the aggregation of these extraneous materials at the surface, thus increasing the surface free energy, rather than modifying the base polymer by the incorporation of oxygen. Such an observation also indicates why samples for surface analysis should always be provided packaged in aluminum foil or glass containers of known cleanliness and never in crimp top plastic bags, as plasticizer and the like can all too easily contaminate the surface intended for analysis!

As indicated above, the surface treatment process may be responsible for the removal of such material and exposing the bulk of the polymer underneath the segregated layer. Such a situation can be illustrated by the XPS spectra of Fig. 4 from PVC in its extruded form and after flame treatment. The extrudate is protected by a thin film of low density polyethylene (LDPE), and upon removal of this film the spectrum (Fig. 4a) is dominated by carbon and oxygen with significant contributions from PVC-specific elements such as chlorine, lead, and zinc. On flame treatment (Fig. 4b), the carbon level is reduced to a certain extent (from 82% to 70%), while the oxygen increases from 12% to 22%, and the chlorine and inorganic ion concentration is broadly similar between the two, however, the water contact angle reduces from 91° to 59° showing that the flame treatment has increased the surface free energy significantly. This presumably reflects the manner in which the flame treatment has reduced organic material incorporated into either the PVC or LDPE formulations that have segregated to the interface on processing. For a spectrum of the bulk of the PVC, obtained by sectioning the PVC extrudate is shown in Fig. 4c and the intensity of the major peaks (C1s, O1s, Cl2p) are in the expected ratios for a commercial PVC, with approximate concentrations of carbon = 64%, chlorine = 26%, and oxygen = 10%. The inorganic contributions to the survey spectrum of Fig. 4c are attributed to fillers, anti-oxidants, and the like added to the formulation.

### 10.3 Forensic Investigation of Failed Joints

The investigation of a failed adhesive joint can be approached by many methodologies and these are considered at length in ► Chap. 43, “Techniques for Post-Fracture Analysis.” The aim of this section is to explore the utility of this approach to the understanding of the interfacial chemistry of adhesion for a particular system. As a starting point the application of surface analysis methods, particularly XPS and ToF-SIMS, has much to commend in the definition of the locus of failure of an adhesive joint, and the provision of important information at the molecular scale. For instance, XPS is able to deduce the thickness of organic overlayers up to a thickness of about 10 nm (more if XPS is used in conjunction with cluster ion bombardment for depth profiling) and the presence of unexpected ions at the failure interface, perhaps resulting from a corrosion-induced failure where an excess of anions (e.g., Cl<sup>-</sup>) will indicate that anodic conditions prevailed prior to failure or

**Fig. 4** XPS survey spectra of commercial PVC extrudate. (a) As extruded, (b) following flame treatment, (c) bulk analysis following sectioning by microtomy

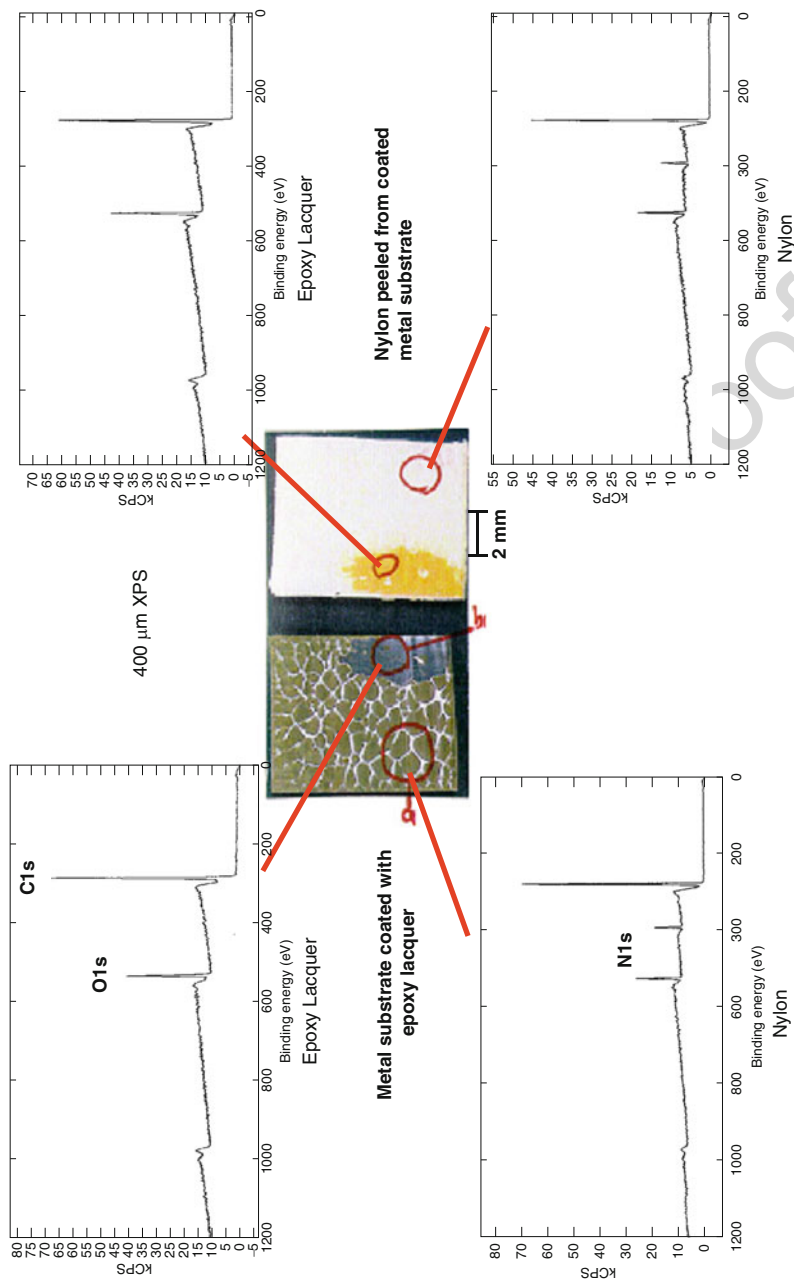

cations (e.g.,  $\text{Na}^+$ ), which are diagnostic of cathodic activity. ToF-SIMS is particularly valuable as it is able to differentiate unambiguously between minor components of an adhesive formulation. This is particularly useful in the identification of instances where the segregation of such species to an interface has compromised joint performance. Two examples of this will be provided later in this section.

### 10.3.1 Failure Prior to Environmental Exposure

As a general rule, and a phenomenon that can be predicted by surface thermodynamics, a joint that is tested in dry air, and that has not received exposure to an aggressive environment such as water, will fail in the bulk of the adhesive. This may be at the center of the glue-line in which case the locus of failure is easily defined using the naked eye. As the locus of failure moves toward a substrate/polymer interface, however, one must resort to increasingly sophisticated methods for an exact definition of the fracture locus. If adhesive residues cannot be observed with the naked eye the next observational methods should be optical microscopy, followed by electron microscopy. Many investigators will stop at this point but an adhesive layer of 10 nm or so will not be distinguishable in a scanning electron microscope (SEM) although it will appear as a uniform polymeric layer by XPS. Thus, XPS has an important role to play in the definition of failure when the residual layer of adhesive is extremely thin. Indeed by resorting to microscopy methods alone it is all too easy to assign a failure as interfacial when it is actually cohesive but very close to the substrate/polymer interface.

As an example of such a forensics analysis the following example relates to the joining of a nylon structure to epoxy-coated steel substrate by thermal bonding. The central photographs provide a visual appreciation of the appearance of the failure surfaces, and the spectra are taken from equivalent locations on the two sides of the failure. This is a standard approach in the analysis of the failure surfaces from adhesive joints, and surface analyses are sometimes referred to as mirror image surface analyses. The left hand failure surface shows characteristics of the coated steel, and at the bottom right hand corner there is a region where the epoxy lacquer appears to have been removed from the steel. The right hand failure surface confirms this with the regions of nylon in white and the peeled epoxy being darker (golden) in color. Turning to the XPS survey spectra of Fig. 5 it is clear that those from both interfacial failure surfaces of the peeled lacquer are very similar with C1s and O1s peaks dominating the spectra and no sign of metallic elements that might be expected from the steel surface. This is clearly indicating that the failure of the epoxy coating has occurred within the lacquer itself but close to the metal/coating interface. The other pair of spectra tell a similar story with failure having occurred in the nylon phase, although visual inspection would indicate failure to be between nylon and the epoxy coat.

Although the definition of the exact locus of failure is a crucial part of any failure investigation, and the examination of complementary surfaces as described above can be very informative, the situation that exists in a dry joint is generally rather

**Fig. 5** The XPS survey spectra from the failure of the bond between epoxy-coated steel and nylon. The upper two spectra are characteristic of the epoxy coating while the lower are typical of nylon. This shows that the two distinct failure regions both exhibit cohesive failure but in the epoxy lacquer (near to the epoxy steel interface) or the nylon (near to the epoxy nylon interface)

straightforward. It is once that the failure has occurred as a result of environmental exposure, particularly if water is involved, the elucidation of failure mode is to an extent more difficult as segregation or degradation process may have occurred during exposure. In the following section, the manner in which the nature of the locus of failure varies will be explored according to system type and also the possibility of using the analyses from failed systems to deduce the interfacial chemistry of adhesion.

### 10.3.2 Failure Following Environmental Exposure

When a coated metal is exposed to water there is always the possibility of corrosion of the metal substrate, particularly when the edge of the metal is exposed. The role of corrosion in the failure of adhesive joints is explored extensively elsewhere (Watts 2010), the most important aspect being that the behavior at cathodic and anodic areas is very different. At the cathodic areas the reduction of water and oxygen leads to the production of hydroxide ions and the generation of a higher pH locally. This in turn leads to a phenomenon known as cathodic disbondment (Watts 1989), which is readily observed by XPS as the failure will be truly interfacial, and cations in the test solution (e.g.,  $\text{Na}^+$ ,  $\text{Ca}^{2+}$  and the like) will decorate the cathodic regions. If gross corrosion occurs beneath the adhesive, failure will occur in the corrosion product itself which is of course the result of the anodic half reaction and the failure surfaces will be decorated with anions such as chloride. This latter failure type is exemplified by the spectra of Fig. 6, which represent complementary failure surfaces from a galvanized steel substrate and the organic phase. As can be seen both spectra are dominated by the Zn2p and Zn LMM (Auger) spectra at 1020–1050 eV and 450–700 eV respectively, and in the case of the zinc surface, the level of carbon is extremely low (typical of adventitious contamination on a voluminous corrosion product) but there is a significant concentration of chlorine (indicated by the Cl2p at a binding energy of 199.5 eV); the chemical shift on the Cl2p confirms the chlorine species as the chloride ion diagnostic of anodic activity. The sample was exposed to a salt spray environment so that there was an ample supply of chloride ions to label these regions. The spectrum from the organic phase is very similar but with an increased concentration of carbon, and a small amount of nitrogen, both elements indicate that the amount of zinc corrosion product is relatively modest with a signal from the organic coating also being present in the spectrum. Although such an investigation is very informative regarding the locus of failure, it provides no information about the interfacial chemistry of the system prior to failure. In more advantageous situations, the spectra of failure surface can provide detailed molecular relating to the interfacial chemistry of the systems.

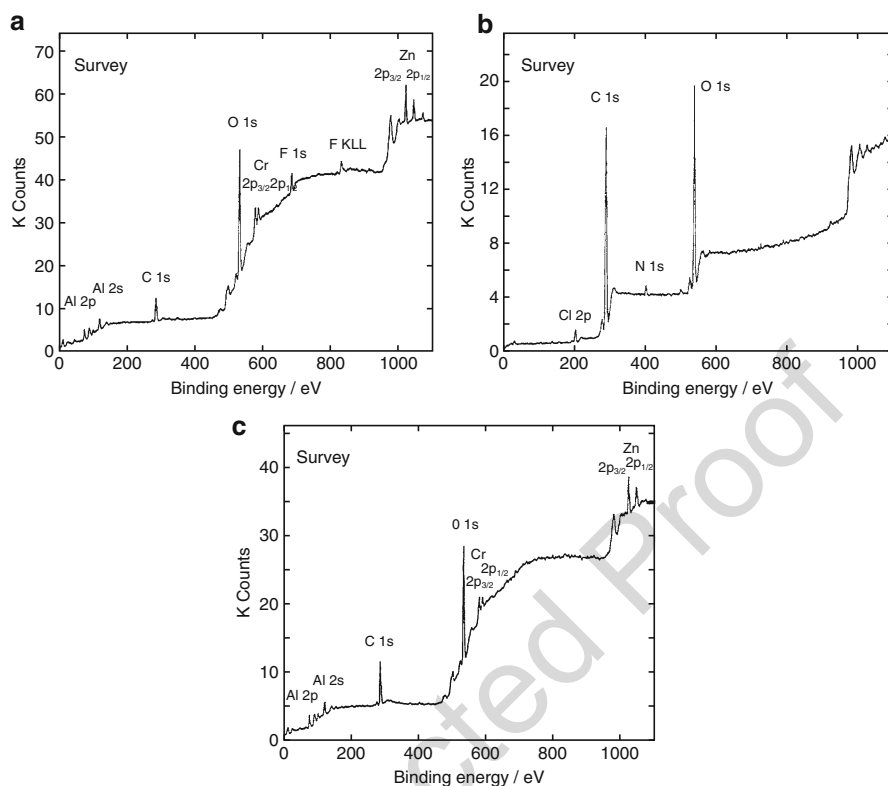

Radiation-cured coatings have been under development for some time and are now commercially widely available for a variety of applications. In the early years of development of this technology, a prototype system (designed for eventual commercial exploitation) exhibited good dry adhesion but when exposed to water vapor the adhesion was significantly compromised (Leadley et al. 1998). XPS and ToF-SIMS

**Fig. 6** XPS survey spectra from a coated galvanized steel panel exposed to salt spray. Both surfaces, (a) metal substrate failure surface and (b) coating failure surface, show extensive mounts of zinc corrosion product and the Cl2p peak (present in both spectra) shows that failure has occurred in the layer of corrosion product

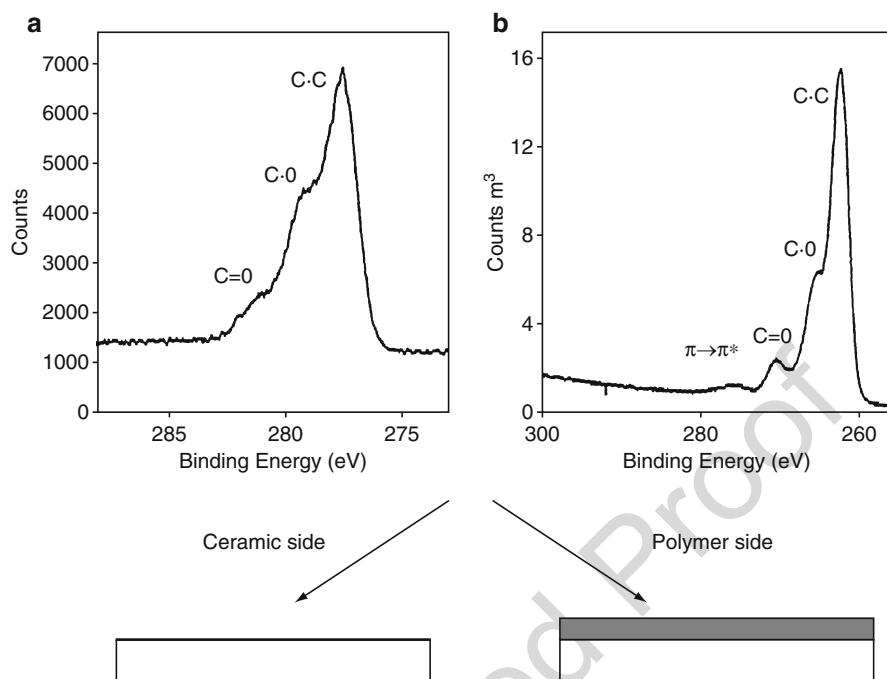

spectra were recorded from the interfacial failure surfaces of both the galvanized steel substrate and the polymer coating. The XPS spectra, together with that of the bare substrate are presented in Fig. 7. Comparison of the two interfacial surfaces appears to indicate an interfacial surface with a fairly clean zinc substrate (aluminum is present as it is a standard addition to the galvanizing bath), Fig. 7a, and a polymer surface showing no signs of any metal transfer, Fig. 7b. When the metal surface is compared with the as received steel surface, Fig. 7c, it is clear that the fluorine detected on the failure surface was not present on the initial surface. ToF-SIMS

**Fig. 7** XPS survey spectra from a UV-cured coating applied to galvanized steel that has then been exposed to water vapor. (a) Interfacial failure substrate surface, (b) interfacial failure coating surface, and (c) steel surface prior to coating (Reproduced from Leadley et al. (1998), with permission)

analysis confirmed that the fluorine was associated with a  $\text{PF}_6^-$  ion, which is the anionic part of the radiation-curing package, and that the cation is a triaryl sulphonium species. The conclusion from this analytical data is that there is the segregation of the curing agent to the interface either during application or prior to the cure process. When the system is tested dry there is sufficient mechanical integrity but on exposure to water vapor the region between the segregated cure package and the bulk of the coating provides a hydrophilic interface along which water can diffuse easily, leading to premature failure. The solution to this short coming was to reformulate the system with a significant reduction in the amount of the cure package in the coating.

This example relies on the identification of an element at the failure interface that can be used as a marker for a particular component in the formulation. More usual is the need to resort to high resolution spectroscopy. The data of Fig. 8 relates to a radiation-cured adhesive being developed for the bonding of components to ceramic substrates for surface mount technology. Once again water reduced the adhesion

**Fig. 8** High resolution C1s spectra from the failure interfaces of an alumina system bonded with a radiation-cured adhesive. (a) Alumina side of the failure that exhibits a thin (ca 1 nm) layer of adhesive, (b) bulk adhesive layer. Note the presence of the  $\pi \rightarrow \pi^*$  shake-up satellite in the spectrum of the bulk adhesive but its absence from the very thin residual adhesive layer of (a) (Reproduced from Watts and Taylor (1995), with permission)

below an acceptable level and XPS and ToF-SIMS analysis of the failure surfaces provides an indication of the cause of the failure. The adhesive has two major components: an aromatic adhesive part and an aliphatic reactive diluent. Inspection of the high resolution C1s spectra from the adhesive side of the failure shows the expected  $\pi \rightarrow \pi^*$  shake-up satellite diagnostic of the aromatic component of the adhesive (Watts and Taylor 1995). The ceramic failure surface shows a small amount of carbon at a thickness of approximately 1 nm (determined by angle-resolved XPS) but the high resolution spectra show no sign of the expected aromatic component of the adhesive. ToF-SIMS identified the adsorbed layer on the ceramic as the reactive diluent while molecular dynamics modeling indicated that this molecule would adsorb on the ceramic surface to provide a monolayer some 1 nm in thickness (Taylor et al. 1995). This information combines to provide a very clear view of the interfacial chemistry and, indeed, why failure occurred. During application of the adhesive there is the segregation of a monolayer of the reactive diluent to the ceramic surface which in turn forms an interface with the bulk adhesive. On exposure to water the situation is similar to that described for Fig. 7, the water can readily diffuse along the interface leading to failure. The solution to improving the performance is

also similar, the concentration of reactive diluent in the formulation being reduced. Such a course of action improves the durability of the joint although, unfortunately, it also changes the viscosity of the adhesive that precludes its use in certain applications.

From the above examples it can be seen that the locus of failure generated by a mechanical test, either before or after environmental exposure is an uncertain route to exposing surfaces that will allow the elucidation of interface or interphase chemistry directly. In the following sections, a number of methods are described that allow the interfacial chemistry of adhesion to be examined directly by analytical methods. They fall into two categories: those in which a real interface is sectioned to allow surface analysis and other methods to probe the interfacial region, and those which make use of model systems, often in the form of very thin (<2 nm) films of adhesive where the interphase chemistry is directly accessible by surface analysis methods.

## 10.4 Probing the Buried Interface

In a review of polymer-to-metal adhesion, of more than two decades ago (Watts 1988), a variety of mechanical and chemical methods that would potentially enable the interface region of a coated or bonded system to be investigated were documented. Although the capabilities of the analytical techniques themselves have improved tremendously in the intervening years, the preparation methods themselves are essentially the same. Of the four methods mentioned one, the analysis of a simple metallographic cross section in the SEM, was discounted for not having the required spatial and chemical resolution. This is still the case, and although SEM remains an invaluable method to provide high quality images, the spatial resolution attainable in X-ray analysis by EDX or WDX is limited by the size of the electron beam interaction with the specimen (of the order of 1  $\mu\text{m}$  in both lateral and depth resolution); similarly these techniques only provide elemental analysis with no chemical resolution. The other three are in use and involve sectioning the specimen or chemical dissolution.

The sectioning of a specimen by microtomy to provide an electron transparent section for TEM microscopy and analysis is widely used in many areas of materials science. The use of TEM images in adhesion studies was first demonstrated by Thompson et al. (see, for example, Bishopp and Thompson 1993), and the addition of analysis by parallel electron energy loss spectroscopy (PEELS) provides a powerful technique as illustrated by Kinloch et al. (2000). The TEM images of Fig. 9 are false-color elemental images (obtained by PEELS) of the interfacial region of an aluminum alloy treated by phosphoric acid anodizing to develop a porous film, bonded with an epoxy paste adhesive. In Fig. 9a, the adhesive has been applied directly to the anodic oxide layer and there is very little penetration of the adhesive into the porous oxide. If a primer is applied, however, there is a significant interpenetration of the organic and inorganic phases to form a microcomposite interface as shown in Fig. 9b. The durability performance of these two systems can be related

**Fig. 9** False color PEELS images of the interphase region of adhesive joints manufactured from aluminum alloy treated by chromic acid anodizing. (a) Paste adhesive applied directly to the anodic pretreatment layer, which yields a very abrupt interface between organic and inorganic phases, (b) application of a primer prior to adhesive bonding that leads to interdiffusion of organic and inorganic phases and the resultant microcomposite interphase (Reproduced from Kinloch et al. (2000), with permission)

directly to interphase characteristics with the system without primer (which yields a planar interface between organic and oxide) being poor but the system that makes use of a primer (and generates a microcomposite interphase) showing excellent performance. This method has been used to good effect by Bertho et al. (2010) to study the fate of an organosilane adhesion promoter incorporated into an epoxy formulation, and the development of a chemical interphase some 20 nm in thickness at the metal/adhesive interface.

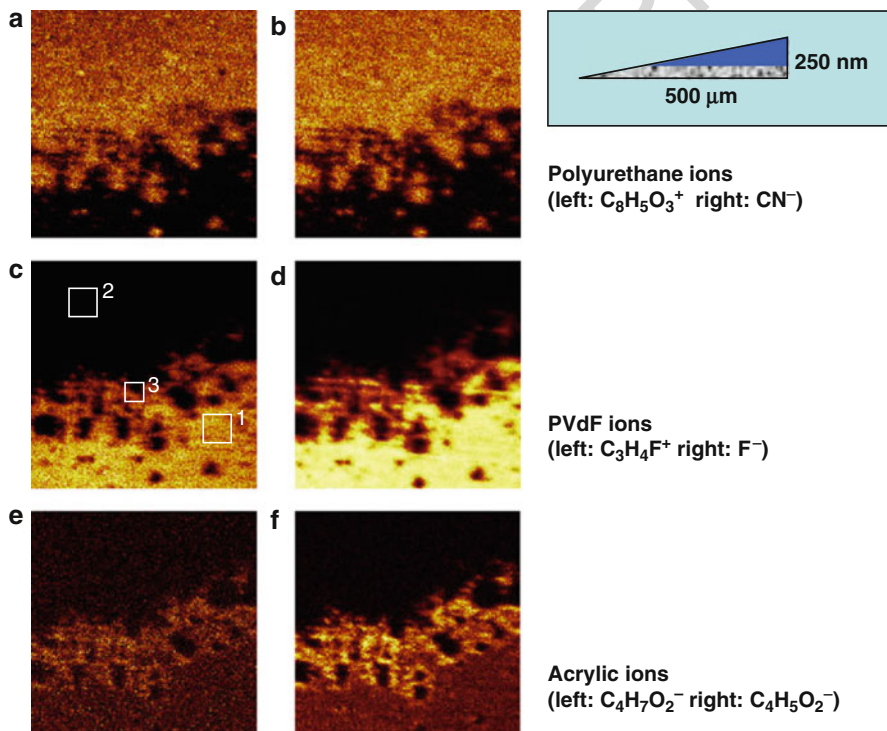

An alternative manner in which the interface region can be approached is by the production of very gentle ( $<5^\circ$ ) taper sections so that the interphase and its environs are magnified making them amenable to direct analysis by XPS or SIMS. Initial work with this approach made use of an ultra high vacuum mechanical taper sectioning rig, with a cryo-stage, that could be directly attached to the preparation chamber of the spectrometer. Although successful, this method has now been superseded by the use of a technique known as ultra-low angle microtomy (ULAM) (Hinder and Watts 2004; Hinder et al. 2004, 2005). This method makes use of a histological microtome and employs stainless steel spacer blocks between microtome bed and sample so that extremely low angles are subtended between sample surface and microtome blade ( $0.03^\circ$ – $0.33^\circ$ ). In this way it is possible to use a high spatial resolution surface analysis method to provide extremely good depth resolution (Hinder et al. 2004). For example, using the lowest angle of  $0.03^\circ$  and a small X-ray spot of 15  $\mu\text{m}$  for XPS, a depth resolution of 13 nm is theoretically attainable; if the spot size is increased to 100  $\mu\text{m}$  the depth resolution is reduced to 60 nm. An example of how a depth profile can be obtained using this method is provided in

Fig. 10, the specimen is a polyurethane primer on a metal substrate overcoated with a poly(vinylidene fluoride) plastisol layer. The specimen prepared by ULAM is shown in the upper left of Fig. 10, and the microtome cut, exposing the lighter (yellow) primer below the darker (dark blue) topcoat can be clearly seen. The black solid line represents the location of the XPS line scan that was carried out with a spot size of 15  $\mu\text{m}$  and a step size between analyses of 18  $\mu\text{m}$ . The compositional line scans for fluorine and nitrogen concentrations are presented on an abscissa that has been converted from distance along the specimen to depth toward the interface from an arbitrary position on the PVdF coating (on the black line of the specimen image of Fig. 10). The analysis depth considered in Fig. 10 is some 170 nm and the interdiffusion of fluorine and nitrogen is readily appreciated. The interface widths ( $\Delta Z$ ) of the nitrogen and fluorine profiles are 27 nm and 50 nm, respectively, indicating some diffusion of the PVdF into the primer coating. A reasonable observation as the primer would have been cured prior to the application of the topcoat. Although such a line scan provides useful information, the analysis of a similar region by ToF-SIMS enables additional information to be extracted (Hinder et al. 2004). Mass-selected ToF-SIMS images with a 500  $\mu\text{m} \times 500 \mu\text{m}$  field of view from the

**Fig. 10** Depth profile obtained by small spot XPS and ultra-low angle microtomy at the interface region of a PVdF coating applied to a polyurethane primer (Reproduced from Hinder and Watts (2004), with permission)

interphase region of the same sample are shown in Fig. 11 with pairs of images chosen to represent the polyurethane primer (Fig. 11a, b), the PVdF top coat (Fig. 11c, d) and also ions representing a minor component in the formulation of the PVdF plastisol, an acrylic co-polymer. It can be seen that although the acrylic material is distributed uniformly through the PVdF layer, its presence is enhanced at the interface between primer and topcoat. The depth dimension of the field of view is shown in the schematic of Fig. 11g, which indicates that the region of enhanced acrylic material concentration at the interphase is about 50 nm in thickness. The acrylic component is added to the formulation to enhance the adhesion of the plastisol to the primer and it appears that this is achieved by the development of an acrylic-rich interphase some 50 nm in thickness. The study of interactions with metals using this method is perfectly feasible so long as thin metal foils or vacuum-deposited layers are used as the substrate. Recent unpublished work carried out in the author's laboratory has shown that iron foil as thick as 25  $\mu\text{m}$  can be sectioned successfully by microtomy.

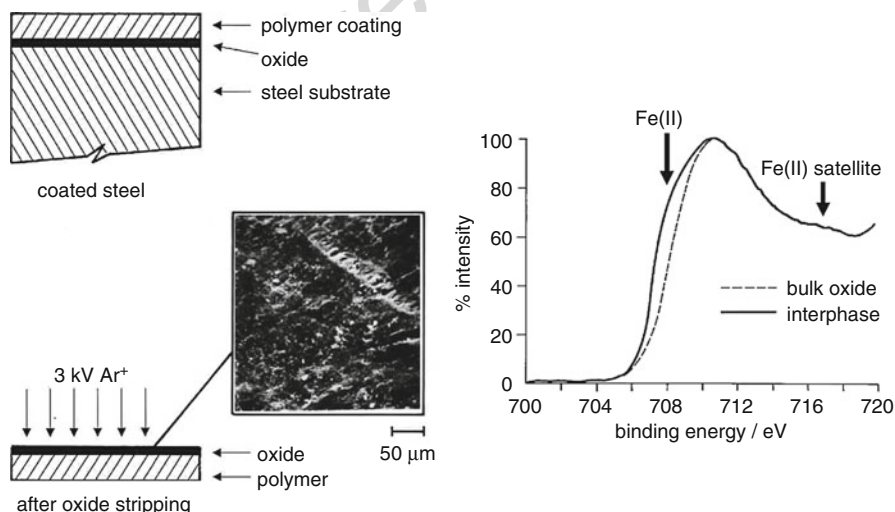

**Fig. 11** Mass-selected ToF-SIMS images of the PVdF/PU interface of Fig. 10. The field of view is 500  $\mu\text{m}$ , which is equivalent to a height difference of 250 nm from top to bottom of image. Images shown represent PU (a & b), PVdF (c & d), and acrylic adhesion promoter that segregates to the interface (e & f). Both positive (a & c) and negative (b, d, e & f) images are shown (Reproduced from Hinder et al. (2004), with permission)

In addition to microtomy it is possible, in some systems, to dissolve the metallic substrate (but not the oxide) and then use surface analysis in conjunction with sputter depth profiling, to approach the interphase between oxide and adhesive. This method has been used to good effect to study the interphase between a low carbon steel substrate and a polybutadiene coating (Watts and Castle 1983). In this work, the steel was dissolved in a methanolic iodine solution, and the subsequent duplex film of a thin oxide supported on the polymer was mounted oxide uppermost for analysis by XPS with sputter depth profiling. The depth profile showed a change in the shape of the  $\text{Fe}2p_{3/2}$  spectrum as the interphase was reached; in the oxide the iron was exclusively in the  $\text{Fe(III)}$  state but at the interphase some  $\text{Fe(II)}$  was seen in the spectrum as shown in Fig. 12. The presence of the  $\text{Fe(II)}$  component in the interphase is the result of the reaction between the polybutadiene (which cures by oxidation) and the native oxide on the steel substrate during cure. At the boundary between polymer and oxide the polymer acts as a reducing agent for the iron oxide leading to the production of an organometallic complex involving the reduced form of the oxide,  $\text{Fe(II)}$ .

A similar method has been used to investigate the interfacial characteristics of laminated aluminum systems used for beverage cans. When produced by this process a stock laminate is punched into blanks and the can body produced by deep drawing and wall ironing. To investigate the polymer/oxide interface the aluminum is dissolved in sodium hydroxide solution, and to study the polymer surface the oxide can be removed by treating with hydrofluoric acid. To investigate the metal/oxide region, as the oxide will undergo much fragmentation during the deep drawing process, the polymer is removed with trifluoroacetic acid. In this work,

**Fig. 12** XPS examination of the interphase between a polymer coating and low carbon steel. The preparation method is shown schematically on the left hand side; the change in shape of the  $\text{Fe}2p_{3/2}$  spectrum, as the interphase is approached showing significant  $\text{Fe(II)}$  character, is shown on the right

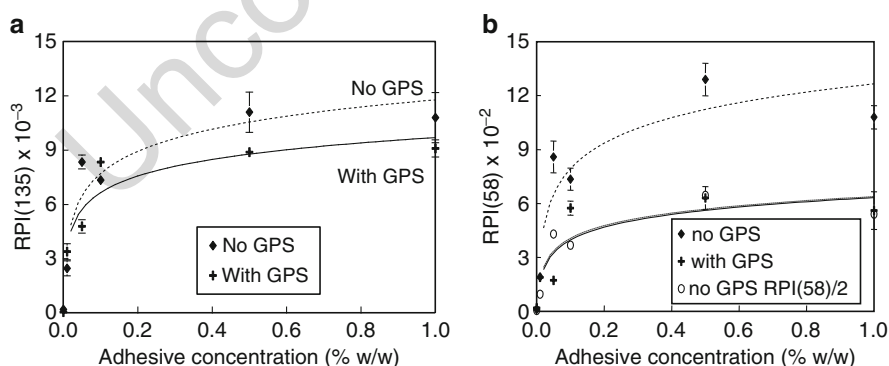

the emphasis was to study the interphase morphology but if chemical information is required it is always important to establish that the reagents used for dissolution are not, themselves, reacting with the system to change the chemistry at the interphase.

## 10.5 Model Systems

### 10.5.1 Adsorption Isotherms

The determination of adsorption isotherms to study the reaction of gas phase molecules with a solid substrate is a well-established procedure in traditional surface chemistry. This method can be successfully adopted to study the adsorption of molecules incorporated in an adhesive formulation on a metal, or other, substrate (Watts and Castle 1999). The uptake of adsorbate from liquid solution as a function of solution composition is monitored by XPS or ToF-SIMS on a series of substrate coupons. The adsorption isotherm is plotted in the same manner as a conventional gas phase study but with surface composition (determined by XPS or ToF-SIMS) being plotted against solution concentration. In this manner, the adsorption of adhesive components can be compared on the same substrates, or the same adsorbate compared on different substrates such as metals with and without pretreatment (Rattana et al. 2006). An example of such an investigation is shown in Fig. 13, where the adsorption of adhesive components diglycidyl ether of bisphenol A (DGEBA – the epoxy building block) and the curing agent (toluene diisocyanate – TDI – urone) are compared on bare aluminum and aluminum that has been treated with an epoxy tipped adhesion promoter (glycidoxo propyl trimethoxysilane – GPS) (Watts et al. 2004). Figure 13a shows the adsorption of the epoxy component (DGEBA) from the adhesive solution, and it can be seen that there is very little difference in adsorption characteristics between the bare aluminum and the substrate

**Fig. 13** Adsorption of the epoxy component (a) and the curing agent (b) from dilute solutions of adhesive onto bare aluminum (“No GPS”) and aluminum treated with an organosilane adhesion promoter (“With GPS”). In (b) the data from the bare aluminum is shown divided by two as “no GPS RPI(58)/2” to illustrate the close match with the data from the silane treated substrate

466 treated with the organosilane. The situation is very different, however, for the  
467 toluene diisocyanate urone curing agent, where it is clear that the adsorption on  
468 the bare aluminum is significantly more than that of the GPS-treated substrate. A  
469 clue to the source of the large difference can be found if the data for the bare  
470 aluminum is divided by two and replotted (as the “no GPS RPI(58)/2” curve) and  
471 it is now coincident with the data set from the substrate treated with GPS. The reason  
472 for this becomes clear when the molecular architecture of the curing agent is  
473 considered. TDI urone is a symmetrical molecule. And in the case of the bare  
474 aluminum, it is weakly adsorbed on the substrate by donor–acceptor interactions,  
475 and both ends of the molecule can yield the  $m/z = 58$  ion ( $\text{CH}_3\text{NHCO}^+$ ) used in the  
476 analysis of this adsorption process. In the case of the GPS-treated aluminum, one end  
477 of the molecule can interact directly with the strained oxirane ring (epoxy group) of  
478 the organosilane adhesion promoter. It is more likely that there is now only one  
479 amine functionality to generate the diagnostic fragment. In this manner, it is  
480 possible to deduce the nature of the bonding between silane and curing agent, and  
481 specific ions indicative of such an interaction were also seen in the ToF-SIMS  
482 spectrum (Rattana et al. 2002).

483 In addition to providing information regarding the capacity of the solid surface for  
484 the liquid phase adsorbate, the adsorption isotherm can also provide valuable  
485 conformational and thermodynamic information. The data of Fig. 14 presents the  
486 adsorption isotherms for poly(methylmethacrylate) (PMMA) on oxidized aluminum  
487 and silicon surfaces (Watts et al. 2000). Figure 14a shows the behavior at low and  
488 medium concentrations, and this follows the expected form for chemisorption. The  
489 data at higher concentration, Fig. 14b, shows a sharp rise in adsorption that is  
490 consistent with multilayer rather than monolayer adsorption. The answer, however,  
491 lies in the conformation of the molecules; at low concentrations they are in an  
492 extended form (illustrated by the schematic inset of Fig. 14a), while at higher  
493 concentrations they are in a more compact form and pack more efficiently on the  
494 surface (shown in the schematic of Fig. 14b). Another useful feature that can be  
495 established qualitatively from inspection of the isotherms of Fig. 14a is the heat of  
496 adsorption. The sharpness of the “knee” at low concentration provides an indication  
497 of this value, thus for the data of PMMA on aluminum and silicon the heat of  
498 adsorption for PMMA on aluminum is more exothermic than on silicon. This is as  
499 one would expect as the silicon surface will be rich in acidic silanol groups very  
500 receptive to the basic PMMA, whilst the aluminum oxide surface is amphoteric and  
501 will not react so readily with PMMA.

502 The plateau of the adsorption isotherm indicates the concentration(s) at which all  
503 adsorption sites for the adsorbing species are occupied, in surface chemistry terms the  
504 fractional surface coverage of the substrate by the adsorbate is unity. Such a specimen  
505 provides an ideal opportunity to probe the interfacial chemistry of adhesion directly  
506 using what is sometimes referred to as the thin film approach. As the layer of organic  
507 material, such as adhesive, is very thin (as a result of monolayer coverage) the  
508 contribution of interfacial chemistry at the interface will be maximized in the resultant  
509 XPS or ToF-SIMS spectrum. For this reason, the construction of adsorption isotherms  
510 is often used as a precursor to direct interphase analysis in this manner.

**Fig. 14** Adsorption of PMMA onto oxidized aluminum and silicon. (a) Shows the behavior of molecules at low concentrations when they are extended while (b) indicates the apparent deviation from monolayer coverage at high concentrations as a result of the molecule adopting a more compact form (Reproduced from Watts et al. (2000), with permission)

## 10.5.2 Direct Interphase Analysis

The concept that by carrying out a surface analysis on a model specimen one can obtain direct access to the interphase chemistry is a potentially very exciting and rewarding idea. The interaction of PMMA with various metals (as exemplified by Fig. 14 above) has been studied in some detail using high resolution XPS (Leadley and Watts 1997). In this work the manner in which PMMA formed specific interactions with oxidized metal surfaces was studied by the nature of the fine structure in the XPS spectrum. In this manner, it was possible to show that the polymer formed hydrogen bonds with oxidised silicon (an acidic substrate), a bidentate structure with oxidised aluminum (an amphoteric substrate) and would undergo acyl nucleophilic attack with oxidised nickel (a basic substrate).

In the case of the GPS organosilane adhesion promoter applied to aluminum (and used as a substrate in the data of Fig. 13), ToF-SIMS has established the formation of a covalent bond between the GPS molecule and the oxidized aluminum substrate (Abel et al. 2000). The chemistry leading to the formation of the diagnostic fragment ( $\text{Al-O-Si}^+$  at  $m/z = 70.9534$  u) and the high resolution spectrum at a nominal mass of 71 u is shown in Fig. 15. The formation of the specific bond is associated with good durability of the resultant bond, and examination of the fracture surfaces of failed joints shows that the presence of the ion in the ToF-SIMS spectrum correlates well with good durability.

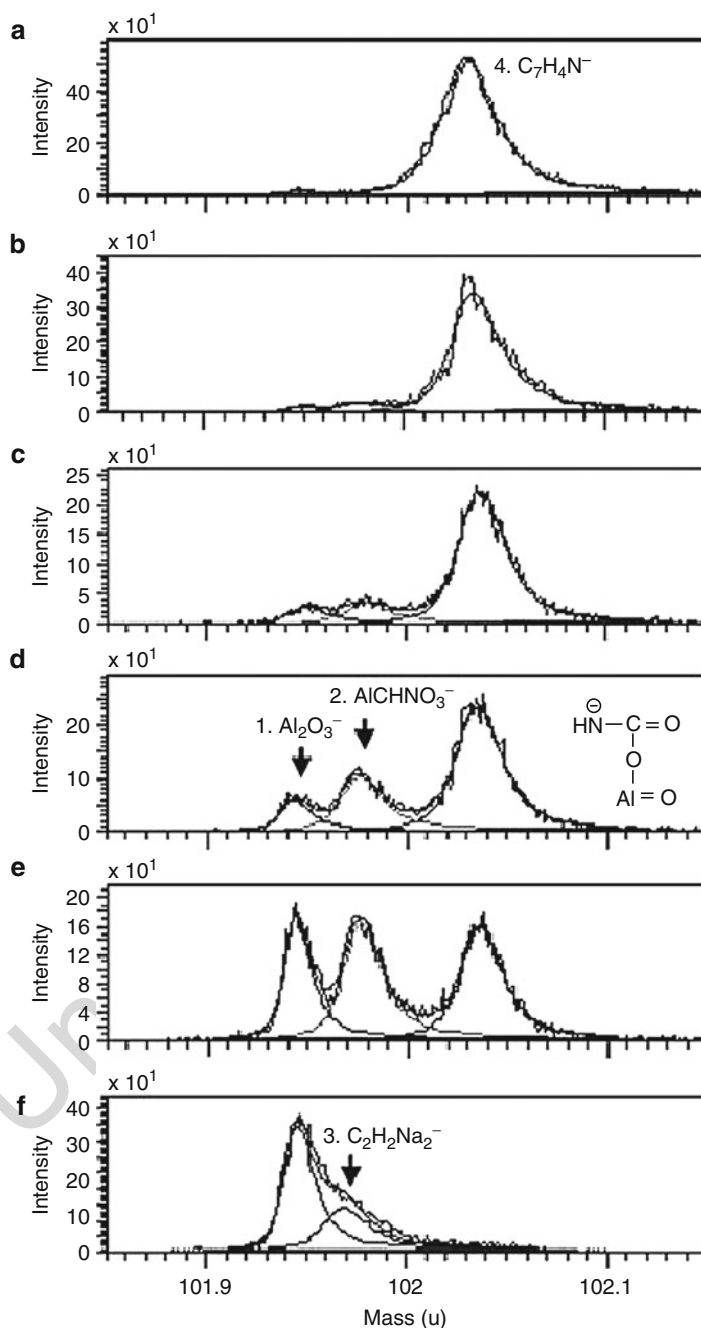

ToF-SIMS has been used in a similar manner, in the work of Shimizu et al. (2010) to identify the specific interaction between aluminum and polymeric methylene diphenyl diisocyanate (PMDI). A series of ToF-SIMS spectra from the region of nominal mass  $m/z = 102$  u is shown in Fig. 16, and the spectra have been peak-fitted which is not a standard practice in ToF-SIMS (first demonstrated by Abel et al. 2009), although it is readily accomplished using standard XPS software such as CasaXPS (CasaXPS 2009). These range from a concentrated solution (Fig. 16a, 5 v/v%) through to a dilute solution and the bare aluminum substrate (Fig. 16e, f, respectively). For the two most concentrated solutions (Fig. 16a, b) a thick layer is deposited and the only fragment in this region of the spectrum is  $\text{C}_7\text{H}_4\text{N}^-$  characteristic of the PMDI material. The two dilute solutions show fragments from the substrate ( $\text{Al}_2\text{O}_3^-$ ) and the PMDI but also an ion at  $m/z = 101.9772$  u indicative of the  $\text{AlCHNO}_3^-$  ion, which results from the formation of a covalent bond between the aluminum substrate and PMDI. A possible structure of this ion is shown in the inset to Fig. 16d.

## In Vacuo Testing for the Provision of Interfacial Failure Surfaces

Almost all investigations seeking to elucidate mechanisms of adhesion, or define the locus of failure, are carried out on specimens which are generated outside the ultra-high vacuum of the surface analysis systems. For the most part this works extremely well, and the distinction between adventitious hydrocarbon materials and residual, vanishingly thin, layers of adhesive or organic coating are made in quite a straightforward manner. This is particularly true with the molecular specificity of ToF-SIMS that enables the individual components of the formulation of adhesive or coating to

**Fig. 15** The specific interaction of glycidy propyl trimethoxysilane with hydrolyzed aluminum. **(a)** Reaction mechanism, **(b)** high resolution ToF-SIMS spectrum of  $m/z = 71$  u region showing the  $\text{SiOAl}^+$  fragment attributed to the specific bond

**Fig. 16** Specific interaction of polymeric methylene diphenyl diisocyanate (PMDI) with aluminum. Negative ToF-SIMS spectra at nominal mass  $m/z$  102 u from aluminum treated with PMDI of varying solution concentration. (a) 5 v/v%, (b) 0.5 v/v%, (c) 0.35 v/v%, (d) 0.1 v/v%, (e) 0.05 v/v%, (f) no PMDI (Reproduced from Shimizu et al. (2010), with permission)

be identified explicitly. There are situations when it is desirable and sometimes essential, to carry out the fracture process in a chamber of the spectrometer under UHV, clean conditions. There may be a number of reasons for the need to proceed in this manner; fracture may be thought to occur at a metal–oxide interface (of an anodic layer, for example), and the metal substrate will oxidize on air exposure making the failure indistinguishable from one that is within the oxide layer; an unfunctionalized carbon component in the formulation (a wax for example) may be thought to segregate to the interface forming a weak boundary layer that will be spectroscopically indistinguishable from adventitious hydrocarbon; there may be concerns about post-failure contamination of the surface by airborne material that is also in the organic material formulation.

The concept of *in vacuo* fracture as a means of sample preparation for adhesion studies has been developed in the author's laboratory in a gradual manner over many years. Initial studies made use of an impact fracture stage designed to provide an Izod (three-point bend) geometry for use with metallic samples that yielded intergranular fracture at cryogenic temperatures. This was modified for composites research. And small samples that are 30 mm in length and some 2 mm square (with fibers oriented in the 2 mm direction) could be accommodated in the stage using small sleeves, and fracture could be generated at, or around, the fiber–matrix interface at room temperature. The resulting fracture surfaces could then be examined by XPS, ToF-SIMS, or AES. The disadvantage of these early experiments were that it was not possible to control strain rate or loading geometry and the next step of development was the design of a controlled strain rate stage that could be arranged for Mode I or Mode II loading of the samples as described by Prickett et al. (2001). This established the concept of controlled geometry of loading but neither the applied load nor the strain rate was monitored in this intermediate fracture stage. The current solution to *in vacuo* fracture is a fully instrumented fracture stage, interfaced to a personal computer, that allows the strain rate to be controlled as the load applied is recorded (Wood et al. 2008). The use of this stage is illustrated below with an example involving the reinforcement of an unsaturated polyester resin (of the type used as a matrix in glass fiber–reinforced composites) with organically modified silica nanoparticles (ormosil).

The specimen geometry was a miniature compact tension specimen and samples were made of the unmodified polyester resin and polyester resin with ormosil added at a level of 1 v/v%. In order to compare the efficacy of the fracture stage a comparison was first made between surfaces produced in the fracture stage firstly at ambient atmosphere and then when the stage is pumped down to ultra-high vacuum and the fracture surfaces produced in these clean conditions (Wood et al. 2009). The high resolution ToF-SIMS spectra from the  $m/z = 28$  region of the spectrum shows clear differences between the spectra from these two surfaces. The spectrum from the sample fractured at ambient pressure shows a significant intensity of the  $^{28}\text{Si}^+$  ion (Fig. 17a), while the surface fractured in UHV shows no sign of silicon contamination, confirmed as poly(dimethyl siloxane) by the inspection of the complete ToF-SIMS spectrum. Turning now to the spectra from the fractured ormosil modified polyester fracture surfaces, it can be seen that the  $^{28}\text{Si}^+$  ion

**Fig. 17** ToF-SIMS spectra of nominal mass  $m/z = 28$  u for the polyester/ormosil system. (a) Polyester fractured in air, (b) polyester fractured in vacuo, (c) polyester + ormosil fractured in air, (d) polyester + ormosil fractured in vacuo (Reproduced from Wood et al. (2009), with permission)

intensity is significant on both surfaces (Fig. 17c, d, respectively). The question is, of course, the source of the silicon on these two surfaces as both have the potential to be from either PDMS or the SiO<sub>2</sub>-based ormosil particles. The resolution of this quandary, of course, lies in the information provided by the spectra of Fig. 17a, b, which indicate that fracture in situ will be PDMS-free but when fractured in air there is always the possibility of contamination by airborne PDMS. This example illustrates in a very powerful manner the benefit of in vacuo sample preparation. The source of the PDMS is thought to be personal care products used by many within the laboratory and the local environment.

---

## 10.6 Conclusions

The use of XPS and ToF-SIMS has much to recommend for the investigation of the interfacial chemistry of adhesion. In the most advantageous cases the analysis of fracture surfaces has the potential to provide such information but one must ensure that failure has occurred within the interphase; this will not always be the case and the onus, as always, is on the researcher rather than the analyst, to interpret the analytical data correctly in the context in which the analysis was made. If fracture surfaces do not provide access to the interphase it is necessary to resort to sectioning of the system to expose, possibly with sputter depth profiling, the interphase region itself for analysis. An alternative method is to use dilute solutions, based on either individual components of a formulation, or the complete adhesive or coating itself. This allows the determination of adsorption isotherms that measure the capacity of a solid surface for adsorbates in the liquid phase, and also confirms the development of monolayer coverage. By the analysis of a specimen from the plateau region of an isotherm, it is possible to probe the interfacial region with XPS or ToF-SIMS that allows spectroscopic identification of the interphase to be achieved. ToF-SIMS with its molecular specificity is particularly informative in this regard and may enable the nature of the bond to be identified explicitly if spectra are recorded at very high mass resolution.

## Abstract

Being amongst the most versatile molecules available to promote adhesion, organosilanes nonetheless remain a bit of a conundrum for some as one needs to know their chemistry thoroughly in order to utilize them in a useful fashion. In the first instance, this work starts with a short presentation of organosilanes defining this class of chemicals as well as explaining their genesis followed

M.-L. Abel (✉)

e-mail: [M.Abel@surrey.ac.uk](mailto:M.Abel@surrey.ac.uk)

immediately by a section of this chapter dedicated to their chemistry which includes a few words of warning. Closely related are the necessary interactions that such molecules have to develop on materials in order to fulfill their main role as adhesion promoters, and this is described too but more particularly when considering metallic substrates and polymers. Reactions in a medium are also covered briefly as silanes are commonly included in a matrix which precludes a more comprehensive section of silanes behavior in formulations later on in this document. Is also covered other usages of silanes than as adhesion promoters together with principles to follow in order to chose a silane for a particular application. The following section is concerned with the use of silanes as primers particularly where the user aims to improve adhesion or protect from corrosion. To complete this work, a small section covers some other organic or nonorganic adhesion promoters.

---

## 11.1 Introduction

Although initially the development of organosilanes adhesion promoters was a response to a technological need, more recent developments in the use of such molecules illustrate the reflection of recent legislation and need for more “green” materials. This is true in particular when considering such applications as replacements for chromic acid rinses used in the aerospace industry or corrosion protection where silanes are used as primers in the purest sense of the word. Unfortunately or fortunately, what lies at the heart of this class of molecules is their chemistry. It is both the tenor of their flexibility and complexity, and full understanding of such matters is of foremost importance. As such, explanations of the various intrinsic reactions they may undergo together with a review of how such molecules interact with a variety of materials is essential. The obvious next step from using silanes as adhesion promoters/primers consists into incorporating the silane within a formulation in order to interact with a surface while saving a step in the process. For example, an adhesive formulation may already contain a silane which is destined to diffuse and bond with the surface of choice. Apart from the obvious economy of time, one can anticipate large savings of a more real nature. This chapter will therefore also cover reactions of silanes when not in solution, i.e., for organosilanes incorporated in formulations such as inks or adhesives. Another major part is concerned with the parameters which influence the deposition of organosilanes as primers, some of which are often overlooked, as well as with the various uses of silanes either as adhesion promoters or otherwise including their sometimes controversial usage as corrosion protection coatings. One part is also dedicated to the manner in which one should choose one’s silane, although this section is certainly not exhaustive. The ultimate in the matter remaining a series of tests and experiments for the particular system considered. However, the present author acknowledges that this is not always timely or practical, especially when one considers the resources required and, hence, some pointers are provided to perform an adequate selection. Finally, and although this chapter will examine primarily organosilane adhesion

promoters as well as their use as primers, and within formulations, a short summary of other available adhesion promoters will also be presented at the end of the chapter.

## 11.2 What Silanes are and Where do they Come from

### 11.2.1 Definition

Organosilanes are hybrid molecules with at least one hydrolysable alkoxy silane. They usually bear the alkoxy silane functionality at one end and an organic functionality at the other end. The general formula is  $R'-Si(OR)_3$ , where  $R'$  corresponds to the main chain as well as any desired functionality, while  $OR$  is the hydrolysable alkoxy functionality. However, it is possible to find bis-silanes with alkoxy silanes at both ends of the molecules and one functionality within the middle chain. Various combinations of such structures may also be purchased according to the particular application sought after and/or the type of usage. There are many silanes available, but the most used bear the following organic functionalities: vinyl ( $-C=C-$ , double bond), epoxy, amino (primary amine as well as others,  $-N-$ ) and mercapto ( $-S$ ). They may be applied from solution as well as incorporated in formulations. They may be used on their own or in conjunction with other silanes. They can be deposited on several substrates: glass, metallic, as well as, more recently, organic. Their applications are vast and include composites, paints, adhesives, paints, and inks, and they can impart many properties on and to the materials they are used with, including hydrophobicity, temperature, and abrasion resistance. But mostly, what organosilanes are most famous for is their usage as primers and adhesion promoters where their role is to promote and improve adhesion between two dissimilar and/or incompatible materials.

### 11.2.2 The Origin of Organosilanes

The thought of creating such molecules originated from the will to render glass and an organic matrix compatible as well as to increase the durability of glass fibers-based composites. Indeed, although such composites were exhibiting strong initial strength, they would “fall apart” once introduced into a humid and hot environment. The debonding was attributed to water ingress and hydrolysis of glass. These composites were also exhibiting problems with stresses across the interface because of the very different properties of the glass and the matrix in terms of thermal expansion (Pluedemann 1991). A hybrid molecule with chemistry similar to glass on the one hand and similar to an organic matrix on the other hand was needed. A few organic reactions later, the first silane was born, itself a composite of the chemistry of glass (alkoxy silane part hydrolyzing into a silanol) and any chosen matrix (organic functionality born on the molecule in order to interact with a matrix). This was of course a major contribution to the world of chemistry and science by Edward D. Pluedemann, probably better known as “Mr Silane.” They

were obviously used on glass first, but their usage subsequently progressed onto the surface of metals and a lot recently on polymeric materials too (Pluedemann 1991, Smith 1999). The chemistry of those molecules is at the origin of their being but is also at the very root of their flexibility and the many domains in which they find valuable applications. Therefore, the following section will cover the chemistry of organosilanes and what other reactions they can undergo, including how they interact with other media be it with their surfaces or matrices.

### 11.2.3 Silanes Chemistry

First and foremost, one should make the distinction between all silanes molecules and the more specific organosilanes which are used in solutions or formulated systems as adhesion promoters. The former are basically any molecule-containing silicon, carbon, hydrogen, and possibly oxygen, and encompass both organosilanes and more simple gaseous silicon-based molecules mostly used for plasma deposition of silica or silicone like films. The molecules considered here are more complex as is explained further up in this paragraph. Organosilanes can undergo several types of reactions; they can be summed up as follows: hydrolysis, condensation (either between themselves or with a substrate) and, finally, less likely but nonetheless possible, alcoholysis. Organosilanes usually bear three alkoxy functionalities but may bear only one or two or present functionalities on both sides of the molecule or more. Examples of various silane structures are provided in Fig. 1 where one can see examples of silanes with either three (Fig. 1a) or more (Fig. 1b) alkoxy functionalities. An overview with a few vignettes is provided here, but for a more comprehensive review, one could consult the excellent work by Osterholtz and Pohl in particular where reactions in solution are concerned (Pohl and Osterholtz 1992).

**Fig. 1** General silane structure (a) one-sided silane molecule and (b) organosilane with multiple silane functionalities

## 11.2.4 Reactions in Solution

**Hydrolysis**

Hydrolysis is the conversion of the alkoxy present on the silane molecule in silanols and leads to the production of the alcohol corresponding to the alkoxy present in the silane. This reaction is illustrated in Fig. 2a for an aminosilane,  $\gamma$ -aminopropyl triethoxysilane (APS), and many factors can influence it. This is an important reaction because it is usually preferable, though not compulsory, that the molecule should hydrolyze prior to bonding. The kinetics of hydrolysis depend on how easily the alkoxy to hydrolyze may be approached. One the factors to be considered is therefore steric hindrance. Initially and usually, three alkoxy are present on the molecule. It has been shown that the first one will take longer to hydrolyze followed by increasing kinetic constants for the two left. It also depends on the actual type of alkoxy (methoxy, ethoxy, or longer) as well as the length of the chain connected to the silicon atom, and this has been shown by Arkles et al. who compared the kinetics of hydrolysis for i-butyltrimethoxysilane and i-butyltriethoxysilane (Arkles et al. 1992). Another factor includes the type of functionality attached at the other end of

**Fig. 2** (a) Schematic of APS organosilane hydrolysis, (b) schematic of APS organosilane self-condensation, and (c) APS organosilane condensation with aluminum surface

the organosilane chain and one can demonstrate that, by example, an amino functionality tends to be self-catalyzed compared to an epoxy or a vinyl as in the work by Blum et al. as seen in Fig. 3, where the study was performed using proton nuclear magnetic resonance ( $^1\text{H}$ -NMR) (Blum et al. 1991): (A) represents the signal of methoxysilane (reactant) and (B) the resonance of methanol. The decrease of A versus the increase of B indicates that hydrolysis is taking place. Once the intensity of B is constant, the reaction is complete. This work is also a very good illustration of the rapidity with which amino-functionalized silanes can hydrolyze. It is very important to isolate them from water if not in use as they are autocatalyzed for both hydrolysis and condensation to such an extent that such molecules will even react with the air moisture and absorb  $\text{CO}_2$ . Such reactions can be controlled better paradoxically if performed in an aqueous solution as one can monitor the kinetics of reaction using catalysis by setting the pH of the solution. The catalysis for hydrolysis is usually acidic, although it is possible to use basic catalysis which is usually preferred for condensation, particularly self-condensation. A small paragraph on catalysis will be provided at the end of this section.

In addition, one should also emphasize one particular aspect of organosilane hydrolysis: the effect of other solvents and more particularly that of alcohol, understood as the organic class of molecules of course. It is often advised as

**Fig. 3** Illustration of hydrolysis: A represents the methoxysilane signal and B the methanol resonance in an extract of a nuclear magnetic resonance spectrum. The decrease of A versus the increase of B indicates that hydrolysis is taking place. Once the intensity of B is constant the reaction is complete

largely seen in the literature to proceed to the hydrolysis of a silane in aqueous solution; often also, one is advised to use an alcohol together with water as another solvent, and many authors happily mention using a mixture of water and either methanol or ethanol while waiting for a given time (of say 20–30 min) for hydrolysis. This is rather contra-intuitive as this clearly contradicts Le Chatelier principle. Indeed, hydrolysis of alkoxy functionalities should lead to the production of the corresponding alcohol. By example, an ethoxy will produce ethanol. Hence, adding the correct alcohol (only correct by the virtue that it will allow avoidance of alcoholysis, see below) can only slow down or even stop the hydrolysis reaction. Such problem has been illustrated clearly by some work where the hydrolysis is shown to clearly being extremely or even on existent when methanol is added to a solution of  $\gamma$ -glycidoxy propyl trimethoxysilane (GPS) (Abel et al. 2006). Again, NMR was used, and it was possible to show that adding methanol in solution was significantly slowing down the hydrolysis reaction even if only added at a concentration of 10% (v/v) in solution. However, notwithstanding the problem of volatile organics, one can comprehend that in some cases, it is preferable to use an organic solvent because it evaporate faster but remains the problem of controlling hydrolysis. A good answer to the conundrum would be to use a concentrated aqueous solution at ideal pH (see Sect. 2.4.4 below) and then diluting in an organic solvent once hydrolysis has occurred in order to obtain a solution in which the monomer is stable, i.e., with a longer shelf life. This is not valid though for aminosilanes.

### Condensation

Two types of condensation are possible. One is self-condensation, while the other corresponds to condensation with a substrate of choice such as a metallic substrate. The latter will be covered in more detail in another section below. By definition, condensation corresponds to the reaction of two hydroxyls ( $-\text{OH}$ ) functionalities, leading usually to the formation of water and an ether bond; there is a possibility, however, that condensation may occur before hydrolysis has taken place, but this is not as likely unless catalysis is being used. Figure 2b illustrates the reaction. Similar to hydrolysis, condensation and particularly condensation as oligomer formation is influenced by the value of the pH of the aqueous silane solution. Both condensation and hydrolysis can be controlled using catalysis, although, as mentioned before, amino-functionalized silanes are autocatalyzed with an extremely rapid tendency to polymerize and are also influenced by the amount of silanols present. Condensation is mostly performed under basic catalysis. One of the interests of the users would be of course to be able to establish whether a solution of silane has polymerized without resorting to complex and often expensive tools. One of the recommendations on the silane “grapevine” is to check whether the solution has gone cloudy. This, however, is not valid if the silane polymerizes clear, which is indeed the case of  $\gamma$ -GPS but not of  $\gamma$ -aminopropyl triethoxysilane (APS) or vinyl silanes which polymerize cloudy. One should also be aware that in spite of the opinion of various authors on the subject, organosilanes will not always go down happily on a surface in order to form

bonds. In the case of oligomeric solutions, this is totally false and can lead to premature bond failure if used as a primer.

### Alcoholysis

Alcoholysis is the exchange of the alkoxy borne on the silane with the corresponding alcohol functionality if alcohol molecules are used within a silane solution. By example, if the silane is an ethoxy and that a solution containing methanol is made, then there is a possibility that the ethoxy may substitute for a methoxy.

### Catalysis

Either hydrolysis or condensation may be controlled using acidic or basic catalysis. Essentially, when examining these two reactions, one would ideally like to be able to freeze them in time in order to obtain solutions with long shelf life. Although this is only possible by, for example, cooling down a solution/mixture, it is preferable to use a solution of monomeric-hydrolyzed silanes as a primer solution and catalysis conveniently allows this. The kinetic constant of the hydrolysis and/or condensation reaction vary as a function of the pH of the solution. If acidic catalysis is examined for hydrolysis, then the constant, plotted as  $\log k$  as a function of pH, exhibits a “V-shaped” curve with a minimum specific value of pH. This value corresponds to the slowest kinetics of the reaction, usually around pH 6 for hydrolysis and 10 for condensation. Figure 4 shows an example of such a shape. The position of the minimum of the curve will itself depend on the structure of the molecule.

**Fig. 4** Illustration of the pH dependence of the kinetics of hydrolysis for phenyl-bis (2-methoxyethoxysilanol). On the left of the triangle, one can see acidic catalysis, while on the right, basic catalysis occurs

## 11.2.5 Specific Interactions at the Interface

### Interactions with a Metallic Substrate

As far as metallic substrates are concerned, the anticipation is that the silane will react with hydroxyls functionalities present at the surface in a reaction similar to that of self-condensation. An example of APS bonding on aluminum is given in Fig. 2c. It is important to point out that such interaction will be facilitated by a prior hydrolysis, but this is not necessarily compulsory, as silanes can even hydrolyze within a formulation and subsequently condense. This, for example, is particularly easy for aminosilanes which are autocatalyzed for both hydrolysis and condensation. A silane film is often shown as a “clean” monolayer being deposited on the surface of choice. This is far from reality, and often the film deposited on a substrate will represent several layers and have formed cross-linking of its own. This said, it is possible to deposit very thin films as well as monolayers in order to study the interaction of a possible silane with a substrate. Such methods include the use of adsorption isotherms, for example, as described by Watts in ► Chap. 10, “Use of Surface Analysis Methods to Probe the Interfacial Chemistry of Adhesion” of the present volume, or modelling of a silane layer using adequate softwares. Davis et al. showed that some silanes form a stable interaction when presented with a model aluminum surface; depending on the molecule, the interaction can occur via the silanol, the organic functionality, or forming a bridge while interacting with both sides of the molecule (Davis 1997). Kinloch et al. have also shown that the order, meaning geometry, in which silane will deposit on a surface is correlated with the length of the chain attached to the silane part, where it is above a length of 20 carbon atoms. At certain lengths, the molecules will order with a particular angle to the surface of choice, something not seen for short silane chains or below a length of 10 carbons (Hobbs and Kinloch 1998). Another example where the directionality of the interaction can be demonstrated is shown in the work of George et al. (George et al. 1996). In order to understand the interfacial chemistry of certain joints formed in the semiconductor industry and using angle-resolved x-ray photoelectron spectroscopy, George et al. have studied the interactions of APS with a silicon wafer as well as with Pyralin, a polyimide precursor. Their work shows that APS absorbs CO<sub>2</sub> indeed and can interact on both sides of the molecule with the substrate. The most interesting feature of the article is the demonstration that under a temperature of 125 °C, a thin APS film (1.5 nm) can “flip” from one side to the other (from –NH<sub>2</sub> interacting to silanol interacting), an interesting fact as most drying and cure processes will involve a step at temperature usually preferably above a threshold that will rid of most of the water present in the film. What remains is demonstrating the existence of bond formation. While acid-base type of bonds can sometimes be determined using x-ray photoelectron spectroscopy, showing the presence of covalent bond formation can be readily achieved by various methods such as time of flight secondary ion mass spectrometry (ToF-SIMS) but also with more accessible and cheaper techniques such as infrared spectroscopy (Abel et al. 2000, 2004). Figure 5 shows the region of nominal mass 71 in a positive mass spectrum (ToF-SIMS) for a GPS-coated grit-blasted aluminum where the fragment illustrating a bond formation between aluminum and a silanol is clearly visible, as shown by the fragment  $\text{AlOSi}^+$ . This was initially shown by Gettings and Kinloch at nominal

**Fig. 5** High-mass resolution of ToF-SIMS spectrum in the positive mode of grit-blasted aluminum coated with GPS at nominal mass 71. The most intense peak may be assigned to  $\text{AlOSi}^+$  and provides proof of silane bonding to aluminum substrate. The difference in mass between assignments and recorded masses is provided in mμ

280 mass  $m/z = 100u$  for  $\text{FeOSi}^+$  easier to demonstrate in spite of the lack of mass  
 281 resolution because of its occurrence at an even mass which is unusual for most organic  
 282 fragments, as shown in Fig. 6 (Gettings and Kinloch 1977).

### 283 11.2.6 Interactions with a Polymer or Polymeric Substrate

284 Although the interaction of organosilanes to metals or more generally surface-  
 285 bearing hydroxyl functionalities is usually well known, it is another matter when

**Fig. 6** ToF-SIMS spectrum in the positive mode of detection of steel coated with silane, showing the presence of an ion at nominal mass  $m/z = 100u$  and indicating the presence of  $FeOSi^+$  resulting from bond formation of steel with silanols

interactions of the same molecules to polymer are concerned. If the silane has been selected properly, it is usually anticipated that the organic functionality borne by the silane will interact with the polymer of choice in some way either by forming a covalent bond or a Lewis (electronic type of interaction) acid-base type of bond. This is exemplified easily when a silane is incorporated in an epoxy resin; as most structural adhesives contain an epoxy part and an amine curing agent, one can see that an aminosilane will also react with the epoxy resin, and that an epoxy silane (such as  $\gamma$ -glycidoxo propyl trimethoxy silane or GPS) will react with the curing agent. Such a reaction was shown to occur by Rattana et al. using thin film deposition of an amine-curing agent on the top of an epoxy silane. The reaction mechanism is the same as seen for the curing of the resin itself (Rattana et al. 2002). Other authors have shown similarly that a methacrylate-functionalized silane will bond to an unsaturated polyester resin (Dow Corning 2011). Just as for any interactions with

metals, any film formed by the silanes on polymeric surfaces cannot be assimilated to a simple monolayer and, in the case of two organic materials (polymer/silane), this leads to the hypothesis proposed initially by Pluedemann that a silane coupling agent can form an interpenetrating network as a possible mechanism of adhesion (Pluedemann 1991). This provides another mode of interaction between silanes and polymers, where no chemical reaction is necessary.

### 11.2.7 Reactions when Not in Solution

Silanes can be incorporated in formulations as will be discussed later in this work. However, and for the sake of clarity, reactions in a bulk material will be briefly covered here. Silanes used in formulations can be used for different purposes but, most of the time, they are present in order to aid bonding between the matrix of choice (whether adhesive, ink, or else) and the chosen substrate. In order to do so, they have to undergo the exact same reactions that a silane and/or a primer prepared from a solution should, namely hydrolysis and condensation. The particular difficulty resides in the observation of reactions within a system which may contain other sources of silicon and where the silane is introduced at small concentrations of the order of 1% (w/w). Abel et al. have had some success in observing the reactions undergone, in particular, by an aminosilane within an epoxy system. Using ToF-SIMS, it was possible to observe peaks which are indicative of hydrolysis at nominal mass 79 ( $\text{Si}(\text{OH})_3^+$ ) as well as other fragments characteristic of condensation on both substrate (bonding) and as self (polymerization) (mass 71 and 72, for respectively  $\text{AlOSi}^+$  and  $\text{Si}_2\text{O}^+$ ). In these figures, two superimposed spectra are shown, and they correspond to two different regions close to the interface of an adhesive-containing APS deposited on aluminum foil. An example of such fragments is shown in Figs. 7, 8, and 9, where high-mass resolution spectra are shown for the masses mentioned above, together with other fragments present at the same nominal mass. The lower spectrum corresponds to the region closer to the substrate for nominal mass 79 and 72 while  $\text{AlOSi}^+$  was only observed for this region. For such reactions to occur, water must be present in some form; the most obvious way in which water may be found in a system is within the matrix itself or adsorbed on the substrate. Increase of temperature when curing an adhesive, for example, may be a further incentive for bond formation, be it covalent bond formation with the substrate or self-condensation. When an aminosilane is used, there is no doubt that the autocatalysis is aiding the reactions to occur as well as their identification.

## 11.3 Uses of Organosilanes Other than Adhesion Promoter

It is actually useful to look at the actual application for which organosilanes can be used rather than a particular field as well as the actual properties of materials provided by silanes. The major use of silane is obviously in the context of adhesion and very specifically as an adhesion promoter; however, this concept can be turned on its head and provide functionalized surfaces where silanes do not interact or with

**Fig. 7** High-mass resolution at nominal mass 79, showing the presence of  $\text{Si(OH)}_3^+$  and indicating that the silane incorporated in the formulation has hydrolyzed

very small interactions. Most silanes bear alkoxy silanes and another functionality; usually the latter is designed to interact with another material, but it is possible to prepare silanes bearing an alkyl chain opposite to the alkoxy. This results in a molecule only capable to interact with van der Waals interactions. Such molecules when grafted/bonded to a surface of choice may therefore be used as water repellent and contribute to properties of materials in this manner. Apart from the obvious usage, this may, for example, provide such properties as thixotropy to adhesive and paints and also help in increasing toughness of materials as a “non-interaction” as the interface of two dissimilar materials can provide a deflection path for a fracture crack and hence increase resulting toughness. Another application uses the same concept as an adhesion promoter, and this is when a silane is used as a cross-linker. The very same functionalities used to promote adhesion can also be used within a matrix or formulation and promote cross-linking by forming bonds with neighbouring functionalities. Silanes can also impart temperature resistance, and to do so, the organic

**Fig. 8** High-mass resolution at nominal mass 71, showing the presence of  $\text{AlOSi}^+$  and indicating that the silane incorporated in the formulation has bonded with the substrate

**Fig. 9** High-mass resolution at nominal mass 72, showing the presence of  $\text{Si}_2\text{O}^+$  and indicating that the silane incorporated in the formulation has polymerized

functionalities that the silane must bear are very specific. A good example of this is a phenyl functionality, which is not surprising as such chemistry also provides higher temperature resistance to molecules that bear it. Other applications include mechanical improvement with abrasion resistance as well as corrosion protection which will be described in more detail in Sect. 2.4 as it is invariably connected to adhesion.

---

## 11.4 Selection of a Coupling Agent

The general rules when choosing a silane is to work with a molecule which will be compatible with the system considered. This is why often the chemistry of the silane used will be considered and will provide a fairly good rule of thumb for selection. Examples include epoxy silane for epoxy adhesives, although an aminosilane can work as well, and vinyl can be used for rubber. The compatibility in the chemistry goes further than just exhibiting similar functional groups. Another way to choose a silane is of course to consider which type of reaction such molecule may undergo. For example, a vinyl silane will be compatible with a system that reacts through free radical process/polymerization. In that sense, an epoxy silane such as  $\gamma$ -glycidoxypentyl trimethoxy silane is compatible with an epoxy resin not only on the account of similar chemistry but because it will undergo the exact same reaction through the epoxy ring than cure reactions based on the same functionality in the resin/adhesive.

---

## 11.5 Organosilanes as Primers

When a material is to be bonded to another, various case scenarios may be considered. One would, of course, like to improve adhesion between these materials by treating the surface in some way which can be observed macroscopically by increased wetting. However, other considerations include protection of the substrate against corrosion or oxidation, especially but not only if metallic, as well as increasing the surface area available for bonding. These aims may be achieved in many ways with a treatment of the surface to bond. Abrasive mechanical, chemical, plasma, flame and coatings treatments are available and produce surfaces with improved, often combined characteristics (like higher surface energy and increased surface area by example), and properties which vary in benefit according to whatever technique is used and which effect is desired as well as how some of these methods are combined (abrasion plus primer).

One method that combines in attaining several of the properties considered in the previous paragraph is the application of a primer. This is achieved by depositing a relatively thin film of material, usually in liquid form, on the material to be bonded or coated. The role of the primer is to act as some kind of barrier (against possible corrosion for example) and/or to provide functionalities for bonding and hence make the two surfaces to be bonded more compatible. One particular type of molecules which seems to be used with some success in both cases is organosilanes. The use of silanes in such applications is popular because of its relative harmlessness compared

to for example chromium VI based treatments. They can also be prepared in aqueous solutions and this helps for applications where volatile organic compounds are either prohibited or reduced considerably as indicated by recent European Directives making them a good application in an industrial context. As described above these molecules were designed in order to compatibilize glass and coatings and in particular in order to increase durability of matrix to glass fibers in composites acting in stopping untimely hydrolysis of the glass acting therefore both as a barrier and providing ideal chemistry at the interface. Subsequently it was also found that silanes could be used on metals and more recently on polymers. Their use will be examined in the light of two of the mains aims for primers: as a barrier and creation of functionalities/compatibilization with other materials. In other words in two domains where silanes have potentially a great importance: adhesion and corrosion sciences.

### 11.5.1 Organosilanes as Adhesion Primers

Many parameters may influence the mechanical properties of a joint formed with a silane primer and the interactions formed when depositing the silane. One can roughly divide them in three categories prior to implementation in the field. Firstly, the solution used initially, then the application, and finally the curing of the coating and/or adhesive deposited on the top of the silane layer. If one considers the solution first, the tenor of using a silane primer or coating properly is to know the chemistry. One point which is never emphasized enough is that one should advise strongly to use a solution which only contains monomers of the hydrolyzed silane of choice or failing that a solution that does not contain oligomers of the silane of choice. Bertelsen and Boerio have shown quite cleverly using both fracture mechanics as well  $^{29}\text{Si}$  NMR and vibrational spectroscopy that poor durability of a joint formed with an epoxy adhesive and a hydrolyzed epoxy silane could be explained by the oligomerization of the solution used which is related with time and hence shelf life (Bertelsen and Boerio 2001). Figure 10 shows the relationship between the amount of polymerization present in the solution and the correlation with the onset of the increase of the crack length of a test joint. In other words, the higher the amount of oligomers/polymerization in the solution, the least durable is the joint. Similarly, other coworkers have shown that the amount of adsorption of  $\gamma$ -GPS decreases as a function of hydrolysis time which is consistent with Bertelsen and Boerio's studies (Abel et al. 2000). This also undoubtedly illustrates the importance of the hydrolysis parameters in solutions which include, to name but a few, hydrolysis time, pH of the solution, concentration of silane-used solvents (from aqueous only to mixtures of alcohol). Porrit underwent a very exhaustive study of the parameters which can influence durability when a particular silane primer is used in an epoxy adhesive joint (Porrit 2001). The parameters considered included details concerning the solution used (as exemplified by the sentence above) but also considered the substrate surface treatment prior to coating the silane solution, mode of deposition such as dipping or brushing the solution on, as well as time and temperature of cure for the adhesive. In his work, the durability tests were performed using the

**Fig. 10** (a) Relationship between composition and hydrolysis time for a 10% solution of  $\gamma$ -GPS in water. (b) Relationship between the composition in a 10% solution and total crack length of wedge test specimens prepared from adherends treated with a 1%  $\gamma$ -GPS solution

rather convenient and quick Boeing wedge test, and he was able to eliminate unfavourable conditions and obtain the optimum concentration of silane, time, and pH of hydrolysis for an aqueous solution, lag time between drying and bonding, mode of deposition, time and temperature of drying. Parameters considered for the surface treatment included type of cleaning and, type of surface roughening. This shows that to obtain the full benefits of silane usage, one must know in detail not only the chemistry but also the favourable or unfavourable conditions such application may encounter once deposited on a substrate. This section is going to review some of these parameters.

First and foremost, the cleanliness of the substrate should be of uppermost importance but is not always necessary, which confuses the silane application issue further. Usually, one should deposit a coating or film on a clean surface to avoid any weak boundary effect, but it is not unusual to see that some adhesives and/or coatings subsequently deposited on a surface can absorb the contaminants or displace them (usual culprits include and not particularly in industry only polydimethyl siloxane (PDMS) and materials akin to polytetrafluoroethylene better known under the designation Teflon™ or PTFE). For example, Watts and Prickett have shown that adhesion to composite samples exhibiting PDMS on their surface can be good and explained this fact by assuming that the contaminant was being absorbed by the adhesive (Prickett 2003). Producing a similar final effect, it is assumed that silanes deposited on a surface can displace contamination. This is probably true of organics but is not the case for salts such as carbonates, and one should be aware that anything present on the surface prior to bonding may compromise strength and/or durability of a joint.

Another point of importance is the roughness of the substrate. It is usually thought that the rougher the surface, the better the adhesion or at least the mechanical anchorage of the coating on a substrate. Actually, what roughening produces is indeed an increase in surface area available for any coating, but this translates in particular into an increased number of available bonding sites. This is one of the reasons why phosphoric or chromic acid anodizing are so attractive for aluminum-based alloys notwithstanding their barrier properties. When Porritt studied the effect of surface preparation on the durability of joint prepared, the best effect was reported for a “boiled” aluminum surface where the microstructure obtained resembles that of phosphoric acid anodizing albeit at a smaller scale. The various parameters that were shown to be of importance were as follows: pH of the water used to hydrolyze GPS, time of hydrolysis, conditions of deposition, temperature of drying, and concentration of the solution. Figure 11 shows the results of the measurements of the fracture energy resulting from the optimized surface treatment using  $\gamma$ -GPS. This figure actually shows two optimized treatments: one optimized treatment corresponds to the best parameters as cited above, while the best treatment utilizes the same parameters and 1 h hydration (“boiling”) of the aluminum prior to deposition of the silane primer. It is rather remarkable that this final treatment happens to exhibit even better durability than the system usually assumed to be the best in terms of aluminum-based alloys for aerospace, namely chromic acid anodizing and phosphoric acid anodizing.

### 11.5.2 Organosilane as Corrosion Protection Films

The advantage of a protective coating containing silanes is supposed to be twofold: it can protect the metal on which the film will be applied, and it is also supposed to interact chemically with both substrate and covering coating. The treatment usually consists into the application of a mixture of silanes as it has been shown that a mixture exhibits a better performance in terms of corrosion protection than a single

**Fig. 11** Fracture energy comparison for several treatments, including two optimized silane treatments. CAA denotes chromic acid anodizing, while PAA means phosphoric acid anodizing

silane solution (van Ooij et al. 2005). Much has been done to ascertain the efficacy of such corrosion protection primers as shown by one of the main protagonist of such methods, Win van Ooij based at the University of Cincinnati (van Ooij et al. 2005; Zhu and van Ooij 2004).

The mixture is typically a combination of “monosilanes” and “bis-silanes,” where the formula of the former is  $X_3Si(CH_2)_nY$  and the later is  $X_3Si(CH_2)_nY(CH_2)_mSiX_3$  (or even  $X_3Si(CH_2)_mSiX_3$ ). X represents the hydrolysable group and Y a functional group such as an amine or vinyl. The bis-silanes provide a pronounced hydrophobic polysiloxane layer resulting from SiOSi linkages. Unfortunately, such molecules are usually fairly hydrophobic and make the use of other solvents than water necessary, which is a clear handicap for the use of such solutions. Such systems include the use of bis-[triethoxysilyl]ethane (BTSE,  $(OC_2H_5)_3Si(CH_2)_2Si$ ). However, bis-silanes functionalized with amines are compatible with aqueous solutions and have allegedly shown the same resistance to corrosion as chromate based systems. Such systems are tested for corrosion resistance using various methods, mostly electrochemistry based.

## 11.6 Silanes in Formulations

Silanes can be used in various ways, but when it comes to adhesion, they are either deposited as a coating or are incorporated within formulations. Those formulations include adhesives, coatings, and inks, but the list is not exhaustive. The intention is for these molecules to find their way toward the substrate and help bonding at the interface by rendering the substrate and the material deposited on it more compatible. This kind of application is important as it helps reducing time of application and

hence saves money but also because silanes are considered as a substitute to many other not so green materials. Using silanes in such a way can be considered as a “built-in” (within adhesive or coating for example) primer deposition as it is possible to show that a silane incorporated within a formulation will diffuse toward the desired interface. This is why relevant research will be described in this section.

The main problem encountered here is that there is hardly any control of the rate of the reactions happening within the system and similarly no control of the diffusion be it rate amount, type, etc. To confuse the issue further, many manufacturers will incorporate several organosilanes within a system on the off-chance that they have “missed something” without regard for the possible consequences on the interactions at the interface and durability of such joints. Although not many studies have been performed on the subject due to the intrinsic difficulty of the research, two were performed at the University of Surrey with two very different materials. One was concerned with the adhesion of polyamide coatings to steel in order to protect such items as dishwasher baskets from damage and corrosion; the other with the adhesion of an epoxy-based adhesive on aluminum to avoid the use of a silane (or other) primer. In both cases, only one organosilane was incorporated, and the aim was for the durability and/or protection resistance of the coating to be improved compared to a formulation without silane. In accordance with the general rules of silane choice, an epoxy functionalized (GPS) was chosen for the epoxy adhesive or an aminosilane (APS) for either the adhesive or the polyamide material (Guicheney et al. 2004, 2006a, b). In both cases, it was found that the addition of a silane is beneficial to durability and/or corrosion resistance. It was also possible to follow the diffusion of respective silanes using the now well-known method of ultralow-angle microtomy (ULAM) which allows access, amongst other advantages, to the still bonded material and hence the intact interface between either epoxy adhesive and aluminum or polyamide and steel (Hinder et al. 2005). Figure 12 shows an example of reconstructed diffusion profile of the concentration of silicon from the interface (distance zero) with the substrate toward the bulk of materials for an epoxy system. The analysis was performed using XPS after microtoming samples and calculation of the actual depth covered through ULAM cut (this is achieved through a simple trigonometry calculation, for more details see (Hinder et al. 2005)). Silicon is obviously used as a marker for the silane, and all precautions have been taken to eliminate other sources of silicon, including the silica (incidentally functionalized with an alkyl silane), usually included in the formulation to achieve thixotropy of the adhesive. One can see that the concentration of silicon is higher toward the substrate for aluminium whereas it has been shown that it increases also for while it was shown to be higher toward the steel and the air/polyamide interface in Guicheney et al.’s work (Guicheney et al. 2004, 2006a, b). This indicates that the silane has indeed diffused toward the desired interface but also toward the external surface of the coating. One can point out that the diffusion seems to occur in a similar way and achieve similar concentration of silicon at interfaces around 1–2 at.%. In the two examples provided, only the silanes are identical, while all other materials and conditions are totally different: two different substrates, a thermoplastic versus a thermoset as polymeric matrix which implies that the factors determinating the

**Fig. 12** Schematic indicating diffusion of silane within a formulation. On the left is the interface with aluminum and, on the right, the bulk of the adhesive

diffusion are similar and correspond to the molecule properties and behavior rather than anything else. This diffusion is most likely to occur when either material is still in a liquid/soft form with the difference that the temperature used is not the same, although it does not seem to be reflected in the diffusion.

Several driving forces can be invoked here. In order for the molecule to segregate to the interface with the substrate, it has to be mobile enough, and the local enrichment has to be driven by thermodynamic considerations. They have been described in detail by Abel and Watts as well as by Guicheney (2006b), but they can be summed up here. The metallic substrate capable of forming bonds with the silane may act as a sink for the silane molecules, solubility parameters should be considered also to assess the compatibility of matrix to silane to check on exclusions mechanisms as well as possible of interdiffusion with matrix as shown by Gentle et al. (1992). Another possible explanation lies into the value of the chemical potential (partial molar Gibbs free energy) of the silane, within the matrix considered as flow will occur spontaneously from a region of high chemical potential to a region of low chemical potential.

Several concentrations were tested, and one can find that if such a system is to be used, the concentration to be used has to be optimized and most likely will go an optimum then exhibit a detrimental effect on the properties considered. For example, adhesives containing a range of concentrations of GPS or APS were tested, and it became clear that too much silane within a formulation can exhibit similar properties to a formulation without silane, exemplifying beautifully the famous saying of “overegging the pudding.”

## 11.7 Non-silane Coupling Agents and/or Adhesion Promoters

Although silane adhesion promoters are probably the most known, used, and versatile, there are many others. Some are based on titanium, chromium, or zirconium, while others, still based on silicon chemistry totally differ in their structure

from regular organosilanes. This section will highlight briefly a few examples with their chemistry, mechanisms, and fields of applications.

### 11.7.1 Metal-Based Coupling Agents: Example of Zirconium and Titanium

Together with titanium, zirconium has a similar chemistry to that of silicon because of the group they belong to in the periodic table of elements. Zirconium tends to form polymeric species both in aqueous and solvent-based solution chemistry with a clear tendency to form bonds with oxygen. The zirconium compounds are classified as either anionic cationic or neutral. If organic species are involved in a system, it is generally admitted that zirconium will react readily with carboxyl groups rather than oxygenated functions such as an ether compound. They find applications, for example, in the industry of printing inks, lithographic printing plates for which they also contribute to corrosion resistance, aluminum drinking cans and pigment coating, as well as dental coupling agent between enamel polymeric filler. Several mechanisms can be put forward, and they include hydrogen bonding with zirconium as well as reactions with carbonyl functionalities. Titanium complexes on the other hand are believed to interact through surface hydroxyl groups. Other adhesion promoters based on other metals are also available, including one of the earliest known in the field dating from the 1960s and based on a methacrylate-chrome complex (Volan<sup>®</sup>).

### 11.7.2 Other Silicon-Based Coupling Agents

Some other coupling agents more recently highlighted include molecules which are again based on silane chemistry but do not have the same structure as organosilanes. Such an example is the use of cyclic azasilanes in particular in the field of micro-electronics and optoelectronics. The interest resides in a usage for a field in which the presence of water is totally undesirable and allows the avoidance of parasite by-products with the surface of nano-objects. Another reason for which the conventional adhesion promoters cannot be used is the propensity of organosilanes to self-condense or polymerize, inducing the creation of nanoscale domains thus potentially creating disturbances in the system or compromising its properties. For such an application, volatile molecules are needed to be able to use vapor phase deposition, one of the main deposition methods at the nanoscale. Another factor consists into the poor amount of sites functionalized using conventional silanes. If one considers pyrogenic silica, for example, only half at most will be functionalized which is far from desirable. Arkles et al. (2004) have shown the potential of such molecules and synthesized seven of this type with various functionalities on both the silicon and nitrogen atoms, including alkoxy functionalities with either one or two cycles in their structures. Cyclic azasilane molecules have been used to modify fillers with a showing higher bonding efficiency than a linear analogue (Vendamuthu et al.

2002), achieving a high-density monolayer deposit. The authors also concluded that although nitrogen had a catalytic action on bonding, further activity is provided by a ring-opening reaction.

## 11.8 Conclusions

Many parameters can influence the application of organosilane to whichever system is of interest. The major obstacle in their use is often the lack of knowledge of their mechanism as well as their chemistry, and although one would like to be able to pick any molecule and get on with work, this is not truly possible when using silanes. The only true answer is to test the system, coating, or formulation of interest to ascertain which are the optimum conditions to use a silane or even a mixture as is often done for corrosion protection for example or for formulations sometimes on the "of chance" to miss something out!!! However, when chosen carefully, silanes can provide an exceptional primer treatment even more performing than accepted though soon to be redundant surface treatments such as chromium VI based rinses. Testing does not have to always involve complex instrumentation, and often industry will use simple tests to decide on optimum conditions and concentrations. These molecules can find applications in so many domains that a little care and dispersing a few myths is well worth the effort and, hopefully, this work will have helped in achieving this goal.

## Abstract

In this chapter, classification of adhesive and sealant materials is presented. For this purpose, various categories are considered depending on the polymer base (i.e., natural or synthetic), functionality in the polymer “backbone” (i.e., thermoplastic or thermoset), physical forms (i.e., one or multiple components, films), chemical families (i.e., epoxy, silicon), functional types (i.e., structural, hot melt, pressure sensitive, water-base, ultraviolet/electron beam cured, conductive, etc.), and methods of application. The classification covers high-temperature adhesives, sealants, conductive adhesives, nanocomposite adhesives, primers, solvent-activated adhesives, water-activated adhesives, and hybrid adhesives.

## 12.1 Introduction

This chapter aims to provide general information about the structure, properties, and applications of polymers and their composites that are used in the production of adhesives and sealants. The chapter is divided into six parts including: Function; Method of reaction; Physical form; Method of application; Conclusions, and References.

As discussed in earlier reviews, such as those by De Lollis (1980), Shields (1985) and Brinson (1987a, b, c), adhesive and sealant materials are classified using categories based on the nature of the following:

- Polymer base, i.e., natural or synthetic
- Functionality in the polymer “backbone,” i.e., thermoplastic or thermoset
- Physical forms, i.e., one or multiple components, films
- Chemical families, i.e., epoxy, silicon
- Functional types, i.e., structural, hot melt, pressure sensitive, water-base, ultraviolet/electron beam cured, and conductive

In order to be able to describe polymers and their composites which are used in the production of adhesives and sealants, a general classification of engineering polymers need to be considered first. The nature of a polymer defined as a plastic, an elastomer (rubber), or a fiber depends on the strength of its intermolecular bonds and molecular structure. At temperatures above their  $T_g$ , elastomers (rubbers) are typically noncrystalline polymers with weak intermolecular forces. Polymers with moderate intermolecular forces are classified as “plastics” at temperatures below their  $T_g$ ’s. On the other hand, polymers with strong hydrogen bonds and, especially, those with high crystallinity can be made into strong fibers, which are usually used to reinforce elastomers and plastics (Fig. 1). Furthermore, rubbery polymers that are flexible and readily deformable can acquire a reversibly elastic property by a cross-linking process. Many other processes are available to alter or transform the basic structure of a polymeric adhesive to suit a specific design need; e.g., an adhesive’s thermal insulating efficiency can be increased, if necessary, by foaming it with an appropriate cell structure, such as in polyurethane foam adhesives (Klepner and Frisch 1991).

## 12.1.1 Classification of Engineering Polymers

### Thermoplastics

#### High-Performance Thermoplastics

- Polyamides (nylon)
- Polyamide-imide
- Polyarylates
- Polyaryletherketones
- Polyarylsulfones
- Polybenzimidazoles
- Polyetherimides
- Polysulfones

**Fig. 1** Stress–strain behaviors of typical fiber, plastic, and elastomer materials

For example, polyamides are typically applied as one part hot melts but are also available in alcohol base solution. Blending of polyamides with other polymers is frequently used to obtain tack and other required properties. For example, blending of amorphous polypropylene enhances peel adhesion to acrylic and canvas, and blending of phenolic resin produces high peel adhesion to plasticized polyvinyl chloride (PVC), porous materials, and metals.

### Other Thermoplastics

- Acetals
- Acrylics
- Acrylonitrile-butadiene-styrene
- Polycarbonates
- Polyethylene
- Polyethyleneterephthalates
- Polystyrene
- Polyvinylchloride

For example, tackified ethylene-vinyl acetate hot-melts are mostly used in the manufacture of exterior grade plywood, where water resistance is required, as well as in other general wood-bonding applications. They are also used in book binding, carton and case sealing, shoe manufacture, carpet seaming, as well as pressure-sensitive adhesives.

Polyvinyl acetate (PVA), used in emulsion form and sometimes called “white glue” has a glass temperature ( $\sim 28^\circ\text{C}$ ) above room temperature, thus requiring the addition of plasticizers to its formulation. This type of adhesive is typically used in packaging, for bonding paper, book binding, carton sealing, bag seaming, tube winding, cup adhesives, remoistenable adhesives (stamps), and in furniture industry.

Polyvinyl acetals, which are derived from the reaction of polyvinyl alcohol (a by-product of PVA) with formaldehyde, can be applied from solution as a one- or two-part system. Plasticizers (phosphates) can be added to improve their impact strength. These adhesives are typically used in the structural bonding of metals and auto safety glass. Hybrids of polyvinyl acetals with epoxies are used in structural bonding. Hybrids with phenolics (vinyl phenolic) are used in honeycomb manufacture for the aircraft industry, and also in printed circuits.

Higher  $T_g$  acrylic polymers are used for bonding of ceramic tiles, lamination of aluminum foil or plastic films to paper and wood, and in the treatment of textiles. The lower  $T_g$  (tacky) versions of the polymer, where the acrylic component is secondary to the elastomeric-based adhesive component, are used in pressure-sensitive adhesive applications.

Polyvinyl chloride copolymers are typically used in solution form for bonding PVC films to metals, paper, cloth, leather, and also used for foam lamination on plastics. PVC blended with plasticizers are used in automotive industry in adhesive form for bonding inner and outer hood and roof panels, and as a gap-filling adhesive.

## Thermosets

### General-Purpose Thermosets

- Amino
- Phenolics
- Polyesters
- Acrylics

For example, amino-resins are water-based condensation products of formaldehyde in urea or melamine. They are typically used for bonding wood, particle board, and decorative laminates.

Phenolic resins may be blended with elastomers, epoxies, and vinyl acetal resins to obtain versatile hybrid adhesives, especially to increase bond strength at elevated temperatures. Phenolic powders are also used as binding agents between glass and mineral fibers in the manufacture of thermal insulators. Fabrics, mats, and papers can be manufactured in laminate form by impregnating the sheets with a phenolic resin. Multiple layers of these products can be molded into various shapes, such as gears and cams, subsequent to drying. Phenolics are also used as binders in abrasive devices, such as grinding wheels.

Polyester resins can be used as a hot melt adhesive in shoe and textile industries.

Cyanoacrylates and anaerobic adhesives are the cross-linked versions of acrylic-based adhesives, cured by catalyst reactions.

### Engineering Thermosets

- Epoxy
- Polyurethane

For example, one-component isocyanate-terminated polyurethane prepolymers in solution are cured by reaction with moisture in 2–24 h, depending on bond thickness. Carbon dioxide is released during this cure, causing porosity in the bond and making them not suitable for structural adhesive applications. Consequently, they are mainly used in the packaging industry due to compatibility with cellophane, nylon, and polyester. On the other hand, two-component cross-linking urethane adhesives are used as structural adhesives in automotive and construction industries for plastic-to-metal and plastic-to-plastic bonding.

Thermoplastic and aqueous forms of the polyurethane-based adhesives are also available. Thermoplastic polyurethanes are soluble polymers, depending on the starting materials and differing greatly in their degree of crystallinity. For adhesives with high crystallinity, heat activation is required for adequate bonding resulting in high peel strength and high softening temperatures. These types of adhesives are typically used for bonding plastics, rubbers, leather, wood, vinyls, and metals. Aqueous forms of polyurethanes are applied with the use of compounded surfactants.

Epoxies provide good adhesion to a large spectrum of substrates and exhibit low shrinkage, low creep, the ability to formulate at 100% solids, and a large number of co-reactants. For example, its hybrids can be obtained with phenolics, polyamids, and elastomers.

### Specialty Thermosets

- Silicone
- Polyimide

For example, silicone adhesives can cross-link with moisture or with catalyzers, providing high elongation, chemical inertness, and heat resistance. On the other hand, silicones are used more as sealants than as adhesives and can also be prepared as pressure-sensitive adhesives.

### Elastomers (Rubbers)

- EPDM (Ethylene-Propylene)
- Fluorocarbons
- Natural
- Nitrile (Acrylonitrile butadiene)
- Polybutadiene
- Silicon

For example, polychloroprene/neoprene, with the addition of casein, provides adhesives for high-speed laminating of aluminum foil to paper. They are typically used in the automotive and construction industries for plastics-to-wood bonding (Formica), and also used as contact cements in the shoe industry. These adhesives typically crystallize from solution.

Elastomeric adhesives can be prepared by emulsion polymerization of nitrile rubber films. Blending of nitrile emulsions with phenolic resins, casein, and tackifiers produce “latex adhesives.”

Butyl Rubbers are noncrystallizing materials used in pressure-sensitive applications, such as bonding polyethylene tapes to steel pipes.

Styrene butadiene rubber (SBR) is heavily tackified and compounded with fillers, to be used in pressure-sensitive and spray applications, as construction adhesives in bonding plastic tile, panel, and floor adhesives in solution form and also as tire thread adhesives.

### 12.1.2 Man-Made Fibers

- Carbon
- Glass
- Aramid

### 12.1.3 Natural Adhesives

Adhesives are also obtained from natural resources in the following forms:

1. Starch form is basically made of carbohydrates ( $C_6H_{10}O_5$ ), found in many vegetables. When heated in water, starch swells into granules which disperse to a gel form. Modification with tackifying inorganic salts, fillers, and plasticizers is necessary for obtaining useful adhesive forms.

2. Dextrin is derived from starch by hydrolysis and is also marketed as gums. These adhesives are typically used in cellulose-based applications such as tube forming and laminating.

Starch-based adhesives degrade in humid service environments.

3. Protein-based glues typically cure with loss of water and require plasticizers such as glycerol. They are made of the following types: (a) Fish glues usually need glyoxal or formaldehyde addition due to their water solubility. They are compatible with acrylate and other emulsions. (b) Animal hide glues produce good tensile and shear properties in bonded joints. They are typically applied for binding in book and sandpaper production, as well as production of furniture, boxes, and gummed tapes. (c) Casein-based adhesives are often compounded with calcium hydroxide and/or formaldehyde for moisture/water resistance. These types of adhesives are mostly used in bonding wood. (d) Blood glues typically need addition of formaldehyde, manganese, and calcium salts for moisture resistance and have been steadily replaced by phenolic adhesives. They are mainly used in plywood and veneering applications. (e) Soybean adhesives are made of a combination of protein and carbohydrates and form a cross-link structure. They are mostly used in wood bonding.

4. Resins are bitumen (hydrocarbon), shellac, pitch, and drying oils.

5. Natural rubber is an elastomer, which is naturally tacky in dry form. With the use of additional tackifiers it acquires serviceable adhesion to itself and other surfaces. For example, in pressure-sensitive applications, the addition of tackifiers in a 40–60% proportion is usually necessary to increase bond strength. One area of application is in shoe manufacture.

Section 1.1 of this chapter classifies adhesives according to functional types including, structural, hot-melt, pressure sensitive, water-base, ultraviolet/electron beam cured, conductive, high-temperature, and sealant type.

Classification with respect to the methods of reaction is discussed in Sect. 1.2 to include thermosets, thermoplastics, high-temperature adhesives, elastomers, sealants, anaerobics, moisture curing adhesives, and primers.

In section “[Thermoplastics](#),” the physical form of adhesives is used for classification purposes and specific adhesives are discussed for each class of adhesives to provide more insight on adhesive categories including chemical families. This is because, many adhesives have cross-category characteristics, as

already illustrated with some of the above listed adhesive examples. Additional examples are epoxies, which are typically listed as structural adhesives, but are also available in “elastomer-epoxy” forms; high-temperature thermoplastic polyimide adhesives, which are also available in cross-linked forms; silicon, which can be used both as a sealant as well as an adhesive; hot-melt adhesives, which are typical thermoplastic resins, but can also be made into pressure-sensitive adhesives; and adhesives, such as epoxy, which can be used as primers subsequent to modification. Consequently, section “[Thermoplastics](#)” starts with the presentation of thermosets with the important example, epoxy. Structure and properties of epoxy are presented, followed by brief descriptions of “nylon-epoxies” and “elastomer-epoxies”; epoxy applications and comparison with other adhesives follow. Thermoplastics are discussed next with the important example, polyimides. Polyimide chemistry and properties, thermoset versions of polyimides, and polyimide applications are presented next. For the “elastomer” types, the important example of polyurethane is presented. Polyurethane chemistry and properties and its applications are discussed next. For the “sealant” category, silicone is discussed as an important example, providing silicone chemistry and properties, followed by its product forms and applications. For that purpose, “silicone fluids,” “room temperature vulcanizing silicones,” “one-part silicones,” “two-part silicones” and “heat-curable rubber types” are described. Cyanoacrylate adhesives are presented next as an important example of “moisture-curing adhesives.” “Advantages” and “limitations” of the different “functional types” presented in Sect. 1.1 are also discussed in section “[Thermoplastics](#),” with respect to their physical characteristics.

Section “[High-Performance Thermoplastics](#)” discusses common methods of application for various types of adhesives and the conclusions are presented in section “[Other Thermoplastics](#).”

---

## 12.2 Function

Adhesives and sealants are usually designed to have different properties even though they are often formulated using the same type of polymeric materials. Adhesives typically have high tensile and shear strengths. They are used to replace or reinforce mechanical fasteners in load-bearing applications. Sealants, on the other hand, typically have lower strength. They are flexible materials used to prevent the passage of liquids, vapors, gases, and solids. Sealants are also used to protect electronic components in aerospace, automotive, and appliance industries. Acrylics, silicones, urethanes, polysulfides, epoxies, and unsaturated polyesters are the primary sealant materials used in these applications. When vibration resistance and impact strength are required, or when materials with different coefficients of thermal expansion are bonded, a flexible sealant-type material is often the adhesive of choice.

The functionality of adhesives and sealants are generally categorized as follows:

### 12.2.1 Structural Adhesives

Structural adhesives are used to transfer loads between adherends in their service environments. They are typically cross-linked/thermosetting polymers, even though some thermoplastic polymers, such as acrylics, are also used in some structural load transfer applications.

### 12.2.2 Hot-Melt Adhesives

Hot-melt adhesives are 100% solids that include all thermoplastics. Hot-melt adhesives have versatile applications and can be used to bond many types of substrates, including metals, plastics, glass, ceramics, rubbers, and wood, in applications generally not requiring the transfer of high loads as in the case of structural adhesives. Applications include industrial and assembly bonding such as packaging, book bonding, and general household usage.

### 12.2.3 Pressure-Sensitive Adhesives

Pressure-sensitive adhesives (PSAs) are typically used to hold objects together by bringing the surfaces into contact under pressure, applied briefly at room temperature. Natural rubber, styrenebutadiene (SBR), butadiene-acrylonitrile rubber, thermoplastic adhesives, polyacrylates, and silicones are the typical materials used for pressure-sensitive adhesive applications. These materials have viscous properties to provide flow while resisting excessive flow, partial elastic behavior to be able to carry some load, the ability to store energy to provide peel and tack, and the capability to dissipate energy during usage. Tack may be obtained by the use of resinous softeners such as pine tar or rosin esters, by the use of mineral fillers and various coal tar or petroleum derivatives.

PSAs are typically supplied in the form of film, fabric, paper, two-face, electrical, and corrosion protection tapes.

Contact adhesives, which are manufactured using materials similar to the PSAs, typically, require little or no pressure to bond.

### 12.2.4 Water-Base Adhesives

Water-base adhesives are made of materials that can be dissolved or dispersed in water. Both natural (cellulosic, dextrin, starch) and synthetic (phenol formaldehyde, polyvinyl acetate, styrene-butadiene rubber, nitrile rubber) polymer materials are used in manufacturing water-base adhesives. Their primary application is in packaging, with a much smaller percentage usage in construction. Their share of the

market, however, has been increasing due to health concerns associated with some of the solvents used in organic-solvent adhesives.

### 12.2.5 UV/Electron Beam–Curing Adhesives

Specially formulated, 100% reactive liquids can be rapidly converted to solids using radiation curing with the inclusion of a photo initiator. Energy sources used for this purpose include ultraviolet (UV), electron beam (EB), visible (IR), and microwave sources. These adhesives are typically used as coatings, inks, sealants, and potting compounds, as well as for bonding purposes. The main advantage of UV/EB-curable adhesives is rapid curing at room temperature. Therefore, they can be used to bond heat-sensitive substrates, such as polyvinyl chloride. Furthermore, the rapid cure process increases production rates. UV/EB-cured adhesives are typically of the cross-linking type (acrylic acid esters of various forms or combinations of acrylates with aliphatic or aromatic epoxies, urethanes, polyesters, or polyethers) and provide good heat, chemical and abrasion resistance, toughness, dimensional stability, and adhesion to a spectrum of substrates. Unlike thermal curing, with UV/EB curing, the depth of penetration, and consequently, the depth of cure can be controlled, providing a distinct advantage over thermal curing. On the other hand, EB equipment and some UV equipment are expensive.

EB-curable adhesives are used in magnetic tape and floppy disk production to bond magnetic particles to films, as well as in packaging applications, such as tapes and labels. The UV-curable adhesive applications include electronics, automotive, medical, optical, packaging industries, as well as usage in tapes and labels.

### 12.2.6 High-Temperature Adhesives

Service temperature ranges for adhesives can be categorized as follows:

1. Low Temperature (under 121 °C): polyurethanes, polyesters, allyls (diallyl phthalate)
2. Medium Temperature (121–260 °C): epoxies, phenolics, silicones
3. High Temperature (over 260 °C): polyimides, bismaleimides, polybenzimidazoles

Advanced aircraft, space vehicles, satellites, missiles, electronics, and automotive industries often have applications requiring high-performance/high-temperature adhesives. Such adhesives are typically used to join plastics, metals, ceramics, and composites, while usage as insulators and coatings are also needed where adherence to the substrate, rather than the joining of two components, is desired. Applications in the aircraft and aerospace industries typically require bonding metals and composites which will be exposed to temperatures of 260 °C or higher. On the other hand, a high-temperature adhesive for missile applications must

perform at very high temperatures ( $\sim 760^\circ\text{C}$ ) for short periods of time, in the order of seconds. For advanced aircraft applications, however, the adhesive must perform satisfactorily for tens of thousands of hours over the temperature range of  $-54^\circ\text{C}$  to  $260^\circ\text{C}$ . Furthermore, the adhesives must resist degrading effects, such as aircraft fuels, hydraulic fluids, and moisture.

In applications involving orbital vehicles such as satellites and instrument platforms, high-performance/high-temperature adhesives may be expected to endure thermal cycling in the temperature range of  $-160^\circ\text{C}$  to  $125^\circ\text{C}$ . Furthermore, in such applications, the adhesive must resist ionizing radiation, such as radiation from photons, electrons, and ultraviolet rays.

In high-temperature applications, it is desirable to have a good match between the coefficients of thermal expansions for the adhesive and the adherend(s), as well as low moisture absorption, high strength and toughness, and high resistivity and stability in an electric field.

### 12.2.7 Sealants

Sealants are used to fill joints, gaps, and cavities between two or more similar or dissimilar substrates in contrast to adhesives which are used to bond two materials together, and usually with a much thinner bondline. Polymers typically used in sealant applications include silicones, urethanes, polysulfides, solvent acrylic, and butyls. Polysulfides, polyurethanes, and silicones are used more in bonding applications.

Sealants are also used to protect electronic components that are used in aerospace automotive and appliance equipment.

### 12.2.8 Conductive Adhesives

Electrical and/or thermal conductivities are the main requirements in these types of adhesives, and conductive (metallic or metal coated) fillers are used for this purpose. Most fillers that provide electrical conductivity in an adhesive also contribute to its thermal conductivity. On the other hand, thermally conductive adhesives are also available for electrically insulating purposes. Electrically conductive adhesive applications include the attachment of lead wires in hybrid and integrated circuits (dies).

Polymer materials which are most often used to provide electrical and/or thermal conductivity include epoxies, polyurethanes, silicones, and polyimides – epoxies being the most commonly used.

For die attach purposes, filled epoxies and polyimides are usually the adhesives of choice. They seem to meet the material requirement for die attach adhesives including the absence of resin bleed before or after cure, good elevated temperature strength after a short cure period, thermal stability, absence of out-gassing, and the presence of minimum ionic impurities.

Conductive adhesives are generally expensive due to the use of silver, gold, or palladium conductive fillers in high loadings (up to 85 wt%). Silver, either in flake or powder form is used in majority of applications because of its lower cost in comparison to gold or palladium, typically providing  $\sim 0.001 \Omega\text{-cm}$  volume resistivity in epoxy matrix. On the other hand, with silver-filled adhesives, migration of silver to the surface can occur under humid environments with direct current (Sancaktar et al. 2005). Uses of gold or silver-coated copper fillers may alleviate this problem. Other fillers that provide electrical conductivity include nickel, copper, aluminum, and carbon particles.

For thermal conductivity, oxide fillers, such as alumina, can be used. The most commonly used filler for this purpose is alumina (aluminum oxide), which is fairly inexpensive. Alumina fillers can be added to epoxies in amounts as high as 75% by weight to result in thermal conductivities, typically ranging from  $\sim 1.38$  to  $\sim 2.73 \text{ W/m-K}$  ( $\sim 3.31$  to  $\sim 4.13 \times 10^{-3} \text{ cal/cm-s } ^\circ\text{C}$ ).

Adhesives can prevent electrochemical corrosion in joints between dissimilar metals. They may also act to dampen vibrations, thus reducing fatigue failures. Changing a property in an adhesive, such as adding fillers, generally produces change in other properties of the joint, such as tensile or shear strength, elongation or resistance to peel.

## 12.2.9 Nanocomposite Adhesives

With the advent of “nanotechnology,” nanocomposite adhesives are fast appearing for many improved applications in aerospace, automotive, medical, and construction industries. For nanofiber-reinforced styrene-butadiene rubber, Kim and Reneker (1999) reported that the Young’s modulus of the nanofiber composite was tenfold greater than the pure material at 10 phr nanofiber content. On the other hand, information on the mechanical properties of nanofibers and nanofiber composites has so far been limited (Sancaktar and Aussawasathien 2009).

Qian et al. (2000) reported that nanotubes increase the composite strength by as much as 25%. However, multiwall nanotubes (MWNTs) are limited in their applications because of weak inter-shell interaction (Yu et al. 2000). Single-wall carbon nanotubes (SWCNTs) on the other hand are quite expensive and difficult to manufacture. Alternative reinforcement materials for nanocomposites include graphitic carbon nanofibers (GCNFs) and graphite nanoplatelets. GCNFs also have excellent properties and can be used as reinforcements in various kinds of matrices. They offer chemically facile sites that can be functionalized with additives thereby resulting in a strong interfacial bond with the matrix.

Wang et al. (1996, 1998, 2000) report that layered silicate nanolayers can be used as alternative inorganic components for the construction of nanostructured hybrid composites. The clay silicate nanolayers possess stable Si–O bonds and high particle aspect ratios comparable to conventional fibers. Their interlayer surface is easily modified by ion-exchange reaction, and the gallery can be intercalated by organic polymer precursors for the formation of organic–inorganic nanocomposites. The

intercalation chemistry of layered silicate clays plays an important role in the formation of polymer-clay nanocomposites. Exfoliated clay composites contain single,  $\sim 1$  nm thick layers of clay dispersed in the polymer matrix. Owing to the platy morphology of the silicate layers, exfoliated clay nanocomposites can exhibit dramatically improved properties such as barrier and mechanical properties that are not available for conventional composite materials. Wang et al. extended the exfoliation chemistry of smectite clay in an epoxy matrix to include the layered silicate magadiite with a layer thickness of 1.12 nm. The chemistry elucidated for magadiite is likely to be applicable to other members of this mineral family for the formation of polymer-inorganic nanolayer composites.

Previous work by Sancaktar and Kuznicki (2006) also showed reduction in water uptake in nanoclay/epoxy composites, specifically when stressed to stagger the clay layers with the action of strain that squeezed the layers to a smaller interlayer distance, thus producing a more effective barrier against water diffusion into the nanocomposite adhesive. This trend was not observed in the unfilled epoxy system, in which barrier properties were not affected by stressing below the yield point.

Use of nanotubes have been reported by Ge et al. (2007) in enhancing adhesion by “gecko-inspired adhesion” in production of “carbon nanotube-based synthetic gecko tapes,” and by Sethi et al. (2008) in the production of “gecko-inspired carbon nanotube-based self-cleaning adhesives.” More information about nanocomposite adhesives can be found in chapter □ 55.

---

### 12.3 Methods of Reaction

Except for pressure-sensitive adhesives, which undergo no phase change for application, adhesives are typically applied as low-viscosity liquids to wet adherend surfaces and to flow into their crevices and asperities. Liquid forms of adhesives are typically obtained by three methods: (1) heating the solid adhesive to the point of facile flow, (2) dispersing/dissolving the adhesive material in a solvent, and (3) starting with the adhesive material in liquid monomer form which is subsequently polymerized. These liquid forms are subsequently solidified by: (1) cooling, (2) solvent evaporation, and (3) chemical reaction.

Therefore, adhesives can be classified based on the method of “activation” as follows:

- Solvent-activated: These types of adhesives become tacky when wetted with an organic solvent. The presence of an organic solvent, however, may present fire and health hazards.
- Water-activated: These types of adhesives are generally based on polyvinyl alcohol, starch or protein glues.
- Heat-activated non-tacky solids: Adhesives based on rubber, vinyl polymers, phenoxies, cellulose, and PVC may be activated by heat.

- 489 • Hot melts: These adhesives are generally thermoplastic 100% nonvolatile  
490 materials heated to a melt to be applied to the substrates. With these types of  
491 materials, the adhesive bond is primarily mechanical, as achieved after  
492 solidification.
- 493 • Film adhesives: They resemble hot melts and heat-activated adhesives in the  
494 sense that heat is used for activation with a subsequent cure schedule, which may  
495 include additional heat application under pressure. They may contain lightweight  
496 fabrics, nylon, polyester, glass mats in the form of “carrier cloth.” Thus, the  
497 adhesive thickness may be controlled uniformly. Epoxies, phenolics, nitrile-  
498 elastomers, polyamides, PVC, polyvinyl butyl, ethylene-carbolic acid copoly-  
499 mers are available in film form with or without carrier cloths.

500 Additional classification is based on the physical form of the adhesive prior to  
501 application, but not much different than the classification based on activation:

- 502 • Solutions: Adhesives of this type have solid contents varying from 5% to 95%,  
503 with 20–50% being the most common.
- 504 • Adhesive solutions in organic solvents include: acrylics, polyurethanes, poly-  
505 amides, phenoxies, polyvinyl acetate, along with natural rubber and other  
506 elastomers.
- 507 • Adhesive solutions in water include: phenolics, amino-resins, methyl ether,  
508 polyvinyl alcohol, protein-based products such as blood and fish glues.

509 All thermosets which form high molecular weight or molecular network struc-  
510 tures after application fall into the classification of “polymerizing types”:

- 511 • Step-growth polymers: Step-growth polymerization starts with liquid monomers  
512 mixed with catalysts, curing agents, or co-reactive additions for step-growth  
513 polymerization. Condensation polymerization is the most common type of step  
514 reaction. The monomers used in this type of reaction are difunctional, i.e., they  
515 have chemically active group on each end of the molecule. Since polymerization  
516 occurs in consecutive reactions, the degree of polymerization and the average  
517 molecular weight increase as the reaction proceeds. The rate constant for the  
518 reaction is determined by the mobility of the ends of the growing molecule, and  
519 not by its size. High molecular weight is attained only at the very end of the  
520 reaction.
- 521 • Chain growth polymers: Chain or addition polymerization typically involves  
522 opening of a double bond by the action of an initiator thus generating an active  
523 site, which propagates down a growing chain. Three types of active sites can be  
524 used for addition reactions: anionic, cationic, and free radical. Chain growth is a  
525 fast polymerization process, which can be 10,000 times faster in comparison to  
526 the condensation polymerization. Addition polymerization may leave a larger  
527 number of monomers behind, thus resulting in a larger polydispersity in compar-  
528 ison to the step-growth polymerization. Cyanacrylates and anaerobic acrylics fall  
529 into the addition polymerization category.

- Aqueous dispersions: Emulsion polymerization is used to prepare this type of adhesives, mostly made of acrylics, chloroprene, and polyvinyl acetate. High shear dispersion can also be used in the presence of surfactants to obtain water borne formulations, as with polyurethanes, epoxies, silicones, and some elastomers.
- Radiation curable adhesives: Inclusion of a photo initiator in some one-component-type resins allows initiation of cure by ultra-violet or visible light, or by an electron beam.

As seen so far, the most descriptive classification method for adhesives and sealants is by physicochemical nature of the base resin. Thus, methods of reaction for different types of adhesives and sealants can also be summarized as follows:

### 12.3.1 Thermosets

As discussed by Lin and Pearce (1993), thermosetting materials consist of three-dimensional cross-linked networks of infinite or immeasurably high weight molecules. Thermosetting resins cure by cross-linking of reactive low molecular weight oligomers or by cross-linking reaction of high molecular weight polymers with reactive functional groups. Subsequent to such thermosetting cure processes, these resins become infusible, insoluble materials.

### 12.3.2 Thermoplastics

Thermoplastics are high molecular weight (ranging from 10,000 or more to several millions), linear polymers (more or less) that can be redissolved and re-fused.

Thermoplastic materials are capable of being repeatedly softened by an increase in temperature and harden by a decrease in temperature. This transition is marked by a particular glass transition temperature,  $T_g$ , for each (amorphous) polymer. This transition involves physical rather than chemical changes and therefore enables shaping of such polymers into articles by molding or extrusion processes in the softened stage. For crystalline polymers, the crystallization temperature,  $T_{cr}$ , and the melt temperature,  $T_m$ , constitute important thermal parameters defining the formation and the destruction of the crystalline structure.

### 12.3.3 High-Temperature Adhesives

Synthetic organics having aromatic (benzene) and/or heterocyclic rings in the main structure (i.e., imidazoles and substituted imidazoles) are used to produce structural adhesives having high-temperature resistance. These prepolymers have open-ring structures which close upon the application of heat during a condensation reaction,

resulting in a highly cross-linked system. Such high-temperature, structural adhesives are available in liquid and film forms.

High-temperature adhesives, including polyimides and polybenzimidazoles, are high-cost materials. They are typically difficult to handle and require long cure times during which volatiles must be released. Polyimides provide superior performance in long-term strength retention at elevated temperatures. At 260 °C in air, polyimides have higher bond strength than do epoxyphenolics, but strength retention following exposure to water is better with epoxyphenolics. Polybenzimidazoles are stable in air for short term exposure up to 288 °C. Both polyimide and polybenzimidazoles are moisture sensitive. Polyquinoxalanes provide another choice with good peel strength on titanium.

#### 12.3.4 Elastomers

As discussed by Morton (1987) and White (1995), rubbery polymers which are flexible and readily deformable can be made into reversibly elastic by a cross-linking process. Generally, such cross-linking reaction is carried out using sulfur along with “accelerators,” which act through the double bonds in the structural units. Elastomers may crystallize if they have regular structure involving the same repeated structural unit. For example, polyethylene, pure stereoisomeric forms of polybutadiene, polyisoprene, and polyisobutylene all crystallize.

Production of materials containing flexible elastomeric segments bound together by thermoplastic segments in the form of ABA sequence block copolymers, by Shell Development Company under the commercial name, Kraton, resulted in “thermoplastic elastomer” materials. These materials possess melt flow properties similar to thermoplastics along with solid properties resembling vulcanized rubber. For example, plasticized polyvinyl chloride, a partially crystalline material, which dissolves into amorphous regions when solvent is added, possesses elastomeric properties. It is also possible to directly blend elastomers with thermoplastics while the elastomer is vulcanized during the blending process. For example, polypropylene and ethylene-propylene terpolymers (EPDM) can be blended while the EPDM vulcanizes. Regular plastics manufacturing equipment such as extruders are used to process thermoplastic elastomers, rather than the use of rubber processing machinery providing a large advantage in manufacturing.

#### 12.3.5 Sealants

Adhesives and sealants may often have the same type of polymeric material formulations but sealants are usually designed to have different properties. Such properties are determined by the selection of ingredients such as fillers, plasticizers, adhesion promoters, and stabilizers. For example, if silicone polymers are fully cured and cross-linked without additives, they result in a soft polymer with very low tensile strength. Silicones have exceptional thermal stability up to 250 °C and remain

flexible at low temperatures ( $-60^{\circ}\text{C}$ ). Silicones exhibit very low shrinkage upon curing and are available in single-component moisture-cured version (known as room temperature vulcanizing, RTV) or in faster-curing two-component version.

Typically, sealant materials used to protect electronic components in aerospace automotive and appliance equipment are acrylics, silicones, urethanes, polysulfides, epoxies, and unsaturated polyesters. Liquid forms of these materials can be irreversibly converted to the solid form with no significant weight loss. These types of sealing processes are called potting and encapsulating.

Polysulfides can be used as sealants and/or adhesives over a temperature range from  $-57^{\circ}\text{C}$  to  $135^{\circ}\text{C}$ .

For polyurethane adhesives, primer use is recommended for improved durability.

### 12.3.6 Conductive Nanocomposite Adhesives

Submicron-size fillers, including electrospun conducting fibers have large specific surface area and tend to form high interconnecting network. These characteristics are expected to enhance the electrical conduction of polymer-matrix nanocomposites to be manufactured using such fillers (Wei and Sancaktar 1996; Sancaktar and Wei 1996).

Aussawasathien and Sancaktar (2008) showed that when carbon nanofiber (CNF) mats were used to render epoxy resins electrically conductive, the rate of cure reaction for CNF mat-epoxy nanocomposites was higher than that for the neat epoxy resin at low curing temperatures, due to the high aspect ratio, high interconnecting network and high thermal conductivity of CNF mats. Compared with the neat epoxy resin, the presence of nonwoven CNF mat in composite form enhanced the cure reaction in terms of residual heat, heat flow rate, reaction rate, and conversion at the initial stages of cure for given cure temperature and time conditions. The full cure of CNF mat-epoxy composites could be achieved at shorter times for given cure temperatures, in comparison to neat epoxy. However, at high CNF mat loading, the cure reaction was retarded since the amount of epoxy and hardener decreased at high CNF's weight fractions when combined with the hindering effect of the CNF mat to the diffusion of epoxy resin and curing agent, leading to low cross-linking density. The cure kinetics of CNF mat-epoxy nanocomposites could be predicted well by curve fitting with Kamal's model (1974).

Zhou and Sancaktar (2008) observed that incorporation of Ni nanopowders in an epoxy suspension resulted in a stable capillary flow at 75 wt% of Ni. Occurrence of agglomerates, however, somewhat nullified this advantage.

### 12.3.7 Other Types of Adhesives

Adhesives which have unique cure mechanisms and applications can be considered under this category.

### **Anaerobic Adhesives**

These types of adhesives remain fluid in the presence of oxygen but cure to solids in its absence. The simplest anaerobic adhesive consists of dimethyl acrylate ester with the peroxide catalyst system and accelerator. They cure by free-radical polymerization in the absence of oxygen. Anaerobic adhesives have strength characteristics equivalent to those of the structural adhesives. One-part anaerobic adhesives cure at room temperature in several hours, but their cure can be accelerated to minutes by high-temperature cure and by the use of certain primers/accelerators. Such elevated temperature, primer/accelerator-assisted cure is especially recommended when anaerobic adhesives are used on inactive surfaces, such as unclean metals or plastics, or inhibiting surfaces such as plated surfaces, chromates, oxides, and anodized surfaces.

### **Moisture Curing Adhesives**

These types of adhesives cure in the presence of moisture. For example, cyanoacrylates cure in an extremely short period (typically 10–15 s) if confined in a thin film between close-fitting parts. The mechanism of cure is an anionic polymerization induced by the presence of a base. A thin film of moisture usually present on bonding surfaces and exposure to normal atmosphere is generally sufficient to harden these materials if they are squeezed to a thin film. Methyl cyanoacrylates provide high strength when bonding rigid substrates such as metals. Ethyl cyanoacrylates, on the other hand, provide durability and high strength in bonding plastics and rubbers. Certain types of polyurethanes and silicones also cure in the presence of moisture.

### **Inorganic Adhesives**

This class of adhesives mostly includes soluble silicates and zirconia. Silicate-based adhesives are typically modified by adding clays to reduce shrinkage, protein glues for water resistance, starch for thickening, surfactants as wetting agents and humectants to increase tackiness and to increase application time. These types of adhesives are used for bonding paper, wood, glass, and metal. Refractory types are used for high-temperature applications involving 1000 °C or higher. They are based on mixtures of soluble zirconia or mixtures of silicates with sand, silicon carbides, clays, and other inorganic salts and oxides. Inorganic adhesives are also available for dental applications in combinations of silicates with zinc phosphates.

## **12.3.8 Primers**

High surface energy adherends such as metals, glasses, and ceramics with tendencies for chemical reactions which can replace existing chemical bonds with adhesives (i.e., hydration, oxidation) are recommended for primer applications prior to bonding. Primers are expected to interact between the substrate and the adhesive by having chemical features which provide chemical bonding for improved adhesion. Thus, primers serve several functions in adhesive bonding, principally by improving

adhesion displayed by improvement in shear, peel, and tension. They are typically applied as thin films on the substrates prior to bonding and are not expected to have high cohesive strength in bulk form. Their function is mainly by chemical bonding in the thin film form, with physical effects such as surface tension and dipole interactions taking the center stage. Thus, primers commonly used as metal surface conditioners mainly serve as adhesion promoters and surface protectors.

Primers used in structural bonding are typically composed of the following five types of materials: (1) resin, (2) curing agent, (3) film former (to promote the integrity of the film by improving the wetting of the primer), (4) corrosion inhibitor, and (5) solvent carrier.

Primers used for surface protection in structural bonding are essentially adhesives in solution. They protect the adherend from contamination or from changes in adherend surface chemistry between the cleaning/surface treatment and the bonding operations. Therefore, the base chemistry of a primer system is often the same as that of the adhesive to be used for bonding and, commonly, it is a one-part system in an organic solvent, usually at low solids content. There are a number of primers that are thermosetting types, in solution with low solid levels. Some of these are two-part and applied similarly, but have limited working life after mixing. Their cure may be accomplished at ambient or elevated temperatures.

---

## 12.4 Chemical Families and Physical Forms

### 12.4.1 Thermosets

Thermosetting adhesives are typically available in liquid, paste, and solid forms. The liquid form is generally one- or two-part system which may contain solid fillers and colorants. The paste form typically exhibits flow behavior different from those of the unfilled or highly filled liquids. Certain pastes are modified to be thixotropic, which are gel-like materials at rest but act as fluid when agitated. Possession of such solid-like yielding behavior allows an unstrained mass of adhesive not to sag or flow unless forced to do so by mechanical action, such as by spreading with a spatula.

Thermoset materials either exist or are converted to liquids of low molecular weight at early stage in their application. They are subsequently cured by heat and/or chemical catalysts, attaining very high molecular weight and a three-dimensional structure. They have outstanding mechanical strength, and thus used as structural adhesives. They do not easily solvate; have low creep and survive in temperature environments moderately above their cure temperatures.

Cross-linking of thermoplastics such as rubbers or vinyl polymers also yield rigid thermoset materials.

Thermosetting adhesives are also available in film form of various thicknesses. These films may be provided in composite reinforced form as supported by synthetic, woven or nonwoven fabrics of nylon, polyesters, etc. Such films are flexible and their drape ability allows them to conform to a particular joint subsequent to cutting or punching to shapes. Film adhesives are typically supplied containing

latent hardeners which are dormant at low temperatures but become active and initiate cure when brought to cure temperature. Refrigeration increases storage life for this type of adhesive.

### **Important Thermosets: Epoxies**

Epoxy adhesives are the most important and versatile of the structural adhesives family. As thermosetting, cross-linked resins, they are strong and brittle, but they can be formulated to be flexible and/or tough without loss of tensile strength by a variety of procedures, including nitrile rubber or thermoplastic toughening, cure control, and solvent addition. Epoxy adhesives are successfully used to bond a variety of substrates, and can be formulated to cure at a range of temperatures: room temperature and higher, and under dry or wet conditions. Service temperature range is  $-55$ – $121$  °C, but temperatures up to  $260$  °C can be tolerated for short periods.

### **Epoxy Polymer Structure**

The main component of epoxy resins is the epoxy or oxirane group which is converted into three-dimensional structures by a variety of curing reactions. In the synthesis of epoxies, the liquid resins are typically obtained by using an excess of epichlorohydrin with respect to bisphenol A in the presence of sodium hydroxide as shown in Fig. 2.

### **Epoxy and Cure Agent Properties**

A two-component epoxy system consists of a resin and a hardener, along with possible additives such as accelerators, reactive diluents, resin modifiers, plasticizers, and fillers. Typical hardeners include aliphatic polyamines, which cure at room temperature or at slightly elevated temperatures; polyamides, which provide flexibility and are widely used; aromatics, which are solid; and anhydrides, which require elevated temperature cure and produce thermally stable but brittle adhesives. Low molecular weight epoxies are liquid and are usually cured by amines, carboxylic acid anhydrides, and Lewis acid and base catalyst. Higher molecular weight epoxies are cured through their hydroxyl groups. Cure of epoxies involves an exothermic reaction.

### **Nylon-Epoxies**

Nylon-epoxy is typically used in film and tape adhesive applications and has maximum service temperature of  $\sim 138$  °C, compared with  $177$  °C for unmodified epoxies. The addition of nylon provides increased flexibility and peel strength compared to unmodified epoxies. Nylon-epoxy is a tough material with excellent tensile lap shear strength and good fatigue and impact resistance. However, the addition of nylon results in deterioration in creep resistance and poor peel strength at low temperatures. Furthermore, the hydrophilic nature of nylon imparts poor moisture resistance in both uncured and cured forms of the resin. Consequently, nylon-epoxies are not as durable as elastomer-epoxies or other thermoplastic modified epoxies.

**Fig. 2** Synthesis of diglycidyl ether of bisphenol A (epoxy)

## **Elastomer-Epoxies**

Elastomer-epoxies are prepared mostly by nitrile rubber addition as the elastomeric component and are usually called “modified” or “toughened” epoxy. The bond strengths of elastomer-epoxies are lower in comparison to those of nylon epoxies. Their durability with respect to moisture resistance is better, but not as good as those of vinyl phenolics or nitrile-phenolics. A wide application is in films and tapes. Elastomer-epoxies typically cure at low pressures and temperatures, and over short cure periods, by adding a catalyst to the adhesive formulation.

## **Epoxy Applications**

Epoxies are typically used as adhesives, in coatings, composites, in electrical and electronic applications, and building materials, and civil engineering applications.

The wide usage of epoxies in coatings is due to their excellent adhesion, toughness, and corrosion and chemical resistance. The second wide usage of epoxies is as encapsulating materials for electrical and electronic devices.

Reinforced epoxy adhesives provide high strength and desired thermal and electrical properties. For example, fiber reinforcement, such as glass, carbon, and aramid fiber reinforcements, provide higher mechanical properties and render epoxies suitable for many versatile structural applications. Addition of powdered metal fillers provides electrical/thermal conductivity; alumina fillers provide thermal conductivity; mica provides electrical resistance; silica and calcium carbonate provide cost reduction; and graphite powders provide low friction. Silver-coated glass spheres can be used to replace the expensive silver powder to provide electrical conductivity in epoxy systems. Furthermore, the use of fillers can also serve to raise  $T_g$ , increase the thermal conductivity and thermal resistance of the composite, and to reduce shrinkage. The rheological behavior, and thus, the wetting/spreading behavior, pore penetration, and the yield behavior of the filled resin depends on the amount and the type of filler used.

Epoxy resins see large applicability in the aerospace and defense sector for a large number of structural applications as adhesives, as coatings, and in composite forms. Epoxies are used in composite manufacture and repair, missile manufacture, and bonding of aluminum skins to the aircraft body.

## **Comparison of Epoxy with Other Adhesives**

Unsaturated polyester resins provide properties somewhat competitive with the thermosetting epoxies, and are widely used for composite applications because of their low cost.

Vinyl esters are derivatives of epoxy resins and provide improved thermal performance and chemical resistance over the standard unsaturated polyester adhesives.

Phenolic adhesives provide better thermal resistance in comparison to epoxy adhesives, but require elevated temperature cure, while epoxies can be cured at room temperature. Phenolics produce volatiles during cure. Silicones also have thermal resistance characteristics similar to those offered by phenolics compared with epoxies.

Cyanoacrylates and acrylics provide fast cure and good strengths in comparison with epoxies, but they cost more.

## 12.4.2 Thermoplastics

Thermoplastic polymers are available in various molecular weight ranges with varying melt viscosity values. Their tensile modulus and strength values and impact resistance also exhibit a wide variation. Softening points are in the 100–200 °C range, and application times are 15–90 s.

Thermoplastic adhesives are typically available in liquid and solid forms similar to the thermosets, except for the paste form. In the liquid form, a solution and/or dispersion of the base thermoplastic polymer and other compounding ingredients are used.

Some widely used thermoplastic adhesives are polyvinyl acetate, polyurethane, polyamides, and aromatic polyamides.

### Important Thermoplastics: Polyimides

Fully imidized aromatic thermoplastic polyimides (TPI) are linear polymers with good thermomechanical performance, used in high-temperature (>230 °C) applications. PIs based on aromatic diamines and dianhydrides exhibit excellent heat resistance. In addition to their outstanding high-temperature resistance (Sancaktar et al. 1984; Sancaktar and Schenck 1985; Sancaktar and Dembosky 1986), toughness and good dielectric properties, low flammability, and high radiation resistance are desirable characteristics for this class of adhesives.

### Polyimide Chemistry and Properties

Aromatic TPIs are typically produced by condensation reaction of aromatic dianhydrides with aromatic diamines or aromatic diisocyanates (Fig. 3). An important advantage of the TPIs over their thermoset counterparts is that no further chemical reactions occur during their processing.

### Thermoset Versions of Polyimide Adhesives

Linear TPI materials are increasingly used in various fields, including advanced composites applications, in which both resistance to high-temperature environments and good mechanical performance are required. There are, however, serious

**Fig. 3** General structure of aromatic TPI materials

limitations with linear aromatic, condensation type TPIs, as they are difficult to process, typically requiring high temperatures (315–400 °C) and high pressures. They also degrade easily by solvents. Because of these limitations, addition type TPI's with monomeric or oligomeric imide compounds containing reactive end groups (maleimide, norbornene, acetylene) are cross-linked by curing process and offered as an improved version of the linear thermoplastic TPIs. Compared to the high molecular weight linear PIs, these adhesives are comparatively easy to manufacture by melt or solution processes, thanks to their low molecular weights. The asymmetric diaminophenylindane isomeric mixture is incorporated in the PI backbone as shown in Fig. 4.

### Polyimide Applications

PIs are finding increased use in aerospace and automotive applications as structural adhesives due to their excellent mechanical property retention at elevated temperatures. Another major area of PI usage is the electronics/electronics industry. They are used as thermal and electrical insulators due to their excellent hard radiation resistance and good insulation characteristics.

### 12.4.3 Elastomers

Elastomers are polymers with rubberlike properties. The word “elastic” refers to the ability of a material to return to its original dimensions when unloaded, and the term “mer” refers to the polymeric molecular make up in the word “elastomer.” Vulcanized rubber materials typically have more than 200% elongation in a tensile test and are capable of returning rapidly and forcibly to their original dimensions when load is removed. This elastic response is due to the three-dimensional cross-linked network molecular structure they have. An elastomer, on the other hand, typically has elongation rates of 100% or more and a significant amount of resilience. Resilience is represented by the area under the elastic portion of the stress–strain curve, and therefore, refers to a material's ability to undergo elastic deformations.

### Important Elastomer Adhesives: Polyurethanes

As discussed by Woods (1990), polyurethane resin systems are usually formed by addition polymerization involving the reaction between alcohols with two or more reactive hydroxyl groups per molecule (polyol or diols) and isocyanates that have

**Fig. 4** A typical structure in which the asymmetric diaminophenylindane isomeric mixture is incorporated in the PI backbone

more than one reactive isocyanate group per molecule (a diisocyanate or polyisocyanate).

### Polyurethane Chemistry and Properties

Polyurethane is produced by the reaction of isocyanate group ( $-\text{N}=\text{C}=\text{O}$ ) with hydroxyl groups as shown in Fig. 5.

All polyurethanes are based on toluene diisocyanate (TDI) and polymethylene diphenylene isocyanate (PMDI). MDI is produced from aniline and formaldehyde, reacted together using hydrochloric acid as a catalyst, under a condensation reaction producing a complex mixture of polyamines, which are phosgenated to obtain a polyisocyanate mixture. The polymeric MDI product is mainly used for rigid foam manufacture. The polyisocyanate mixtures can be formulated to possess a range of differing functionalities, which are the average number of chemically reactive groups on each individual molecule. The polyol structure also plays an important role in determining the final urethane properties. The size and flexibility of polyol molecular structure and its functionality (i.e., the number of isocyanate-reactive hydroxyl groups per molecule of polyol) controls the degree of cross-linking achieved in the polymer formed by the reaction with the polyisocyanate. The degree of cross-linking has a dominant effect on the stiffness of the polymer. In order to obtain a more flexible polymer, a proportionally lesser degree of cross-linking is needed. The “hydroxyl value” is used as a measure of the concentration of isocyanate-reactive hydroxyl groups per unit weight of the polyol, and it is related to molecular weight and functionality of the polyol.

Moisture-curing polyurethane coatings can be produced by mixing polyisocyanate and solvent while excluding moisture. A moisture scavenger, such as paratoluene sulfonyl isocyanate (pTSI) can also be added during this stage along with polyol and other additives for the mixture to be stored in a dry, airtight container.

### Polyurethane Applications

Polyurethane is supplied in elastomer form, as flexible and rigid forms and as a liquid for coatings, adhesives, binders, sizing fibers, sealant, and biomedical applications. The elastomer form of polyurethane can be used for applications requiring high toughness and resistance to tear and abrasion and for high impact and flexibility characteristics under cold temperature. Applications include flexible and wear-resistant coatings on textiles, floors, and outer skins of aircraft, as adhesives, and

**Fig. 5** Reaction of isocyanate group ( $-\text{N}=\text{C}=\text{O}$ ) with hydroxyl groups for polyurethane production

in paints. They are also widely used as finishes on automobiles. Polyurethanes in coating form are generally based on TDI formulation.

#### 12.4.4 Sealants

Typically, adhesives have high tensile and shear strengths and are used to replace or reinforce mechanical fasteners in load-bearing applications. Sealants, on the other hand, typically have lower strength. They are flexible materials that are used as barrier to the passage of liquids, vapors, gases, and solids. When vibration resistance and impact strength are required or when materials with widely differing thermal coefficients of thermal expansion need to be bonded, a flexible sealant type material is often the adhesive of choice. Application size and complexity, function of the structure, movement capability of sealant, cost, and life expectancy play an important role in sealant selection.

##### Important Sealants: Silicones

The chemical structure of silicon is different from that of carbon-backbone-based (organic) polymers with C–C repeat units. Specifically, the polymer chain backbone consists of repeat units shown in Fig. 6.

The Si–O bond is stronger and more flexible than the C–C or the C = C bond. Thus, silicon polymers are physically stronger and more flexible than typical organic polymers. Furthermore, silicone possesses rubber elasticity due to its organic functionality allowing limited cross-linking between polymer chains.

##### Silicone Chemistry and Properties

Most commercial silicones are made from a chloro-alkyl, a silicon-metal, and a catalyst and/or pressure. This reaction produces low molecular weight silanes and linear and cyclic siloxane as intermediates products. Silanes are widely used as adhesion promoters in organic and inorganic polymers, adhesion primers, coupling agents for custom reaction syntheses, and coupling agents to promote bonding of fillers to polymer matrices in composite materials. Silicones are typically formulated to provide a three-dimensional network of siloxane. Hydrocarbon radicals such as methyl, phenyl, vinyl, fluoro, amino, hydroxy, ethoxy, and other organic groups are attached to the silicon atom under heat, frequently combined with the action of metal catalysts, such as tin or platinum compounds, to condense the polymer into a rigid thermoset material. Use of functional vinyl improves compression set resistance and provides higher cross-linking density. Use of functional fluoro increases chemical and ozone resistance and provides higher temperature resistance. It also decreases

**Fig. 6** Silicone polymer chain backbone

polymer opacity by preventing haze-causing crystallinity with increased steric hindrance along the polymer chains. Silicon can also be synthetically polymerized with starting materials of quartz (sand) and chlorine and an organometallic reagent.

Silicons have excellent thermal and oxidative stability at high temperatures, up to 260 °C, and remain flexible at temperatures down to -75 °C. They possess excellent electrical properties, including resistance to corona breakdown. They exhibit general inertness, exhibited as resistance to weathering, ozone, and many chemicals and also exhibit general noncorrosiveness to other materials, with the exception of some construction adhesives in contact with ferrous alloys in closed, moist environments. They are inherently nonflammable and have self-extinguishing properties. Silicons exhibit lubricity and other unusual surface properties, such as low surface tension of the fluid resin, and the capability of preventing other materials from sticking, as well as very low water absorption. Even though its tensile strength is lower than most organic rubbers at room temperature, silicon rubber has higher tensile strength than most organic polymers at 204 °C.

### **Silicone Product Forms and Applications**

Silicon fluids: Methylsilicone fluid is the most common product, with relatively constant viscosity over a range of temperatures and it exhibits shear stability with high pumping pressure. Industrial applications of silicon fluids include uses in fermentation adhesives, and sealant manufacturing.

Room temperature vulcanizing (RTV) type: RTV silicon rubbers are used as one- and two-part adhesives and sealants. Applications include bonding of metals, polymers, and ceramic substrates, as well as formation of sealant barriers against liquids and certain vapors. RTV rubber cures by either a condensation or an addition reaction. In the condensation cure, the basic polymer is a silicon fluid in either one-part or two-part form. Vulcanization chemistry of RTV materials must be kept in mind during material selection since some condensation cure reactions release acetic acid and ammonia vapors which can be corrosive. Alternatively, natural-curing RTV materials are available with alcohol, oxime, platinum, and tin vulcanizate reactions. Rheologically, RTV materials range from a flowable, pourable consistency to the thixotropic paste form.

One-part type: For one-part-type silicones, both the catalyst and the cross-linking agent are incorporated in the base compound at the time of manufacture, which involves compounding a silanol-stopped silicone polymer with an excess of cross-linker. The one-component silicones typically cure with moisture. Exposure to atmospheric moisture causes further curing of the silicone rubber to take place. Diffusion of moisture into the rubber progresses vulcanization from the surface inward. One-part component type silicones are excellent adhesive sealants and can be formed in place as gaskets. They can also be used to form films by solvent dispersion.

Two-part type: As for one-part-type silicones, both the catalyst and the cross-linking agent are incorporated in the base compound just before use. They are generally silanol polymers, cross-linked with alkoxy silane or oligomers and organic

tin compound catalyst. Two-part-component-type silicones are typically used for applications in coatings, adhesives, and encapsulants.

Heat-curable rubber (HeR): These are typically silicon rubber compounded with catalyst, color, and additives mixed and milled into siloxane polymers. HCRs are often used in molded parts for high-temperature service or in applications that utilize their chemical and weathering resistance, but also see applications as seals and gaskets.

#### 12.4.5 Important Moisture Curing Adhesives: Cyanoacrylate Adhesives

Cyanoacrylate adhesives are single-part, solvent-free polymerizable adhesives. They start to cure within seconds by adsorbed moisture or by alkaline sites on the substrate, which can be nearly any solid or semisolid material. They have the advantage that no by-products are released during cure.

##### Cyanoacrylate Chemistry, Properties and Applications

The general structure of cyanoacrylate esters is:  $\text{H}_2\text{C} = \text{C}(\text{CN})(\text{COOR})$ . Most cyanoacrylate adhesives are based on either methyl-2-cyanoacrylate or ethyl-2-cyanoacrylates. Methyl cyanoacrylates yield better strengths when bonding metals or other rigid surfaces. In addition, impact resistance is slightly better. Ethyl cyanoacrylates are stronger and more durable when bonding rubber or plastic substrates.

In general, cyanoacrylates cure rapidly at room temperature, and exhibit excellent tensile strength and good shelf life. They have long pot life and good adhesion to metal. Limitations include high cost, poor peel strength, brittleness, limited elevated-temperature properties, and capability to fill only small gaps. Substrates need to be mated as quickly as possible to reduce the possibility of contamination and premature cure or vapors. Cyanoacrylate bonds are typically capable of withstanding long-term exposure to temperatures up to  $82^\circ\text{C}$  and can maintain their strength at temperatures as low as  $-54^\circ\text{C}$ .

The cured cyanoacrylate adhesives are brittle, high tensile polymers. These polymers show strong adhesion to metals, plastics, rubber materials, and wood. Initial strength of bonds between these materials is often higher than the strength of material itself. Cyanoacrylate adhesive bonds are typically durable, and bonds often show no significant change in strength over a period of years, under ambient indoor conditions.

#### 12.4.6 Conductive Adhesives

It is well known that metallic materials are excellent conducting fillers commonly used for improving the electrical properties of polymer composites, when included above their percolation threshold. A large portion of such applications include electrically conductive adhesives as illustrated by Sancaktar and Dilsiz (1997,

1014 1999a, b), Wei and Sancaktar (1996), Sancaktar and Wei (1996), and Sancaktar  
1015 et al. (1996).

1016 Metal-coated nonconductive or low-conduction fillers can also be used to induce  
1017 electrical conductivity in polymer composites. Dilsiz et al. (1997) coated spindle-  
1018 type hematite and magnetite particles and nickel filaments with silver by using  
1019 chemical reduction. The concentration of the reactants, the reaction time, and the  
1020 type of reducing agent greatly influenced the morphology of the silver coating and  
1021 the conductivity of the coated particles.

1022 Submicron-size fillers, including electrospun conducting fibers have large spe-  
1023 cific surface area and tend to form high interconnecting network. These character-  
1024 istics are expected to enhance the mechanical properties of polymer-matrix  
1025 nanocomposites to be manufactured using such fillers (Sancaktar and  
1026 Aussawasathien 2009; Sancaktar et al. 1996; Sancaktar and Zhang 1990).

## 1027 12.4.7 Physical Characteristics of Various Types of Adhesives

### 1028 Structural

1029 These are mostly one- or two-component thermosetting resins. They can be cured at  
1030 room or elevated temperatures. Joints bonded with these adhesives can be stressed to  
1031 a high proportion of maximum failure load under service environment.

- 1032 • Advantages: Resistance to elevated temperatures, solvents, and creep.
- 1033 • Limitations: Two-component systems require careful metering and mixing. Some  
1034 types are difficult to remove and repair, have poor peel strength, require heat to  
1035 cure, and some produce hazardous products during cure.

### 1036 Hot Melt

1037 These are typically 100% solids, rapid setting thermoplastics, which do not require  
1038 cure. They are typically compounded with additives for tack and wettability, and can  
1039 be produced into pressure-sensitive forms. They abruptly melt into a low-viscosity  
1040 liquid, which can be applied to substrate surfaces. Consequently, melt viscosity is an  
1041 important consideration with these types of adhesives.

- 1042 • Advantages: They require no solvents (100% solids), exhibit fast bond formation,  
1043 gap-filling capability, barrier properties, and wide deformability range.
- 1044 • Limitations: Thermoplastic properties, resulting in limited elevated temperature  
1045 resistance, poor creep resistance, limited penetration to substrate due to fast  
1046 viscosity increase upon cooling, and limited toughness with solid viscosity.

### 1047 Pressure Sensitive

1048 These adhesives are typically used to hold substrates together after brief application  
1049 of moderate (manual) pressure at room temperature. They are typically available in  
1050 organic solvent-base, water-base, or hot melt forms. They are primarily used in tapes  
1051 and labels, as well as in medical applications.

- 1052 • Advantages: They are easy to apply, have uniform thickness, permanent tack at  
1053 room temperature, and no activation is required by heat, water, or solvents.
- 1054 • Limitations: They are largely based on rubbers, requiring compounding; they  
1055 have limited heat resistance and poor gap-filling ability.

### 1056 **Water-Base**

1057 These include adhesives dissolved or dispersed (latex) in water. The water solvent  
1058 needs to be absorbed or evaporated for bonding. On nonporous substrates, water  
1059 must be removed prior to bonding. They are mostly used in non-pressure-sensitive  
1060 applications, but pressure-sensitive forms are also available.

- 1061 • Advantages: They have low cost, long shelf life, good solvent resistance, and are  
1062 nonflammable high molecular weight dispersions with high solids content and  
1063 low viscosity.
- 1064 • Limitations: They are slow drying, have limited heat resistance, poor creep and  
1065 water resistance. They exhibit shrinkage with certain substrates in supported films  
1066 and tapes and have tendency to freeze.

### 1067 **UV/Electron Beam Curing**

1068 These are typically 100% reactive liquids cured to solids. One substrate must be  
1069 transparent for UV cure, except when used in coating applications. Absorption  
1070 coefficient of the top substrate material affects penetration of the UV/EB irradiation.  
1071 Curable formulations are used in laminating, PSA, and some medical applications.

- 1072 • Advantages: They cure fast (2–60 s), require no mixing and contain no solvents.  
1073 They are typically one component liquids, yield high tensile strengths and have  
1074 the ability to bond heat-sensitive substrates at high production rates.
- 1075 • Limitations: They need expensive processing equipment, have high material cost,  
1076 limitation of UV transparent substrates. They possess application difficulties on  
1077 parts with complex shapes and the possibility of continued curing when exposed  
1078 to UV rays (sun exposure) may render them excessively brittle.

---

## 1079 **12.5 Methods of Application**

1080 The method of application for adhesives depends on several factors, including: the  
1081 type and rheological characteristics of the adhesive used, whether it is one- or  
1082 two-part type, the geometry of the parts to be bonded and the rate of their assembly.

1083 In many cases, manual application is employed with the use of: spatulas, squeeze  
1084 bottles, tubes, rollers, brush, mechanically fed brushes, and glue guns.

- 1085 • Applications requiring speed and/or precision over large flat areas utilize roll  
1086 contact.

- 1087 • One-part liquid adhesives can be applied by atomization using air or airless  
1088 spraying.
- 1089 • Two-part adhesives must be metered or mixed first.
- 1090 • Robotic applications have also become popular in many industries.

### 1091 **12.5.1 Thermosets**

1092 Small quantities are typically hand-mixed for two-part types, and heat-cured  
1093 versions are typically delivered directly from tubes or cartridges. For industrial  
1094 applications involving two-part forms, metering and mixing equipment are used.

1095 Since heat and pressure need to be used in advanced aircraft/spacecraft, military  
1096 etc., applications, usually involving long-fiber composite substrates, special auto-  
1097 clones or vacuum bag techniques are used.

### 1098 **12.5.2 Thermoplastics**

1099 Thermoplastic adhesives are available in liquid or solid forms. In liquid form, they  
1100 are dissolved and/or dispersed in solvent, which needs to be evaporated to obtain the  
1101 solid form of the resin and, consequently, proper bonding.

1102 In solid form, thermoplastic adhesives are available as unsupported or  
1103 supported films, granules, and in lengths of extruded, flexible, cordlike materials.  
1104 The fluid form is obtained for bonding by either solvent or heat activation. Heat  
1105 activation requires substrates which can withstand the required temperatures.  
1106 If the resin compound also contains a thermosetting resin, heat application  
1107 is continued to cross-link it. Solvent activation, on the other hand, requires  
1108 substrates to permit the release of the solvent by diffusion if the bonding area is  
1109 large.

### 1110 **Hot-Melt Adhesives**

1111 Thermoplastic adhesives which are applied in viscous fluid form obtained by heating  
1112 are called hot melt adhesives. They, typically, do not contain any heat-reacting resin  
1113 and are especially suitable for use with high-speed application machinery. Hot-melt  
1114 adhesives are frequently modified with plasticizers, tackifiers, antioxidants, and  
1115 fillers.

1116 In general, hot-melt adhesives are in solid form at temperatures below 79 °C,  
1117 and as the temperature is increased beyond this point, the solid adhesive material  
1118 rapidly melts to a relatively low-viscosity fluid that can be applied easily. Upon  
1119 cooling, the adhesive solidifies rapidly. Since these adhesives are thermoplastics,  
1120 the melting/resolidification process is repeatable with subsequent heating/  
1121 cooling cycles. Consequently, these adhesives allow reworking of the bonded  
1122 parts, when necessary. Typical application temperatures of hot-melt adhesives are  
1123 149–188 °C.

### 1124 **12.5.3 High-Temperature Adhesives**

1125 High-performance/high-temperature adhesives are developed, formulated, and  
1126 applied according to their specific applications. For example an adhesive used to  
1127 join honeycomb structure to face sheets has flow requirements that are different from  
1128 one designed for metal-to-metal bonding. In honeycomb structures, the adhesive  
1129 must flow sufficiently to form fillets at the honey comb cell/face sheet boundaries  
1130 under relatively mild pressures.

### 1131 **12.5.4 Water-Base Adhesives**

1132 When water-base adhesives are applied to a substrate, they simply set upon removal  
1133 of water. Some water-base adhesives (rubber-based adhesives) can be vulcanized or  
1134 cross-linked by the application of heat or by activation provided by catalyst.

### 1135 **12.5.5 UV/Electron Beam Curing Adhesives**

1136 Most UV/EB adhesives are based on an addition polymerization curing mechanism.  
1137 Materials consist of acrylic acid esters of various forms or combinations of acrylates  
1138 with aliphatic or aromatic epoxies, urethanes, polyesters, or polyethers.

### 1139 **12.5.6 Sealants**

1140 All sealants used for electrical encapsulation or joint sealing purposes must fill a  
1141 specific space to create a seal, form a barrier impervious to fluid flow, and maintain  
1142 the seal in operating environments.

1143 An important sealing application utilizes techniques known as potting and encaps-  
1144 ulating to protect electrical/electronic devices and components from the environ-  
1145 ment, to allow the heat generated by the device to dissipate and, sometimes, to mount  
1146 these devices/components. In these techniques, the liquid forms of sealant materials  
1147 are converted irreversibly to solids with no significant weight loss. Potting involves  
1148 placing a device or component in a container, or pot. The container is then filled with  
1149 potting sealant material, which becomes the exterior wear surface of the component  
1150 or device. Encapsulation involves protecting an electronic or electrical device or  
1151 component with a sealant which forms a thick protective envelope around it.

### 1152 **12.5.7 Conductive Adhesives**

1153 Zhou and Sancaktar (2008) observed polymer binder migration under static pressure  
1154 for epoxy-based conductive adhesives with 50 wt% of etched Ni flake particles,  
1155 during cure. Such binder migration led to unstable flow and electrical conductivity

1156 gradients after extrusion. Lower resin viscosity and shear rates facilitated the flow  
1157 instability and filtering of polymeric binder during dynamic capillary flow of epoxy/  
1158 Ni suspensions with 75 wt% of Ni, thus leading to a change in the bulk electrical  
1159 conductivity during processing. As the shear rate increased, the average plunger  
1160 force and force oscillation frequency increased. Ni concentrations of 70 and 62.7 wt%  
1161 gave rise to stable flows in these systems.

1162 Incorporation of Ni nanopowder in the suspension resulted in a stable capillary  
1163 flow at 75 wt% of Ni. Occurrence of agglomerates, however, somewhat nullified this  
1164 advantage.

### 1165 12.5.8 Anaerobic Adhesives

1166 Anaerobic adhesives are typically applied using bottles, cartridges etc., made for  
1167 specific applications. Since air exclusion is imperative for premature polymerization,  
1168 metering and dispensing equipment is designed specially to prevent contact of  
1169 anaerobic adhesives with air, prior to use.

### 1170 12.5.9 Moisture Curing Adhesives

1171 As with the anaerobic adhesives, moisture-curing adhesives, such as cyanoacrylates,  
1172 are typically applied using bottles, cartridges etc., made for specific applications.  
1173 Since moisture exclusion is imperative for premature polymerization, metering and  
1174 dispensing equipment is designed specially to prevent contact of moisture-curing  
1175 adhesives with air, prior to use.

### 1176 12.5.10 Primers

1177 Primers can be applied by either dipping the part in primer solution or by spraying it  
1178 with air gun. Spraying appears to be the most popular technique used in structural  
1179 bonding. Higher solid-level primers are typically applied by brush. In certain  
1180 applications, settling of the insoluble inorganic chromate corrosion inhibitor needs  
1181 to be avoided by agitation during primer application. Since peel performance  
1182 typically decreases with increasing primer thickness, proper pigment suspension,  
1183 and the control of film thickness and uniformity must be assured during primer  
1184 application.

---

## 1185 12.6 Conclusions

1186 Adhesive bonding has many advantages, including more uniform stress distributions  
1187 in comparison to the use of mechanical fasteners such as bolts, rivets, etc. Adhesives  
1188 provide full contact with mating surfaces, thus forming a barrier to fluids and gasses

which may cause degradation in the assembled structure. Adhesives can also function as electrical and/or thermal insulators or conductors in joints.

As described in this chapter, adhesives can be classified based on their chemical type and physical form, and their reaction/processing conditions. Such classification helps in determination of the method of application and setting of the adhesive, as well as in assembly and fixturing as they relate to the nature and purpose of the objects to be bonded. Therefore, attention to classification facilitates adhesive selection.

## Abstract

Adhesives and sealants are generally developed and prepared for many applications such as packaging, construction, automobile, electronic, etc. An adhesive formulation will depend on the base materials and requirements of a particular application. Development managers or formulators have to have a public knowledge about the chemical composition and role of many components for reducing trials and errors. This chapter focuses on the definition and function of adhesive composition such as primary resins, solvents, fillers, plasticizers, reinforcements, and various additives.

13.1 Introduction

An adhesive is a polymer mixture or polymerizable material in a liquid or semiliquid state that adheres substrates together (Petrie 2000). Adhesives may be composed of many components such as polymer, oligomer, filler, and additives from either natural or synthetic sources. It is very important to understand the components for adhesive formulation. The information of composition gives us an adhesive selection guide based on functional properties, curing mechanisms, and other relevant information supplied by the adhesive manufacturer.

An adhesive is a complex formulation of many components that have a unique function. The adhesive manufacturer or developer selects actual ingredients depending on the end-user requirement, the application, processing requirement, and the cost as shown in Fig. 1. The various components of an adhesive formulation include the following: primary resins, solvents, fillers, plasticizers, reinforcements, thickeners and thixotropic agents, film formers, antioxidants, antifungal agents, emulsifiers, and wetting agents (Petrie 2000).

The adhesive formulator gets a lot of information from raw material suppliers, books, papers, and patents. The number of possibilities for innovation seems to be endless. However, the formulation of an adhesive is fixed according to the formulator's experience and education. Knowledge of how to incorporate ingredients together into a practical, workable formulation is also required.

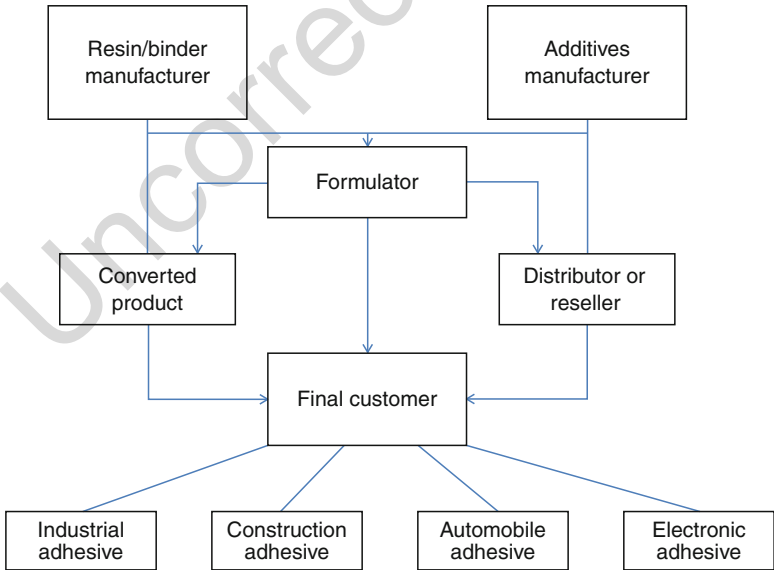

Fig. 1 Flow chart of adhesive applications

13.2 Primary Resins

The primary resins of adhesives and sealants are the principal component that provides a lot of characteristics such as wettability, adhesion strength, thermal property, chemical resistance, and environmental resistance. The word “resin” means a hydrocarbon secretion of many plants, particularly coniferous trees. In the adhesive industry, the primary resin means a polymer that is the main chain in the adhesive molecular structure. The understanding of primary resins is essential for adhesive curing, application, reliability, and adhesion failure analysis. For example, a modified epoxy acrylate is one of the primary resins for the main sealants of the liquid crystal display (LCD) (Park et al. 2009). The main sealants are used to adhere the thin film transistor and the color filter. To produce sealants for LCD, the primary resins have to have absolutely high purity to prevent pollution of the liquid crystal. However, some primary resins have a large range of performance depending on molecular weight, molecular structure, additives ratio, etc. Table 1 gives a classification of applications and primary resins (Dostal 1990).

Adhesives are classified by many methods such as dispensing method, application, and primary resin. The classification by primary resin is very useful to select a good

**Table 1** Various adhesive classifications and primary resins

Main category	Subcategory	Primary resins
Characteristics	Anaerobic adhesive	Polyester, urethane, epoxy, silicone, acrylate
	Elastic adhesive	Silicone, urethane, polysulfide
	Conductive adhesive	Epoxy, acrylate, polyimide, silicone, EVA, phenol
	Flame-retardant adhesive	Polybenzimidazole, polyquinoxazoline, polyphenylquinoxazoline, polyimide, bismaleimide, epoxy
	Damping adhesive	Silicone, polyvinylalchol
Curing methods	Quick-drying-glue	Cyanoacrylate
	UV-curable adhesive	Acrylate, polyene
	EB curable adhesive	Acrylate
	Visible light curable adhesive	Acrylate, polyene, polythiol
	Hotmelt adhesive	SBC, polyamide, polyacrylate, EVA
Applications	Medical adhesive	Fibrin, gelatin, cyanoacrylate, polyurethane
	Shoe adhesive	Polyurethane, phenol, SBR, rubber latex
	Structural adhesive	Phenol, epoxy, nitrile-phenol, vinyl phenol, epoxy, urethane, acrylate

*EVA* ethylene-vinyl acetate, *EB* electron beam, *SBC* styrene block copolymers, *SBR* styrene-butadiene-rubber

adhesive for a given application, because the name of the primary resin involves the chemical structure of the back bone and the sketchy properties such as adhesion strength and heat resistance. In this chapter, the classification of primary resins by chemical composition consists in thermosets, thermoplastics, and elastomeric resins. A thermosetting resin is a prepolymer in a soft solid or viscous state that changes irreversibly into an insoluble polymer network by curing, which can be induced by the action of heat or radiation, or humidity. Thermosetting materials are generally stronger than thermoplastic materials due to 3-D network of bonds, and are also better suited to high-strength and high-temperature applications. Table 2 shows some typical thermosetting resins and their characteristics for adhesives and sealants (Dostal 1990). A thermoplastic resin is a polymer that can turn to a melting liquid when it is heated and returns to solid when it is cooled down. Table 3 shows some thermoplastic resins and their properties (Dostal 1990). The molecular structure of thermoplastic resins is linear or branched. Linear and branched polymers are often soluble in solvents such as

**Table 2** Typical thermosetting resins for adhesives and sealants

	Advantages	Limitations
Epoxy	<ul style="list-style-type: none"> <li>• high strength</li> <li>• good solvent resistance</li> <li>• good gap-filling capabilities</li> <li>• good heat resistance</li> <li>• wide range of formulations</li> <li>• relatively low cost</li> </ul>	<ul style="list-style-type: none"> <li>• exothermic reaction</li> <li>• exact proportions needed for optimum properties</li> <li>• short pot life</li> </ul>

chloroform, benzene, toluene, and tetrahydrofuran (THF). More detailed information for each primary resin is given in ► [Chap. 14, “Adhesive Families.”](#)

### 13.3 Solvents

Solvents are liquids comprising one or more components that are volatile under the specified drying conditions and can dissolve film-forming agents purely and physically without chemical reactions (DIN EN 971-1 1996). Solvents can lower the

viscosity of the formulation to make it easier to apply and to help liquefy the primary resin so that the other additives may be easily incorporated into the formulation (Petrie 2000).

Diluents are defined as ingredients used in conjunction with the true solvent to increase the bulk of another substance without causing precipitation (LeSota 1995). Diluents are mainly used to lower the viscosity and modify the processing conditions of adhesives and sealants. Diluents participate in the partial components of the final adhesives because they have a lower volatility than solvents.

Solvents are used to control the viscosity of the adhesives so that they can be applied more easily. They are also used to aid in formulating the adhesive by reducing the viscosity of the primary resin so that additions of other components and uniform mixing may be achieved more easily. When solvents are used in the adhesive formulation, the similarity of the solubility parameter between the solvent and the primary resin is very important.

The solubility parameter ( $\delta$ -value) is divided as the following equation:

$$\delta_{\text{total}} = \sqrt{\delta_D^2 + \delta_P^2 + \delta_H^2} \quad (1)$$

$\delta_D$  = parameter for nonpolar contribution;  $\delta_P$  = parameter for polar contribution;  $\delta_H$  = parameter for hydrogen bridges contribution.

The indices relate to the nonpolar dispersion forces, the dipole forces, and the interactions caused by hydrogen bridges. Table 4 lists the solubility parameters of various solvents (Goldschmidt and Streitberger 2007).

The prediction of the miscibility between the polymer (primary resin) and solvent can be allowed from a comparison of the solubility parameters of the polymer ( $\delta_{\text{polymer}}$ ) and solvent ( $\delta_{\text{solvent}}$ ) because  $\delta$  is a measure of the interaction forces between molecules of the material. Therefore, the difference of solubility parameter ( $\delta_{\text{polymer}} - \delta_{\text{solvent}}$ ) should be small for good miscibility.

Solvents can be classified into some categories by their chemical character into groups with common features: aliphatic, cycloaliphatic, and aromatic hydrocarbons, esters, ethers, alcohols, glycol ethers, and ketones. Table 5 shows the important physical performance indicators of solvents used for the coatings or adhesives such as the density, refractive index, boiling temperature or boiling ranges, and the vapor pressure or evaporation time. In addition, the flash point, ignition point, and explosion limits must also be needed for safety reasons (Goldschmidt and Streitberger 2007).

General solvent contents used for typical sealants are shown in Table 6 (Petrie 2000).

The use of excessive solvent may cause a shrinkage problem when the sealant cures. Volume shrinkage will always be greater than the weight percent of solvent due to its much lower density than other components in the sealant. Toluene, xylene, petroleum spirits, water, and others are used as solvents in sealant formulations. In case of solvent mixtures, the balance of volatility between solvents is very important to avoid a trouble such as the sealant's skin drying problem.

**Table 4** Solubility parameters  $\delta_{\text{total}}$  of different solvents and their disperse contribution  $\delta_{\text{D}}$ , polar contribution  $\delta_{\text{P}}$  and hydrogen bridging contribution  $\delta_{\text{H}}$ , (unit in  $[\text{J}/\text{cm}^3]^{1/2}$ ) (Goldschmidt and Streitberger 2007)

**13.4 Fillers**

Fillers are generally relatively non-adhesive materials added to the adhesive formulation to enhance mechanical strengths, thermal properties, adhesion performance, etc. Common fillers in conductive adhesives are listed in Table 7. One of the purposes of using fillers is lowering the cost. The incorporation of fillers into the adhesive reduces the resin content and thus the product cost is also reduced. However, fillers can change adhesive properties. Filler selection and loading level are very important in formulation of adhesive because adhesive properties depend on filler type, size, shape, and volume contents. Common fillers are metal powder, kind of clay, dust, glass fiber, alumina, and so on. Sometimes fillers act as extenders or reinforcement materials.

**Table 5** Physical and safety-related data of important solvents (Goldschmidt and Streibberger 2007)

Type of solvents	Mol. Mass	Boiling point/region (°C)	Density at 20 °C (g/cm <sup>3</sup> )	Refractive index at 20 °C	Evaporation number	Vapor pressure at 20 °C (hPa)	Flash point (°C)	Ignition temperature (°C)	Explosion limit (Vol %)

**Table 7** Filler for conductive adhesive in common adhesive formulations

Filler	Improvement in adhesive formulation
Aluminum	Electrical conductivity, thermal conductivity
Silver	Electrical conductivity
Carbon black	Electrical conductivity, color
Graphite	Electrical conductivity, lubricity
Copper	Electrical conductivity, machinability
Nickel	Electrical conductivity
Iron	Electrical conductivity, abrasion resistance
Chromium	Electrical conductivity
Molybdenum	Electrical conductivity
Tungsten	Electrical conductivity

**Fig. 2** Conductivity depends on contact between filler particles within the adhesive (Petrie 2008)

Normally, adhesive can be conductive by adding conducting filler particles. The resin provides an interaction bond between substrates and conducting fillers as well. However, it is the conducting filler that provides the desired electrical interconnection path as depicted in Fig. 2. To make conducting adhesives, the fillers must be in physical contact with each other. Thus, the electrical conductivity increases sharply when a percolation threshold level of well-dispersed conducting filler is accomplished. Figure 3 shows the resistivity versus conductive filler level (Petrie 2008).

**Fig. 3** Conductive filler level versus resistivity in conducting adhesive formulation (Petrie 2008)

Alumina particles are one of the commonly used fillers for improving the thermal conductivity of adhesives in particular insulation adhesives. Aluminum and silver powders or flakes are used to improve the thermal and electrical conductivities for adhesives intended to be an electrical or thermal path. The filler volume content level is very important to get sufficient conductivity. However, excessive filler content might cause degradation in mechanical properties of the adhesives (Kahraman and Al-Harhi 2005; Kahraman et al. 2008).

One of the most effective techniques used to improve the electrical conductivity of polymers is the incorporation of conductive fillers in the polymer matrix. The most popular electrically conductive filler is silver due to its moderate cost and superior conductivity. Silver-coated inorganic particles and fibers are superior compared to carbon particles and fibers as components in epoxy-based adhesives regarding the electrical conductivity of the composite; because the electrical conductivity of silver is much higher than that of carbon. In addition to the high electrical conductivity of silver, the addition/application of silver-plated particles and fibers also leads to composites with high mechanical strength and modulus, low weight, and a high ratio of metal-plated fibers (Novák et al. 2004).

Among the various conductive particles, silver particle is probably the most common filler because of its excellent conductivity and chemical durability. Silver particles are easy to precipitate into a wide range of controllable sizes and shapes, so it can be used to change the percolation threshold of the adhesive formulation. Silver also exhibits high conductivity; however, the silver filler is expensive (Lin et al. 2009).

Graphite is usually used as an electro conductive filler due to its low cost and natural electrical conductivity. It also has a positive influence on the mechanical properties, as well as thermal and dimensional stability (Lin et al. 2009). Substitution of carbon black with renewable filler has been investigated in recent years. Carbon black has some advantages such as low cost, low density, high electrical conductivity, and, in particular, specific structures that enable the formation of conductive network (Wan et al. 2005; Jong 2007).

**Table 8** Filler for other function in common adhesive formulations

Filler	Improvement in adhesive formulation
Aluminum oxide	Flame retardant
Lead	Radiation shielding
Mica	Electrical resistance
Phenolic microspheres	Decrease density
Silica sand	Abrasion
Silicon carbide	Abrasion resistance
Titanium dioxide	Color
Zinc	Corrosion resistance

**Table 9** Fillers commonly used in sealants

Filler	Improvement in sealant formulation
Calcium carbonate	Adjustment of mechanical properties, thixotropic agent
Silica	Common for silicon resin
Clay	Mechanical modifier
Titanium dioxide	Colorant (for white)
Carbon black	Colorant (for black)
Iron oxides	Colorant
Glass fiber	Thixotropic agent

Copper has good electrical conductivity and high adhesion property in conductive adhesive systems. However, copper tends to form a nonconductive oxide surface layer (Zhao et al. 2007).

Nickel is a good nominee for conductive filler in conducting adhesives because of the numerous benefits it possesses. Nickel shows chemical stability and oxidizes relatively slowly compared to copper. But, nickel has disadvantages compared to silver: nickel has a higher electrical resistance than silver (about 25% of silver). However, it is less expensive than silver filler (Goh et al. 2006).

There are many conducting fillers for adhesive formulation. Apart from the ones mentioned above, iron, chromium, molybdenum, tungsten, and other metal particles can be used as fillers for conducting adhesives.

Many other inorganic fillers are used for adding a function to adhesive. Table 8 shows the additional function of fillers. Aluminum oxide (flame retardant), lead (radiation shielding), mica or clay (electrical resistance), and silica and silicon carbide (abrasion resistance) are used to add additional function to the adhesive formulation.

Generally, fillers in sealant formulation are used as additives to boost the viscosity of the sealant and get better gap-filling properties and to reduce the material cost of the sealants. In sealant formulation, fillers cannot affect reinforcement and improved strength. However, they can affect other properties such as water resistance and hardness, etc. The most common filler used in sealant is calcium carbonate, because of its many advantages such as abundant resource, low cost, and stability. Other fillers are clays, silica, titanium dioxide, carbon black, and iron oxide. Table 9 lists commonly used fillers in sealant formulations and functions in sealant systems.

**Fig. 4** The viscosity versus particle size in common adhesives (Chew 2003)

Fillers represent the largest part in terms of weight for many sealants. Calcium carbonate is the most widely used filler for sealant formulations. As a filler for sealants, calcium carbonate acts as an inert extender to reduce formulation cost, modifier for mechanical properties, and a rheological modifier. Normally, properties of fillers such as particle size, shape, and surface properties are very important factors for sealant properties. Figure 4 shows the typical effect of particle size on the viscosity in common adhesives (Chew 2003). Filler volume contents can vary significantly with being dependent on the primary resin and the formulation.

### 13.5 Plasticizers

Plasticizers are substances of low or negligible volatility that lower the softening range and increase workability, flexibility, or extensibility of a polymer (ASTM D907-08b 2008). The main purpose of plasticizers is to modify the property of adhesives and sealants. The addition of plasticizers causes the improvement of flow and flexibility, but the reduction of the elastic modulus, stiffness, hardness, and the glass transition temperature ( $T_g$ ). As a result, the processibility and extrudability of adhesives and sealants can be improved by addition of plasticizers (Tracton 2007; Stoye and Freitag 1998).

Plasticizers also affect the adhesion property. Addition of plasticizer to the adhesive will always lower the cohesive strength, generally reduce the peel adhesion, and will have a variable effect on the tack depending on the type of plasticizer used (Satas 1999). Plasticizers must be compatible with other adhesive ingredients because of their inherent chemical characteristics and nonreactivity with other components (Petrie 2000).

Plasticizers and solvents are governed by the same laws of solubility and have the ability to increase the free volume of the polymer. However, solvents mostly serve as viscosity modifiers and plasticizers are used to modify the properties of the adhesives or sealants, such as softening and lowering the  $T_g$  (Petrie 2000).

Plasticizers have polar and nonpolar components in the molecular structure. The polar components interact with the polar groups of the primary resins. Otherwise, the nonpolar components prevent the intermolecular interaction between plasticizers

**Fig. 5** Lowering the glass transition temperature ( $T_g$ ) of a polymer by a plasticizer (Goldschmidt and Streitberger 2007)

and the molecules of primary resins by steric hindrance. As a result, the mobility of adhesives or sealants can be promoted. Due to the same reason,  $T_g$  is shifted to a lower temperature with an increase of the plasticizer content as shown in Fig. 5 (Goldschmidt and Streitberger 2007).

When a compatible oil is added to an elastomer such as natural rubber, it acts as a plasticizer. The storage modulus ( $G'$ ) of a natural rubber/aliphatic oil adhesive decreased at all frequencies with the increasing amount of plasticizing oil as shown in Fig. 6 (Satas 1999).

A variety of plasticizers can be used in adhesives and sealants as to their primary resin type. Paraffinic oils, phthalate esters, and polybutenes are typical plasticizers (Dostal 1990). Plasticizers for natural rubber adhesives, such as mineral oil or lanolin, are used to reduce the cost of the adhesive mass, and have a depressing effect on the peel adhesion (Satas 1999). Phthalates, chlorinated hydrocarbons, and aliphatic hydrocarbons are commonly used as plasticizers in urethane sealants (Dostal 1990). Most of sealants, except for silicones, contain plasticizers in their formulations. Silicone sealants can be plasticized only by low molecular weight silicone oils (Petrie 2000).

## 13.6 Reinforcements

Reinforcements are used to enhance mainly mechanical properties. Many reinforcements are now available, and some are designed for a particular primary resin. There are various reinforcements for adhesive formulation. Generally,

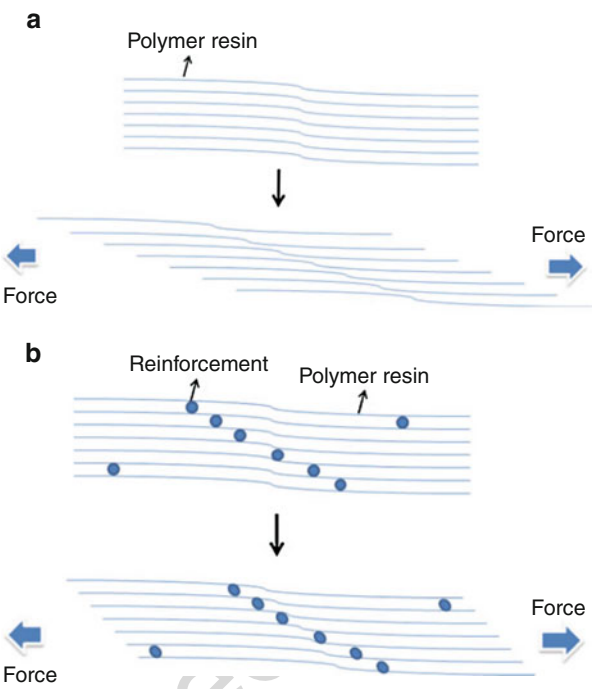

**Fig. 6** Effect of plasticizing oil on the storage modulus ( $G'$ ) of natural rubber/aliphatic oil as function of frequency at 25 °C (Satas 1999)

reinforcements act as the polymer resins in an adhesive system and reinforcing the internal bonding strength of the adhesive. Figure 7 depicts a schematic diagram of an adhesive with reinforcements. Reinforcements act like crosslink agents. It means that the reinforcement reduces the strain in a shear test and can enhance the mechanical strength of the adhesive. The main reinforcements in adhesive formulations are listed in Table 10.

Recently, reinforcement agents in adhesive formulations have received attention due to very high reinforcement ability, simple preparation, and cost. One of the agents is inorganic clay which acts as a modifier of the mechanical and barrier properties. However, clay has some disadvantages for application as a reinforcement agent because of aggregation in the polymer resin. Therefore, many researchers have modified the surface of the clay. Figure 8 shows the clay loading contents versus lap shear strength. It can be seen that the modified clay gives an improved lap shear strength in relation to that of the pure clay (Maji et al. 2009; Osman et al. 2003).

Carbon nanotube (CNT) has excellent mechanical properties. CNT is very similar to graphite. A single-walled carbon nanotube (SWCNT) can be seen as a rolled sheet of graphite, while a multi-walled carbon nanotube (MWCNT) can be viewed as layers of many graphite sheets. Moreover, the stiffness is very high: SWCNT's Young's modulus is about 1 TPa and the shear modulus to be 0.45 TPa. Many researchers have used CNT to enhance the mechanical properties of adhesives.

**Fig. 7** Schematic diagram of adhesive at shear strength test: (a) without reinforcement and (b) with reinforcement

**Table 10** Common reinforcement agents

Reinforcement	Main function
Clay	Mechanical modifier
CNT	Mechanical modifier, electrical conductivity
Graphite	Mechanical modifier
Carbon black	Mechanical modifier, colorant

Figure 9 depicts the shear strength of an epoxy adhesive with different MWCNT contents (Hsiao et al. 2003).

Sometimes, the reinforcement is a carrier in the adhesive composition such as in tapes and films. A carrier is usually a thin fiber fabric, cloth, or paper material. In pressure sensitive adhesives, the carrier is a backing substance for the adhesive being applied. Usually, the backing materials are used for functional or decorative reasons. Glass, nylon fabric, polyester, and paper are common carriers for adhesives. In this case, the carrier acts as a “reinforcement” to ease the use of adhesive. Figure 10 shows a schematic diagram of the carrier for an adhesive tape or film. A carrier is very useful to b-staged adhesive systems because of their semi-cured formulation. The carrier can act as support for adhesive.

**Fig. 8** Lap shear strength versus clay contents in polyurethane adhesive between aluminum and aluminum with PU adhesives (Maji et al. 2009)

**Fig. 9** The average shear strength of epoxy adhesive with different MWCNT weight fraction (Hsiao et al. 2003)

**Fig. 10** Carrier for adhesive

## 13.7 Other Additives

Additives are functional chemicals added to adhesives to ease the process and improve some properties. Many additives, like antioxidants, thermal stabilizers, UV stabilizers, polymer processing aids, anti-blocking additives, slip additives, antifogging agents, antistatic additives, flame retardants, and colorants, have been used for centuries. Recently, additives are used as special functional materials to improve important properties of final products; hence additives application technology is essential for adhesive development.

Antioxidant is any substance that delays or inhibits oxidation during the adhesive manufacturing process, storage, and application. Oxidation is a chemical reaction that transfers electrons from a substance to an oxidizing agent. As a result, reaction produces free radicals (Zweifel 2004). Oxidation during compounding or processing can cause problems such as loss of strength, breakdown, or discoloration. Oxidation can also occur in the final product causing discoloration, scratching, and loss of strength, flexibility, stiffness, or gloss. Antioxidants have some ability to terminate radical chain reactions by removing free radical intermediates or inhibiting other oxidation reactions. Antioxidants can be classified by the chemical structure such as phenol type, aromatic amine type, thioester type, phosphate type, etc.

For example, hotmelt adhesives are 100% solid thermoplastic compounds that are solids at room temperature, but they are changed to liquid when heated to the melting temperature. When applied, hotmelts bond and cool rapidly. To make EVA based hotmelt adhesives, mixing process at high temperature is essential. To reduce the thermal degradation of hotmelt adhesives, 1–2 parts of a phenolic antioxidant by weight were used as a thermal stabilizer (Park et al. 2003, 2006).

A UV stabilizer is a substance to prevent discoloration, surface crack, and decreasing of the mechanical properties by UV radiation that has a high energy wave in the range of 290–400 nm. In particular, UV stabilizers are essential additives for transparent plastics for outdoor application. UV stabilizers can be classified by chemical reaction, such as UV absorption, quenchers, and HALS (hindered amine light stabilizer). UV absorbers absorb the harmful UV radiation and dissipate it so that it does not lead to photosensitization. Typical UV absorbers are hydroxyl benzophenone, benzotriazoles, and modified acrylate. Quenchers are light stabilizers that are able to take over the energy absorbed by the chromophores present in plastic material (Bellus 1971). HALS is a radical scavenger that represents the most important development in light stabilization for many polymers. HALS acts by scavenging the radical intermediates formed in the photo-oxidation process. HALS' high efficiency and longevity are due to a cyclic process wherein the HALS is regenerated rather than consumed during the stabilization process. HALS also protects polymers from thermal degradation and can be used as a thermal stabilizer.

Table 11 shows an example of formulation of the UV-curable coatings, which is composed of isocyanate and acrylated urethane oligomers (Lee and Kim 2006). In

**Table 11** Formulation of UV-curable coatings

	Tinuvin 292 (mixture of bis(1,2,2,6,6-pentamethyl-4-piperidinyl)-sebacate and 1-(methyl)-8-(1,2,2,6,6-pentamethyl-4-piperidinyl)-sebacate (hindered amine light stabilizer type))							
	Dupont R706 (titanium dioxide)							

95% benzenepropanoic acid, 3-(2H-benzotriazol-2-yl)-5-(1,1-dimethylethyl)-4-hydroxy-, C7-9-branched and linear alkyl esters, 5% 1-methoxy-2-propyl acetate (Tinuvin 384-2)

Mixture of bis (1,2,2,6,6-pentamethyl-4-piperidiny) sebacate and 1-(methyl)-8-(1,2,2,6,6-pentamethyl-4-piperidiny) sebacate (Tinuvin 292)

**Fig. 11** Chemical structures of light stabilizers

addition, Fig. 11 shows chemical structures of light stabilizers. UV-cured film with both Tinuvin 384-2 and Tinuvin 292 showed the slight change of optical and mechanical properties. In the case of most UV-cured films, using a UV stabilizer is helpful to discoloration, gloss, and hardness properties after weathering.

Flame retardants are materials that inhibit or resist the spread of fire. Flame retardants can remove thermal energy from the substrate by functioning as a heat sink or by participating in char formation as heat barrier. The additives can also provide flame retardancy by conduction, evaporation, or mass dilution or by participating in chemical reactions (Zweifel 2004).

Adhesives can be separated into two general classes: thermoplastics and thermosets. Thermoplastics can be formulated with halogen-containing and non-halogen-containing additives. Thermosets are commonly treated by adding flame retardants that chemically react with a resin precursor. Table 12 lists flame retardants that are typically used.

Tackifiers are used in formulating rubber based on adhesives to improve the tack property. Tackifiers are low molecular weight compounds with high  $T_g$ . There are two classes of tackifiers: the rosin derivatives and the hydrocarbon resins. The rosin derivatives include the rosins, modified rosins, and rosin ester. The hydrocarbon resins consist of low molecular weight polymers derived from petroleum, coal, and plants. The miscibility between tackifiers and the adhesives is important to choose a tackifier. The viscoelastic property of adhesives can be modified by blending of a miscible tackifier.

**Table 12** Common flame retardants used within thermoset plastics

Resin	Flame retardant	Flame retardant level
Epoxy	Tetrabromobisphenol-A	18 wt.% Br
Unsaturated polyester	Tetrabromophthalic anhydride Chlorendic acid/anhydride	10~22 wt.% Br 15~29 wt.% cl
Polyurethane	Tetrabromophthalate diols Pentabromodiphenyloxide Dibromoneopentylglycol	15~28% 6~18% 5~15%

A curing agent or hardener is a substance added to an adhesive to promote the curing reaction. These affect curing reaction by chemically combining with the base resin and becoming part of the final polymer molecule. They are specifically chosen to react with a certain resin (ASTM D907-08b 2008). Curing agents will have an important effect on the curing features and on the fundamental properties on the adhesive system. A polyamide resin that is used in room-temperature curing epoxy adhesive system is an example of a curing agent (Petrie 2000). Polyamide curing agents are used in most “general-purpose” epoxy adhesives. They offer a room-temperature cure and bond well to many substrates that include elastomers, glass, and plastics. The polyamide-cured epoxy also provides a comparatively flexible adhesive with moisture resistance, fair peel strength, and thermal cycling properties. In general, mixing ratio is not critical. Within limits, the greater the quantity of polyamide in an epoxy formulation, the greater the flexibility, impact strength, and peel strength. However,  $T_g$  is decreased as are the shear strength and temperature resistance. There are some polyamides with changing viscosity. The reaction with conventional di-glycidyl ether of bisphenol A (DGEPA) epoxy resins yields a comparatively low degree of exotherm. In Table 13, the distinct features of curing agents used with epoxy resins in adhesive formulations are briefly stated (Petrie 2000).

Catalysts are substances that markedly speed up the cure of an adhesive when added in a minor quantity compared to the amounts of the primary reactants (ASTM D907-08b 2008). Solidification and crosslink of the primary resins are caused by catalysts. The commonly used catalysts are acids, bases, salts, sulfur compounds, and peroxides. To influence curing, only small quantities are needed (Petrie 2000). Table 14 shows the lists of some catalysts and the reactions they catalyze (Hare 1994). The curing of the adhesives or sealants by transformation into a hardened state is fulfilled by chemical methods, for instance, oxidation, vulcanization, polymerization, or by physical action, such as evaporation of the solvents (Cognard 2005).

### 13.8 Conclusions

There are various commercial adhesives in the market area and various requirements for a specific application: controlling flow, extending temperature range, improving toughness, lowering the coefficient of thermal expansion, reducing shrinkage,

**Table 13** Characteristics of curing agents used with epoxy resins in adhesive formulations

**Abstract**

Adhesive bonding, which addresses applications in an ever-growing number of industrial, handicraft and service sectors, does not exist as a specific research activity in its own right. Every user of bonding technology – from surgeon and handyman to car manufacturer and aeronautical launch vehicle designer – has specific needs, especially in the area of adhesives. In order to answer to these needs, suppliers are diversifying and extending their product ranges in terms of conditioning and bonding processes. This results in some very difficult choices, making it necessary to have at one's disposal “navigational tools” in an extremely complex network (Fabris and Knauss 1990; Pocius 2002). Because the basis of adhesive formulation is inevitably macromolecular in nature, polymer science is

likely to shed valuable light in this area. By using our knowledge of the principles underlying these formulations, and also the basic physical chemistry rules that apply, we can establish a general classification system, allowing us to direct our decision-making processes toward those product “classes” best suited to each specific application. On this basis, adhesives can be presented according to the following main discussion:

- The basic rules to establish a classification system based on the process used to achieve the transformation of an adhesive into a bonded joint.
- The main characteristics of adhesives for which the transformation is based on a physical phenomena.
- The main characteristics of adhesives for which the transformation is based on a chemical process.
- The main properties of adhesives used as Pressure-Sensitive Adhesives.

---

## 14.1 Introduction

Adhesives can be classified according to their areas of application, the nature of the materials that need bonding or the physical state at the time of application. However, none of these classifications allow commercial products to be adapted to specific applications or studies, nor do they enable us to determine the optimum conditions or limitations when using these products. To achieve these additional stages, we need to understand the physical and chemical behavior of the raw materials used as base components of these adhesives and to take an active interest in major developments regarding their formulation. Indeed, the raw materials are responsible for the general adhesive and cohesive properties of the bonded joints, while the “art” of adhesive formulation helps to find the most diverse potential applications possible for products prepared using these raw materials.

An adhesive (or a glue, both terms are used interchangeably, except by certain suppliers, who use the term “adhesive” exclusively for tape, labels, dressings and other types of auto-adhesive film) is a chemical substance used to join materials (substrates), either identical or different, by their surfaces. The key part of the adhesive assembly is the joint, a thin region (rarely more than 50  $\mu\text{m}$  thick) characterized by its cohesion and by its adherence to the substrates. This represents an interface phenomenon, although interactions normally occur within very thin hybrid areas (interphase) (typically less than 10  $\text{nm}$  thick). The very high surface to thickness ratio of the joints distinguishes adhesives from sealants for binders, products of a similar nature, but which are used in significant quantities with the filling of cracks or cavities as an end goal.

Certain adhesives, used to join substrates with a high degree of mechanical resistance, are able to ensure over potentially long periods of time, the survival of the joints, described as structural, under normal conditions of use while exposed to relatively high degrees of stress. Contrary to certain statements made, the minimum level mechanical strength is not quantifiable, if for no other reason than it would

mean having to quantify the amounts involved, the condition of the surface of the substrates, the temperature, etc., indeed all the parameters that determine whether a joint will “hold” or “not hold.” Of more interest is the observation that a structural joint is only able to fulfill its role if it is, itself, mechanically strong and therefore if it is a material with a three-dimensional structure. On the other hand, softer adhesives can be used with the aim to be more or less easily removed from one of the substrates after a certain time, depending on the application.

The multiple physical, rheological, mechanical, and chemical abilities that we demand of adhesives and glued joints can be boiled down to two essential characteristics: adhesion and cohesion.

Adhesion describes the ability of an adhesive to establish and maintain interactions with the substrates. This property corresponds mainly to wetting tendency, which describes how a liquid spreads spontaneously on the surface of a substrate. The laws of thermodynamics describe the wetting of surfaces, but the crucial practical condition for an adhesive to spread on a surface is that it should be in a sufficiently fluid state at the time it is applied. In terms of this concept, the adhesive behave like a liquid.

Although the idea of morphological stability of the assemblies is easier to picture in the case of structural bonding, the need for sufficient cohesion of the joint is, in the same way as the fluidity of the adhesive, a simple question of common sense. This cohesion determines the ability of the joint to contribute effectively to the solidity of the assembly (although liquids, water, for example, are capable of developing strong interactions with many substrates, it is impossible to imagine creating assemblies with them that would present any degree of solidity). In terms of this concept, the joint is a solid. But it is not, however, just any type of solid. It cannot, for example, be a crystalline system since the joint must not be anisotropic. In fact, we generally require that the joint provides the assembly with a minimum degree of flexibility or, at least, of reversible deformability (in order to endure the constraints relating to the differences in size variation of the assembled materials, to absorb the vibrations, to resist to “fatigue,” etc.). The joint should be capable, to a greater or lesser extent, of visco-elastic dissipation of the energy resulting from the stresses to which the assembly is subjected. To this end, it can only be a polymer, either linear (more or less rigid thermoplastic), or three-dimensional (chemically cross-linked, vulcanized, etc. ...).

---

## 14.2 Systematic Classification of Adhesives

The two contradictory requirements – adhesive applied in sufficiently fluid state and joint consisting of a solid visco-elastic state polymer – provides the basis for a classification into three broad groups:

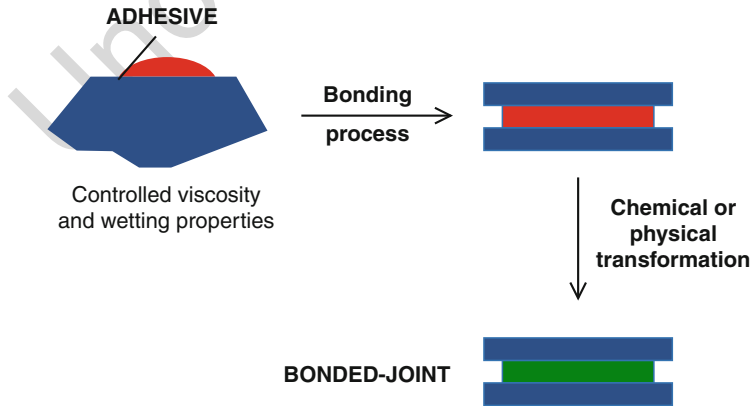

- Adhesives where the polymer is preexisting (and must be placed beforehand in fluid form: solution, emulsion, or “melt” state).

- Adhesives where the polymer is formed during the course of a reactive process, polymerization, at the time as the bonding process itself.
- The particular category of Pressure-Sensitive Adhesives (PSA's) where the polymer exhibit visco-elastic properties able to develop adhesion during the bonding step as well as cohesion to resist to the debonding. No physical or chemical transformation of the adhesive is required to form the bonded joint.

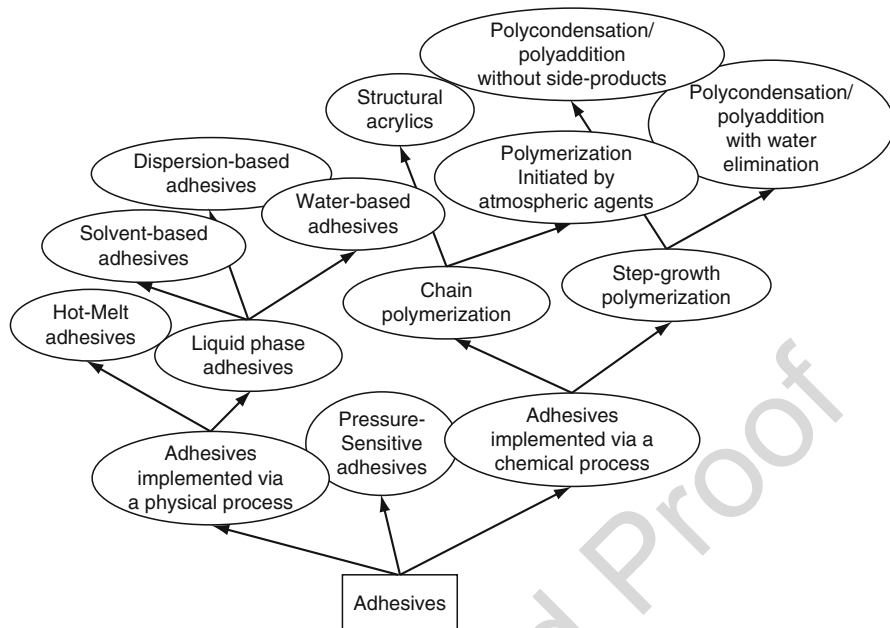

Generally speaking, the polymers belonging to the first group are soluble in various solvents are dispersible in non-solvents or are liable to become fluid at a variable raised temperature. As a result, these are linear polymers, and these rarely produce highly cohesive materials. On the other hand, in the second group, the need to undertake polymerization processes based on monomer or oligomer precursors means mainly that three-dimensional lattices are produced, which in theory are highly cohesive and are capable of withstanding severe mechanical constraints. Therefore, structural bonding adhesives tend to come mostly from this group. Finally, adhesives from the third group exhibit a visco-elastic behavior that answers to the PSA's criteria (Creton and Fabre 2002).

According to the proposed classification, the classes from the first group of adhesives can be distinguished by the way in which the polymer is returned to a solid state (evaporation of the solvent, water diffusion, cooling): we therefore talk about Adhesives Implemented via a Physical Process (AIPPs). In the second group, the distinction tends to be according to the way in which the polymerization or cross-linking process occurs, and we talk about Adhesives Implemented via a Chemical Process (AICPs) (Fig. 1).

A third group is distinguished by the fact that the polymer exhibit particular visco-elastic properties able to develop adhesion during the bonding step as well as cohesion to resist to the debonding: we talk about Pressure-Sensitive Adhesives (PSA's) in that case. The Fig. 2 places the main classes of adhesive within either of these three broad groups.

**Fig. 1** Main route to implement adhesives

**Fig. 2** Adhesive “zoology”

Remark on the adhesive formulations. When adhesives are applied, the different steps, including preparation of the surfaces, application of the adhesive, assembly, etc., consist of key points, which will determine the quality and the result of the bonding process. The importance of these key points can often be explained by the nature of the formulation of the adhesives itself, with similarities but also significant differences between the three groups.

For both adhesive groups, the nature of the formulation reflects the concern that the products should be adapted as much as possible to the various applications for which they will be used. Across the different adhesive compositions, therefore, one can identify concerns relating to the setting process, to the mechanical behavior of the assemblies and to their durability. These concerns lead manufacturers to combine, with the raw polymer materials (or polymer precursors), various additives (products that mix at the molecular level) and types of filler (non-mixable materials dispersed in various-sized particles, from tens of nanometer to tens of micrometer).

There are numerous formulation rules, often driven by empirically concerns, but the most general one is that the mixture of a macromolecular compound with any additive or filler, regardless of how carefully mixed it is, while able to improve several properties, almost always results in a decrease in cohesion and often a lowering of the level of adhesiveness. This justifies, for theoretical approaches, efforts involving the development, via direct synthesis, of macromolecular systems liable to reproduce the behavior of various types of adhesive formulation. It is this research into models that is able to mobilize all the resources of macromolecular chemistry.

Remark on the comparison between adhesives and sealants. One can consider that even if the main properties of sealants differ from the ones addressed by glued joints the mechanisms involved to create the bonding are the same. Controlled chemistry is needed to reach the best level of interactions and formulations are improved to reach the required visco-elastic properties. The mechanism involved in the building of the joint is mainly based on chemical reactions. Nevertheless, the major difference between sealants and adhesives concerns the properties of the resulting joints that are not only adhesion properties. The fact that (1) the sealant joints are much more thicker than glued joints and that (2) additional properties such as, for example, watertightness or vibration absorbing lead us to separate the sealant family from the adhesive classification.

The “philosophy” behind a description of adhesives via their raw polymer materials differs according to whether the area of interest is AIPPs or AICPs. For the first category, the polymer is present within the adhesive formulation, and the adhesive and cohesive properties must be acquired before being dissolved, being made into an emulsion, or being melted. In that case, research and development is aimed at the development of linear macromolecular compounds, endowed with specific properties. Technically, the preoccupation is in the area of chemical engineering, with the solvent dissolution-evaporation, “emulsification”-coalescence, melting-solidification pairs. In the case of AICPs, the polymer is developed in situ in contact with the surface. Research and development efforts are focused on the precursors and on the types of chemical process. Technically, the crucial aspect is the control of polymerization occurring in undefined reactors, often open, where temperature is not regulated, unstirred, but working in thin films. Each class of adhesive meets certain specifications, and examining these helps to illustrate the influence that a number of elements, constituent or environmental, may have.

In the case of PSA’s, the polymer is formulated with additives such as waxes and plasticizers in order to govern at the same time instantaneous adhesion and visco-elastic dissipation and to satisfy a huge variety of bonding processes and performance requirements.

---

## **14.3 Adhesives Implemented Via a Physical Process**

### **14.3.1 Liquid-Phase Adhesives**

Bonding, achieved using single (coating of one substrate only) or double bonding, the spread (mass of “dry” adhesive per unit area) determines the future thickness of the joint. The speed of bonding is linked to the speed of setting of the adhesives, with the significant parameter being the work time, the period between the “gumming time” (after which the adhesion can occur), and the “open time” (after which cohesion becomes too strong, and negates any possible adhesiveness). The set of tools to deposit the adhesives, drying, the environment, the actions of the operators also play a key role, and it is important to take into account the fact that the behavior of adhesives, AIPPs (but also AICPs), is influenced to a much greater extent by the

technical bonding parameters than by the characteristics of their own base polymers. The storage conditions for the liquid-phase adhesives must obviously ensure airtight packaging (to avoid the evaporation of the solvents or to protect against the effects of humidity) and protect against extremes of temperature (especially damaging to emulsions), but do not differ, for example, for a vinyl polymer-based adhesive versus a polyurethane-based one. As a corollary to storage, the removal from storage (the amount of adhesive required for a single unit of work time) is a general parameter that must be carefully managed.

Packaging can occur in volumes ranging from a few tens of millimeters to several hundreds of liters. They can be prepared in units of production or on the site where they are to be used. But there is one parameter that remains constant that stems from the physical chemistry of polymers: as these have many more non-solvents than solvents, the dilution or the return to solution of an adhesive formulation is a risky process, very often doomed to failure.

### "Water-Based" Adhesives

For the most part, adhesives in aqueous solution are natural products, originating from plants (starches, (Fig. 3) (Kennedy 1987) and other starchy substances), from animals (casein, originating from milk, glycogen, taken from bones, from the skin of fish, etc.), or from minerals (silicates).

These are often forgotten because they have been known about for an "eternity"; they have been replaced by synthetic adhesives for more advanced uses, they are not very "media-friendly" and are not suitable for structural bonding. Nonetheless, they represent the largest quantity of adhesive product currently consumed in the world in terms of tonnage. Aqueous glues are often used to assemble together porous materials (paper, cardboard, plaster, wood (Johnson and Karuke 1985), etc.) through which water can easily diffuse. It is rare for the natural hydrophilic polymers to dissolve completely in water. Instead, it is more likely that the polymers will swell (especially the more ramified among them) or that colloidal dispersion will form. Generally, the result is that compositions said to be thixotropic are obtained (do not flow when not exposed to shearing stress), which can justify the use of hydrophilic polymers as thickening agents.

**Fig. 3** Macromolecular structure of starch

**Fig. 4** Chemical structure of polyvinylpyrrolidone (**a**) and polyvinyl alcohol (**b**)

There are also synthetic polymers that are soluble in water or highly hydrophilic: polyvinylpyrrolidone (Fig. 4a), polyvinyl alcohol (Fig. 4b), polyoxyethylene, etc.

As with their natural counterparts, these are important constituents of adhesive formulations used in the presence of water, for example in the paramedical field (Tan and Pfister 1999); it is these substances that make adhesion to humid surfaces, especially the skin, possible.

In spite of its value in terms of safety, toxicity and environment, water is not a very useful adhesive formulation solvent. During the bonding process, it can favor the establishment of interactions with certain substrates, thus depositing itself at their surface and forming layers with no cohesion. In terms of bonding, the water can accumulate near the polar groups of the polymer joints, weakening their adhesive interactions and their cohesion and potentially leading in the long term to their deterioration through hydrolysis.

Porous substrates (paper, cardboard, wood, plaster, etc.) allow the total elimination of water in the formulations, through diffusion. These are the materials that are best suited to water-based formulations. With substrates that are non-permeable to water (hydrophobic polymer films, metals, etc.), water evaporation is the only solution, but it is difficult to ensure that it is achieved completely, due especially to the very strong interactions that occur between the water and the adhesives' polar groups. Optimized formulations, with high "dry matter rates" (60%, even 70% or 75%), as well as specially developed applicator equipment (hot air drying tunnels, infrared radiation, microwave radiation, etc.) are designed to solve this problem.

The absorption of humidity by the joints is one of the main causes of ageing, physically to begin with, often involving the elimination of the plasticizers and other additives or impurities, and possibly chemically as well, with hydrolysis phenomena. This suggests that controlling the reduction in adhesive properties, an active area of research and development across many industries could be achieved through a regulated absorption of humidity.

### "Solvent-Based" Adhesives

A number of linear polymers are soluble in organic solvents that are able to be eliminated rapidly (through evaporation) after the adhesive has been deposited. This

**Fig. 5** Chemical structure of poly( $\beta$ -pinene)

**Fig. 6** Chemical structure of polychloroprene

is the case, for example, for poly( $\beta$ -pinene) (Fig. 5) which, dissolved in methyl ethyl ketone, has for a long time been the basis of “universal glues” (Scotch<sup>®</sup> by 3 M).

The most typical “adhesive solvents” are those based on elastomers, compounds characterized by the fact that they have a strong natural adhesiveness, especially in respect of themselves (the phenomenon of self-adhesion, the instantaneous adhesion of two films of glue after almost total evaporation of the solvent, is the basis for the composition of the “contact glues” especially neoprene-based (Fletcher 1971)). The basic chemical composition of neoprene synthetic rubber is polychloroprene (Fig. 6). The polymer structure can be modified by copolymerizing chloroprene with, for example, 2,3-dichloro-1,3-butadiene to yield a family of materials with a broad range of chemical and physical properties.

They also produce highly flexible joints, providing excellent resistance to peeling. In general terms, the elastomers only display their elastic properties after having been vulcanized. In the case of polydienes, especially (polybutadiene, polyisoprene, neoprene, styrene-butadiene copolymers (Stricharczuk and Wright 1977), etc.), vulcanization occurs spontaneously on contact with the oxygen in the air as a result of a radical-based process or on contact with vulcanizing agents such as sulfurs or phenols.

**Fig. 7** Nano-organization of semicrystalline thermoplastic elastomer

**Fig. 8** Chemical structure of poly(styrene- b-butadiene- b-styrene)

The thermoplastic elastomers (Legge et al. 1987) have the advantage that no vulcanization is required since the cross-linking points are provided by the thermoplastic micro-domains (in the order of 20–40, up to more than 500 nm in diameter), formed due to the non-miscibility of the two phases, elastomer and glassy (Fig. 7).

The thermoplastic elastomers, i.e., poly(styrene- b-butadiene- b-styrene): SBS (Fig. 8) and poly(styrene- b-isoprene- b-styrene): SIS. For a long time, the patent

belonging exclusively to SHELL (Holden and Milkovitch 1966) are now produced by various suppliers and have found highly diverse applications as Hot-melt or Pressure-Sensitive adhesives.

The thermoplastic polyurethane elastomers (Chen et al. 1992) exhibit very similar morphologies to that of the SBS or SIS and, similarly to them, allow the characteristics of both phases, crystalline and glassy, to be combined. Polyurethane adhesives can also be classified in the “Adhesives implemented by Chemical Process” category that can induce certain confusion. To be consistent with our classification one must consider that two types of polyurethane-based adhesives can be commercially available: the ones that exhibit semicrystalline properties that can be implemented via a physical process, and the seconds with dormant reactive functions that can react via a chemical process to lead to a network.

Similarly, although most vinyl and acrylic type polymers could be used as the basis of solution adhesives, it would seem more appropriate to describe them as emulsion adhesives. Other polymers (polyesters, polyamides) would seem to be more appropriately categorized within the Hot-Melt adhesive class.

The impact of the organic solvents on the environment (toxicity, flammability, pollution) is now well known. But there are a large number of elastomer-based adhesives that continue to be essential, in such a way that their disappearance, although a reality for applications involving the general public, is not on the agenda in the sector involving self-adhesive products (tapes, films, labels, bandages, skin patches, etc.). The only obligation is to have in place systems for recovering the solvents and, as much as possible, for recycling.

### “Dispersion-Based” Adhesives

In theory, any vinyl polymer that can be obtained through radical polymerization can be prepared directly in emulsion form (Lovell 1997). However, the most common formulations are the polyvinyl acetate and acrylic emulsions.

While the polyvinyl acetate-based emulsions have multiple applications (office glues, wood glues, packaging industry, etc.), the acrylic emulsions are used mainly for the production of auto-adhesive films and tapes or for other labels (see PSAs part); their main value therefore lies in the large variety of formulations accessible (using variable composition copolymers) and in the good tolerance they demonstrate toward the plasticizers present in certain substrates (bonding of polyvinylchloride films for example).

The ability of the water emulsions to resolve the problems of safety and protection of the environment, combined with the inherent problems associated with the use of dispersions, is leading to highly active research, both theoretical and applied. We are now able to master to a greater and greater extent:

- “Core-shell” materials, which are molecular objects combining flexible polymer cores and rigid shells (sometimes the opposite)
- “Micro-encapsulation” of various substances, finely dispersed, in polymer shells
- Emulsion “creaming,” which increases the stability by increasing the viscosity and which aims to increase as much as possible the dry final content

- The emulsification of various polymers, starting from their organic solutions or even in “molten” phase

On the other hand, there is still work to be done regarding:

- The emulsion stability with regard to “flocculation” – the speed of coalescence during application
- The elimination of the water
- The purity of the materials that come from polymers in emulsion
- The cost price, paradoxically much higher than that of corresponding formulations in solution.

Surfactants, which are essential during polymerization in emulsion or for emulsification, can have a very harmful effect on the durability of certain bondings. They illustrate very well the problem caused by the surfactants present in the joints (as well as remains of initiators or transfer agents, photo-sensibilizers, plasticizers, etc., in relatively great proportions: 1% by mass correspond to amounts of the order of 1,000% in terms of molar fraction, which explains the sensitivity of the materials to the presence of such “remaining chemical species”). For the surfactants, the poor performance of bonded joints exposed to the “humid cataplasma” test, which gives a picture of the resistance to ageing through humidity (used particularly in the car industry), significantly limits the development of “exterior” uses for emulsion adhesives. As a result, there is still very active research into the “neutralization” of surfactants in joints (for example, via the use of “surfmers” capable to polymerize).

### 14.3.2 Solid Phase Adhesives: Hot-Melts

For the adhesive to be capable of wetting the surface of the substrates, bonding must occur at a temperature greater than the melting point temperature. Using semicrystalline-based polymers, “Hot-Melt” adhesives are thus developed (Landrock 1985).

The “melting” of certain thermoplastic polymers, which often corresponds to a softening (going beyond the flow threshold) due to the application of heat, is a reversible phenomenon. Thus a solid adhesive mass, deposited using a hot-melt gun, can “set” while cooling down. Three types of compounds are representative of “Hot-Melt” adhesives: the ethylene vinyl acetate (EVA) copolymers (Fig. 9), the polyamides (referred to as “food adhesives”), and the polyesters (tend to be reserved for high temperature applications).

A concern for obtaining bonded assemblies that are resistant to high temperatures, but that remain “modifiable” has led to research aimed at developing more thermostable thermoplastic adhesives. Bonded joints that are reversible at high temperatures have already been obtained with the following types of compounds: polyether ether ketones, polyether sulfones, etc. Melt viscosity, one of the most important properties, influences the spreading of the adhesive and the wetting of the surfaces is

**Fig. 9** Chemical structure of ethylene vinyl acetate (EVA) copolymers

**Fig. 10** Chemical structure of polyamides –  $x$  is the number of methylene units that can affect the viscosity and the melting temperature

governed by the ratio between polar and nonpolar moieties. The design of polyamide (Fig. 10) or polyester backbones may give the appropriate properties: flexibility of the joint as well as low viscosity for an easier spreading.

One major drawback for this adhesive family is the lack of adhesion with the substrates. Generally speaking, one considers that a competition occurred between the maintaining of interfacial interactions that have been created during the bonding step and the developing of inter-macromolecular interactions due to the crystallization during the cooling-down step. This competition improved the lack of adhesion described by users.

## 14.4 Adhesives Implemented Via a Chemical Bonding

Conceptually, the AICPs are polymer precursors. They illustrate well the dichotomy between:

- Adhesive (liquid state and chemical activity in order, on the one hand, to ensure wetting of the substrates [by establishing with them adhesive interactions], and on the other hand to allow the formation of the joint through polymerization)
- Joint (solid state and chemical inertness in order to ensure the mechanical soundness and the durability of the assembly).

Because the synthesis of a linear polymer in situ is not of much value compared to the physical bonding of this same polymer, AICPs are really more three-dimensional network precursors. They are the products that are associated with the idea of structural assembly.

The capacity for the AICPs to wet the substrates is generally not a problem. The questions that arise relate more to the cohesion development processes, through polymerization. The two alternative approaches, step-growth polymerization (condensation or addition processes) and chain-growth polymerization, have to be conducted in an “undefined” reactor, unstirred, open (in contact, except in specific situations, with the air and humidity), without the possibility of recovering and possibly recycling the reagents or the light products, etc. The options available (excluding specific installations) are therefore limited, in the case of step-growth polymerization to total condensation reactions (without the formation of secondary products), preferably self-catalyzing, and in the case of chain-growth polymerization to free-radical chemistry.

Within these limits and as long as the basic rules of macromolecular synthesis are respected, the chemistry of bonding is a process “that works well.” The main reason for this is its nature, involving a thin film process, which allows it to regulate its own temperature (substrates serving as radiators) and which benefits from the very high degree of reactivity of the outer surface of the solids. Surface treatments that consist of grafting short chains with end groups of the same nature as the adhesive’s constituents are excellent ways of organizing this reactivity.

#### 14.4.1 General Principles Underlying the Use of AICPs

The first problem involved in chemical bonding is the competition that exists between adhesion and polymerization, which is caused by the need to initiate the polymerization process, by mixing the reagents, before the coating of the surfaces of the substrates to be assembled. Most of the methods for applying the AICBs aim to respond in the best way possible to the two conflicting imperatives: the creation of interactions strong enough with respect to the needed performance and the building of the polymer backbone. They essentially concern the activation of the reagents in conditions that respect the rules of macromolecular synthesis and that, at the same time, allow any operator to “do chemistry” without knowing it.

#### Polymerization Initiation – Temperature Effects

The processes vary intrinsically in terms of speed. Some can be accelerated, using catalysts. But all of them tend to slow down as they progress due to the decrease in concentration of the reagents and to the significant increase in viscosity (in such a way that the kinetics are often controlled by the diffusion of the reagents, which is very slow). Generally, viscosity and concentrations in the reactive phase cannot be kept constant (except in the case of a joint with a constitution that is completely non-miscible). To compensate for the slowing down process, the polymerizations can be completed by raising the temperature during the “post-curing” cycles (hence the label “thermal hardening”) that is applied to adhesives as well as to polymers. People need to understand how to vary the viscosity, the molar masses of polymer backbones, the cohesion with the rate of polymerization, and the overall percentage of monomer conversion. For that purpose, an interesting approach proposed in the

early 1980s (Guilham 1983) consists in the building of a “phase diagram,” i.e., a simplified time-temperature-transformation TTT diagram, that shows the evolution of  $T_g$  and the visco-elastic behavior versus the time (equivalent to the conversion). The time of gelation can give interesting information on the window in which adhesive is still processable.

### Relative Proportions of the Reagents

For chain-growth polymerizations, the initiators represent only a few fractions of a percentage in comparison with the monomers or prepolymers; it is difficult under these conditions to achieve homogenous mixtures according to target. Other difficulties occur as a result of the presence, at the surface of the substrates, of impurities that can act as inhibitors (acid traces that can improve transfer or termination reactions) or, on the contrary, as accelerators (very fast reaction speeds, which equate to low levels of polymerization, limiting the work time available, in a way that is sometimes highly problematic in the context of industrial applications, and not allowing the formation of joints with satisfactory cohesion). Initiation via electromagnetic radiation (photo-initiation, “ionization” with X-ray or electron beams) allows, in theory, the “adhesive setting” speeds to be managed. But it is not universally applicable for technical reasons (UV initiation is not possible in the case of nontransparent substrates, something that is fairly common), or for combined technical and economical reasons (cost and limited access to installations using ionizing radiation).

For step-growth polymerizations, it is necessary to respect the stoichiometry between the number of reactive functions of each of the two partners, bi- or multifunctional, involved in the reactions following Carother’s assumptions (Carothers 1936); even a slight imbalance leads to the formation of joints that are not properly polymerized, i.e., molar mass not large enough, with poor cohesion. To avoid bonding errors, the “two-part” formulations come in dual body systems that are equipped with static mixers; the two parts have distinct colors, so that a visual check can be made to ensure they are properly mixed. “One-part” systems involve either processes where the initiator or the reagent is an atmospheric agent (oxygen, humidity), or systems where the initiator, the catalyst, or one of the reagents has been hidden (latent initiator in the case of anaerobic adhesives, crystallized polyamine in the case of “high temperature” epoxy adhesives, hidden isocyanates in the case of polyurethane adhesives, etc.). Based on these systems, “pre-impregnated” tapes or tissues are particularly convenient, to the extent that with these, the users are likely to forget fundamental rules of use, for example, the necessity to store the “one-part” formulations at a low temperature ( $-15\text{ }^{\circ}\text{C}$  to  $-18\text{ }^{\circ}\text{C}$ , typically).

### 14.4.2 Step-Growth Polymerization AICPs

These represent the class with the most types of adhesive, for the most part identified with structural assembly products. Two groups can be distinguished, depending on whether the polymerization is accompanied by the formation of water (which needs to be steadily eliminated) or whether it involves the formation of the polymer only.

### Polymerized Adhesives with Elimination of Water

Aminoplasts (urea formol, melamine formol, and MUF: melamine urea formol) and phenoplasts (phenol formol) have been known about for a very long time and are used as binders in pressed wood panels, as adhesives in plywood panels, and as “coating agents” for paper and cloth (Robins 1986). They are characterized by their reasonable cost and, especially, by their excellent performance in extreme temperatures and fire (the aminoplasts are self-extinguishing in air at atmospheric pressure). The production of the polymer lattices occurs in several stages, passing through intermediary stages such as methylolurea or methylolmelamine and, for the phenolic glues, RESOL issued from acidic conditions or NOVOLAC from basic conditions (Fig. 11).

The intermediary stages often constitute the base components of the adhesives, with the subsequent condensation (still associated with the elimination of water

**Fig. 11** Chemical structure of formo-phenolic resin precursors

**Fig. 12** Schematic representation of a formo-phenolic network

at high temperature up to 200 °C), leading to complex three-dimensional networks (Fig. 12).

Having been somewhat eclipsed in the past, the phenolic adhesives are benefiting from renewed interest, which is linked to their heat stability and fire resistant characteristics, as well as to their compatibility with a large number of other polymers. The formo-phenolic precursors are “hybrid adhesive base components of choice that lead to interpenetrated polymer network-type joints (“IPN” epoxy–phenolic) or semi-interpenetrated ones (elastomers–phenolics), characterized by an excellent resistance to shocks, to vibrations and to shearing stresses” (Robins 1986). The characteristics of the phenolic glues means that they can be used in areas where no other adhesive can compete with them: break-pad assemblies, coating of abrasive substances to their support material, assembling of molds in foundries, bonding of surface panels and edges in furniture manufacturing, aeronautical equipment, etc. There are, however, limits to their applications, relating to the difficulties involved in applying them (elimination of water and heating necessary), their unpleasant odor, and their possible toxicity especially the degradation products.

### Full-Condensation Adhesives

These are high performance adhesives, used in small quantities, for “top of the range” applications that are emblematic of structural-based assembly.

#### Epoxy Adhesive (Wright and Mugge 1986)

Most of the epoxies are heat hardening adhesives, where cross-linking achieves high degrees of advancement only after heating (“curing”) at temperatures as high as 200 °C. Their components are more or less complex prepolymer resin-based mixtures, generally fluid, of type DGEBA: diglycidyl ether of bisphenol acetone (condensation product of epichlorohydrine of the glycerol on the hydroxyls of the bisphenol A, itself a condensation product of two molecules of phenol and one molecule of acetone) (Fig. 13).

**Fig. 13** Chemical structure of diglycidyl ether of bisphenol A (DGEBA)

**Fig. 14** Most common chemical reactions involving epoxies: addition of amine ( $\text{RNH}_2$ ), addition of alcohol ( $\text{ROH}$ ), or addition of alcohol in presence of anhydride

The epoxy adhesives produce, with limited contraction, joints whose main characteristic is an absence of creep at high temperatures (mechanical strength is maintained up to temperatures of 100–150 °C). Epoxy groups exhibit a high reactivity with many antagonistic functions, mainly amines, but also alcohols, anhydrides, and carboxylic acids (Fig. 14).

When you add to this quality a high degree of cohesion (linked to the density that the three-dimensional lattice can achieve in the case, for example, of the polyamine-type hardening agents), which allows thick joints to be achieved and therefore the remediation of surface faults, good adhesiveness on a very diverse range of materials (combined with potential reactions of active sites of surfaces with the oxiran groups and with the reconstitution of a polar hydroxyl group each time one of these rings opens) and a great deal of inertness with regard to humidity and to chemical agents, it is understandable that the epoxy adhesives represent the classic structural (and even thermal-structural) adhesive.

For the “low temperature” epoxies (“setting” at between 0 °C and 50 °C), two-part formulations, the hardening agents are di- or polyamines (diethylene-triamine, for example). For the “high temperature” epoxies (“setting” at above 100 °C), one- or two-part formulations, the hardening agents are acid anhydrides (in the presence of tertiary amine catalysts), resols or novolacs (also in the presence of tertiary amine catalysts) or crystallized polyamines, insoluble in the oligomer except after melting (at a high temperature) (Wright and Muggee 1986).

The diversity of the range of epoxy adhesives, linked to a multitude of base constituents, hardening agents, and catalysts available, is increased by the possibility of formulating numerous hybrid adhesives (with the polyamides, the acrylics, the polysulfurs, the phenolic adhesives). You can find suitable epoxy adhesive formulation for virtually any glue-based assembly problem. This applies equally to conducting glues in microelectronics, to high thermal stability adhesives in space construction, and to “for all time” adhesives for the repair of works of art.

The excellent reputation of the epoxy adhesives is justified, and their applications in industry and at home are without question. But they can also be penalized because they are too high quality. Indeed, “indestructible” joints are in contradiction with the present need for recycling of materials, and as a result current research is aimed at finding tools to manage deterioration of the epoxy adhesives, rather than at improving them.

### Thermo-Structural Adhesives

Intended for limited “high performance” applications, the thermal-structural adhesives are the adhesives of the aeronautics and aeroballistics industries, where specifications are expressed in duration of resistance (maintenance of the majority of the mechanical properties) at a determined temperature, such as those decreed by the American Space Agency:

- Between 150 °C and 260 °C: several 1000 h
- Between 260 °C and 320 °C: several 100 h
- Between 320 °C and 350 °C: several tens of hours
- Above 350 °C: between a few hours and a few minutes (1 h at 535 °C; 5 min at 815 °C).

Besides the epoxies and certain phenolic adhesives, some compounds have gone beyond the stage of secret application (polybenzimidazole, polyimides (Fig. 15), polyarylsulfones), but in most cases, the formulations are adapted by the users (secretly in general) to specific problems.

We can, however, note that an adhesive intended for thermal-structural applications has a prepolymer with a thermostable structure as a base component, which will carry chemical functions that will allow its cross-linking (as widely as possible) at a high temperature. The main difficulty involved relates in fact to the small difference in temperature (“processability” range) between the softening of the prepolymers and the cross-linking reaction: typically 30° between 130–160 °C and 160–190 °C.

**Fig. 15** Chemical structure of LaRC-TPI (Linear Aromatic Condensation-Thermoplastic Imide) (Bell et al. 1976)

**Fig. 16** Chemical structures of toluene diisocyanate (a) and diphenylmethane diisocyanate (b)

### Polyurethanes (Chen et al. 1992)

Due to its richness and diversity, this class of compounds, that results from the polycondensation of di- or multi-isocyanates and of di- or polyols (of di- or polyamines the case of the polyureas), is one of the hardest to place in a classification. Indeed, polyurethanes are just as much elastomers, presented in solution, possibly in emulsion or in the form of structures that are self cross-linking (through atmospheric humidity), as they are structural adhesives, where the polymer networks are obtained from two-part and one-part formulations (with hidden isocyanate functions).

In the case of the elastomers, formulations that use diisocyanates (Fig. 16) and mixtures of long diols (oligomers of polybutadiene, polycaprolactone, or polyoxyethylene) and short diols lead to thermoplastic elastomer behavior, with physical cross-links (rigid sequences) finding themselves associated, dispersed in micro-domains, with a continuous elastomer phase (flexible sequences).

A certain degree of cross-linking can be obtained by using oligomers or triol-like extenders, but the three-dimensional polyurethanes tend rather to be produced in situ from formulations with two parts: prepolymers diisocyanate-diol oligomer (average degree of polymerization that does not exceed 3–5 with isocyanate chain ends) firstly, and secondly, primary diamine-type chain extender. The high degree of reactivity of the amine functions (and also the amide) with the isocyanates allows cross-linking to occur in short periods of time. In the presence of humidity, the diisocyanate-diol oligomers can be used as one-part formulations. Indeed, the action of water gives carbamic acid that decarboxylises spontaneously into primary amine, which reacts immediately with isocyanate groups (faster reaction than that involving water) causing the cross-linking (Fig. 17).

**Fig. 17** Schematic representation of the reaction of isocyanate groups with water

One-part polyurethane adhesives can also correspond to prepolymers with isocyanate functions blocked reversibly (due to reaction with oximes, phenols, etc.). The isocyanate groups are then regenerated, either by heating to a more or less high temperature, or by substitution of the blocking agent by a diol (oligomer, at least partly) (Fig. 18).

The reactivity of water with isocyanate functions, used to produce polyurethane foams (“foaming” from released  $\text{CO}_2$ ), can be a real disadvantage for the adhesive formulations since the reactions with water are in competition with the reactions with diols leading to poor performing joints due to an incomplete polymerization.

### Polymerization Through the Action of Atmospheric Agents

The cross-linking of the polyurethane prepolymers through the action of humidity is an example of adhesive – joint chemical transformation where one of the reagents involved is an atmospheric agent (Fig. 17). Another example involves the silicone adhesives, where water plays a catalytic-type role (in the sense that it is permanently regenerated).

### Silicone Adhesives (Owen 2004)

Due to their very weak surface energy, which allows them to completely wet virtually all substrates, but which then prevents their own wetting by virtually all the adhesives, the silicones are considered, rightly, to be anti-adhesion agents; they are often used as mold release agents. But silicon-based formulations are also used, increasingly, as specific adhesives, especially for applications requiring good performance at a high temperature (oven door windows) and as sealing agents (headlamp assemblies for the car industry). Vulcanization occurs through the action of humidity for the “one-part” formulations, with polydimethylsiloxane oligomer carrying hydrolysable end groups as base components. Hydrolysis releases the “blocking” group, explaining, for example, the release of acetic acid that is characteristic of certain formulations. The spontaneous dehydration of the silanol groups causes the cross-linking while, at the same time, regenerating the water necessary for the hydrolysis of new groups (Fig. 19). The process then carries on gradually.

Cross-linking, at high temperature, of the “two-part” formulations is not related in any way to the action of humidity. The basic process is an addition on an

**Fig. 18** Mechanism of deprotection of oxime-functionalized polyurethanes

unsaturated site, which depends on the presence of catalysts. This leads to formulations that are difficult to use, and there is a tendency to replace these with silicone-acrylate type adhesives (polydimethylsiloxanes  $\alpha,\omega$ -acrylate), just as effective but easier to use. The problems associated with use do not arise with the humidity cross-linking formulations. But with these formulations, the operating conditions are neither easy to master (too much water can have a very negative effect), nor are they conveniently reproducible.

#### 14.4.3 Chain Polymerization Adhesives

The typical image of the “polymerizable” adhesives is provided by the structural acrylic adhesives, which include several classes, but which are all bi- or multi-acrylic monomer based.

**Fig. 19** Schematic representation of cross-linking reactions of polydimethylsiloxanes

### “Structural” Acrylics

The chemical reaction leading to the joint is a radical polymerization, initiated by a peroxide (or an azonitrile) or, when it is possible, by electromagnetic radiation (polymerization under UV, polymerization under radiation, etc.). In the second case, the formulations, one-part type adhesives, do not pose any storage problems (stable in the absence of the initiator) and are easy to use (presentation as liquids, pastes, impregnated films, etc.). In the case of the chemical initiation, the formulations are two-part-type adhesives, the dissymmetry between the quantities is mitigated by mixing the initiator together with the additives and fillers (copolymers acrylate-methacrylate, notably). In this case as well, it is easy to use.

Flexibility of use is a major benefit of the acrylic adhesives in applications such as structural assembly. It allows them to be applied to a very diverse range of materials, in difficult climatic conditions (bonding in water or repairing concrete structures in winter). Performances (sufficient mechanical strength and flexibility) are similar to that of the epoxy formulations, especially since the appearance of the second generation structural acrylic adhesives: hybrids consisting of elastomer nodules distributed throughout the acrylic network. Compatibility is thus ensured by a grafting of the polymethacrylate chains on to the elastomer chains, achieved in situ by using a solution of elastomer in the monomer.

### Bonded Joints Obtained by the Action of Atmospheric Agents

Oxygen in the air, whether in combination with light or not, is capable of causing cross-linking of certain elastomers (dienic polymers and copolymers with residual

double-bonds). Similarly, the polysulfur type adhesives (“thiokols”) are vulcanized by oxygen. However, in both cases, the processes cannot be controlled and no optimization is possible. The situation is different with the particular acrylic formulations made up of the cyanoacrylate adhesives and the anaerobic adhesives.

### Alkyl Cyanoacrylate Type Adhesives

The electron depletion of the site unsaturated by the nitrile and carboxyl groups is such that a process of anionic polymerization can be initiated, at room temperature, simply by traces of humidity (Fig. 20).

Polymerization then occurs very quickly, requiring that major precautions must be observed when this type of adhesive is applied (instant adhesion to the moist skin, but polymerization can be prevented from occurring by immersing in water). The adhesive power of the cyanoacrylates is very strong, although their cohesion is weak (they are linear polymers); this implies that bondings should be done using the thinnest films possible. Under these conditions, almost all materials can be bonded; the assemblies are strong, but they are sensitive to shocks (they can be made more flexible by combining ethyl and butyl cyanoacrylates with methyl cyanoacrylate, the base component of the formulations) as well as ageing under the effect of humidity.

The use of cyanoacrylates does not pose any sensitive problems, whether in automated industrial applications, that use formulations which are often very fluid, or in “household” applications, for which there are more and more gels with slightly longer “setting” times. However, the use of the cyanoacrylates requires, more than that of any other type of adhesive, the understanding of a few principles of chemistry. Thus, the application of cyanoacrylate glues on to “activated” metals or cleansed of fatty residues using PLASMA, LASER, or CORONA treatments (the effect of all of which is to completely dry the surfaces) leads to failures, often not properly explained. The same thing is true for bonding attempts on surfaces that have undergone “acid” treatments before the bonding step, since the anionic polymerization of cyanoacrylate is not compatible with the presence of electrophilic substance residues.

**Fig. 20** Chemical structure of polycyanoalkylacrylate  $n$  is the number of methylene units  $-\text{CH}_2-$

### Anaerobic Adhesives

These are oligomer dimethacrylate based formulations containing latent initiating systems (hydroperoxides in the presence of donor–acceptor systems, of the benzosulfimide type (saccharine) – di-methyl- p-toluidine) that are inhibited as long as they remain in contact with the oxygen in the air.

Away from it and when in contact with certain metal ions (iron and copper in particular), the radical polymerization occurs spontaneously, giving mechanically strong three-dimensional lattices. The anaerobic adhesives are used for the creation of mechanical assemblies (to seal or immobilize nuts) and gaskets (cylinder head gasket); they can be used in relatively thick coats. In this last case, they are capable of tightening up assemblies and behaving as an anti-corrosion barrier.

## 14.5 Pressure-Sensitive Adhesives – PSAs

Pressure-sensitive adhesives (PSAs) (Creton and Fabre 2002), “soft” visco-elastic solids that are able to develop adhesive interactions instantly with the pressure of a finger (exerted on the rear of the material being affixed), are generally applied at room temperature.

These polydiene-, polyacrylate- or silicone-based adhesives are generally formulated products (with waxes in order to lower the glass transition temperature, and tackifying resins to provide tack), used as self-adhesives, coated to materials such as paper, films, and polymer tapes, etc. The term Pressure-Sensitive Adhesive relates to the fact that pressure from a finger on the rear of the material to be affixed is all that is required in order to allow the adhesive mass to wet the substrate sufficiently and to adhere to it more or less strongly. Depending on the visco-elastic properties and the adhesion forces developed at the interface, various behaviors can be reached from nonpermanent in the case of Post-it<sup>®</sup> to semipermanent in the case of dressings.

The description of the behavior of the PSAs take into account the instantaneous adhesion ability as well as the cohesion developed during the separation of the substrates (for example, by peeling) with or without leaving residue. This property is called tack and can serve to describe, for example, the behavior of the repositionable adhesives. Polyacrylates are good examples to illustrate what kind of chemical structure can provide basic tack properties (Fig. 21).

The molar mass, the molecular distribution, the chemical nature of the monomer units, their distribution on the polyacrylate backbone will govern the raw-visco-elastic properties as well as the capacity to create more or less strong interaction with the surface. This behavior will be deeply discussed in ► Chap. 15, “Pressure-Sensitive Adhesives (PSAs).”

## 14.6 Conclusion

A presentation, even in organized and summarized form, of the famous classes of adhesives reveals the considerable diversity of applications that can be proposed for most compounds. When faced with a problem with an assembly, there is normally a

**Fig. 21** Schematic representation of acrylate-based monomer units with various properties

clear optimum solution in terms of the geometry of the joint or the preparation of the surfaces, but there are always several credible answers in terms of the choice of adhesive. Each one has advantages and disadvantages, in such a way that the solution to these problems is often sought in the multiple basic properties of adhesives that all differ in nature. If in the past, technical solution to enhance the bonding performances have been provided by playing with the composition of basic polymer structures, the effort achieved in the polymer science especially in the macromolecular engineering are capable of offering an approach to design multi-functional oligomer molecules, that can associate complex backbone architectures with alcohol, amine, isocyanate, acrylate, or epoxy reactive groups controlled in terms of distribution or concentration; the approaches to “chemical hybrid” adhesives are tending to grow and grow leading to a more complex adhesive classification. The “classical” routes of formulation adds to this richness by giving access to “physical hybrid” adhesives, in such a way that in order to find increasingly high-performance adhesives, one is not relying so much on the discovery of new molecules anymore, but on the right combination of systems, macromolecules, or groups already discovered.

Under these conditions, a chemist’s approach to polymers allows a specific solution to be offered to virtually any assembly problem. Whether this solution will be applicable or not depends afterwards on the correlations between structural and morphological characteristics of the raw polymer materials, physical properties, the mechanics or thermo-mechanics of the formulations, and the characteristics of the joint (via the characteristics of the assemblies). In this regard, we know that:

- The intrinsic properties of the raw components have less influence on the behavior of the adhesives and the joints than the formulation parameters.
- The usage conditions of the adhesive formulations can be the key elements of their behavior.

It is on this last point that one should probably focus: both the academic research aiming to understand the adhesion phenomenon, and the applied research on optimal

and reproducible performance of the adhesives. It is on this basis also that one can ask, going beyond current industry trends and developments, about the principles behind the development of future adhesives:

- Able to preserve the environment (and thus releasing neither volatile solvents, nor unfixed surface active agents)
- Free of industrial and toxicological risk (and therefore negligible volatility, nonexplosive, low combustibility, and also insoluble in water, all of which characteristics are presented by most of the  $\alpha,\omega$  -functionalized oligomers)
- Convenient to use (and so behaving like the AIPPs, but able, through heating or through some other stimulation, electromagnetic, for example, to achieve the three-dimensional structure, with strong cohesion, of the AICPs)
- Able to give strong assemblies, possibly structural and durable (with a premium given to systems with durability that is predictable and, if possible, manageable)
- But also allowing the “repair” of the assemblies as well as the recycling of the materials assembled (the bonding reversibility achieved with certain PSAs is obviously not possible for the structural assemblies performed with AICPs; the solution is, therefore, either to bring about the deterioration of the lattices, thus lowering the cohesion of the joints, or to “invent” a way to disrupt the interactions between joints and substrates).

---

## Appendix

Main ideas can be reached using former published books and handbooks in which readers can obtain an overview on the science of adhesives in Polymer synthesis, P. Rempp, E.W. **Abstract**

The basic concepts, formulations, and test methods of pressure-sensitive adhesives are presented. The importance of interfacial interactions, viscous loss, and extensibility is stressed. The common rheological tests are described, and the equivalence of deformation rate and test temperature is emphasized. The much

longer time scale for bond formation versus the rate of deformation upon debonding in peel or tack is exploited by the formulator to optimize properties. The formulation principles and common ingredients for preparing acrylic and rubber-based adhesives are described, and the performance capabilities of these two types of pressure sensitives are contrasted.

---

## 15.1 Introduction

Pressure-sensitive adhesives (PSAs) are ubiquitous. They are the adhesive of choice for most office applications and for many industrial assembly operations. Consumer applications include common office tape (Scotch<sup>®</sup>), masking tape, packing tapes (for case and carton sealing), sticky notes (Post-it<sup>®</sup>), postage stamps, medical bandages or plasters (Band Aid<sup>®</sup>), and paper labels. Industrially, pressure sensitives are used for most product labels, decals and commercial graphics, protective and tinting window films, and two-sided tapes are used for a variety of product assembly applications such as the bedding of windows into their frames and the assembly of multilayered panels for semi-structural walls. (Scotch and Post-it are registered trademarks of 3M company. Band Aid is a registered trademark of Johnson & Johnson Corporation.)

Pressure-sensitive adhesives are unique in that they form a strong bond with only finger pressure. They exhibit this immediate grab of a substrate (also called “tack”) *without* the need for activation (e.g. heat, water, solvent, etc.). What distinguishes a pressure-sensitive adhesive from other merely “tacky” materials such as molasses or peanut butter is that they have adequate cohesion to hold the bond they form during service, i.e., labels do not slide around on bottles, packing tapes cannot be removed without tearing the cardboard, etc. Pressure-sensitive adhesives are solids. What gives these solids tack? In a word – *softness*. A solid which is soft enough will be tacky, and if it has adequate cohesion, it can be used as a pressure-sensitive adhesive. The demarcation line for adequate softness was discovered by Dahlquist (1966) and is discussed below.

---

## 15.2 Tack and Adhesion

### 15.2.1 Tack: Soft Enough for Rapid Wet-Out

To enable rapid and intimate wet-out of a surface by a film of adhesive requires only that it be sufficiently soft. Dahlquist found that materials with a dynamic shear modulus (stiffness) of less than  $3 \times 10^6$  dynes/cm<sup>2</sup> ( $10^5$  Pa) when deformed in 1 s will exhibit “tack.” When the application requires tack to develop either faster or slower than in a typical finger pressure test, the criterion will obviously be shifted – to higher stiffness values for longer dwell times and lower values for shorter ones or rougher surfaces. Nonetheless this simple criterion provides critical guidance for developing new pressure-sensitive adhesives. Note that nothing about the composition

of the material or the substrate is needed. All materials exhibit tack if made soft enough. The level of tack, however, will vary widely depending on the other characteristics of the material and substrate as described in more detail below.

15.2.2 Bonding: Driven by Molecular Interactions (and Air Elimination), Resisted by Entropy Loss, and Delayed by Viscosity

The Dahlquist criterion says simply that if an adhesive is soft enough, it will bond rapidly when deformed against a substrate with light pressure, and it will maintain this bond when the pressure is released and thus resist debonding with a force known as the tack force. Why does the adhesive not debond spontaneously when the pressure is released? The bond is maintained by the molecular interactions developed across the interface between the adhesive and substrate. These may be strong, such as hydrogen or ionic bonding, or they may be weak van der Waals forces, but they are always stronger than the interaction of the adhesive and substrate with air – which is roughly 1/1,000 as dense as any solid material. Thus any molecular interactions between adhesive and substrate are preferred to air (virtually no interactions).

The strength of the bond that develops depends on many factors, firstly the strength of the molecular interactions. Many acrylic adhesives, for instance, contain acrylic acid groups, and these are known to provide strong interactions with glass, inorganic, and metallic surfaces, since most of these are basic or amphoteric (Pocius 2002). The strength of the bond thereby increases with time as these acid groups find the substrate surface (see Table 1). In addition, while 1 s of finger pressure may

**Table 1** Properties of commercial pressure-sensitive adhesives at 25 μm thickness on a 50-μm-thick PET (polyethylene terephthalate) backing film

70 °C testing used the same weight, but with a 25-mm-high and also 25-mm-wide overlap  
SAFT testing used the same configuration as at 70 °C, but the temperature was ramped 2.8 °C/min until failure. With the SBC sample, the weight was 500 g instead of 1 kg  
<sup>b</sup>50-μm-thick coating

provide wet-out, it is unlikely to be complete, especially if the substrate is rough and/or the adhesive layer is thin. The adhesive will try to continue to wet out the surface but will be slowed by the creep viscosity of the adhesive and inhibited by the entropy loss associated with deforming the polymer network in the adhesive layer. Pressure-sensitive adhesives gain their cohesion from polymer entanglements and crosslinking, but these same features limit their ability to wet out completely. There is a trade-off between the ability to build adhesion through more complete wet-out of the surface over time and the cohesive strength of the pressure-sensitive adhesive.

### 15.2.3 Peel Adhesion (Resistance to Debonding)

Why are pressure sensitives able to bond with minimal pressure but very difficult to debond? And what determines the level of resistance (force)? For one thing, thermodynamics drives bonding as air is displaced and thus must be overcome upon debonding. But more importantly, the time scales for bonding and debonding are quite different. The adhesive is given at least a second to bond (note Dahlquist criterion above) and often longer. However peeling or debonding involves much shorter time scales – typically about 0.01 s. It is this difference in time scale between bonding and debonding that is responsible for the high peel forces that can be obtained upon debonding.

The time scale for debonding may seem slow. Instrumented test frames typically pull the tape off the substrate at a standard speed of 2.5 mm/s (5 mm/s of crosshead speed). One watching the test would think it slow, but at the peel front of the adhesive, things are happening very fast. The time scale for adhesive deformation in the peel front is roughly the thickness of the adhesive/the speed of testing. For a typical 25- $\mu$ m-thick adhesive layer pulled at 2.5 mm/s, this is 0.01 s or 100 times faster than a typical finger bonding process. Because of this at least 100-fold difference in time scale between bonding and debonding, it is the viscoelastic properties that are critical for designing a high performance PSA. The ideal is an adhesive layer which is very soft and liquid like during bonding ( $\geq 1$  s deformation) for complete and irreversible wet-out but which should become much stiffer when deformed quickly (0.01 s) while remaining highly viscous and extensible to maximize the work done on the adhesive.

It is a common misconception that for high peel force an adhesive must be very strong. To the contrary, often weaker adhesives exhibit much higher peel. Peel force is a measure of the work done while removing the adhesive; its units are force/width of tape. This corresponds to the energy consumed on peeling per unit area of adhesive bond:

$$\begin{aligned}
 \text{Peel} &= \text{force/width} \\
 &= (\text{force} \times \text{distance peeled})/(\text{width} \times \text{distance peeled}) \\
 &= \text{energy consumed/area peeled}
 \end{aligned} \tag{1}$$

**Fig. 1** Peel force versus peel rate. For a given peel force, four peel rates are possible. The two with negative slopes are unstable since any fluctuation in peel rate will accelerate the crack to the next stable solution at higher peel rate. Most industrial adhesives are adequately crosslinked, either physically or chemically, so as to avoid cohesive failure in use

As the peel speed increases, the peel force generally also increases until it drops precipitously when the adhesive becomes very stiff and elastic at the pull speed (see Fig. 1). Since the failure is normally interfacial at all test speeds, yet the peel varies dramatically with speed and substrate (see Table 1), peel is clearly not a measure of the strength of the adhesive but rather of the work done on it under a particular set of conditions.

**15.2.4 Performance Test Methods and Variables**

A variety of tests have been developed and standardized. The details vary depending on the standards agency. Numerous customer-specific tests are also used. A comprehensive set of test methods are available from the Pressure Sensitive Tape Council (PSTC 2007). Usually polished stainless steel (S.S.) is employed as the substrate, but for specific applications, the actual substrate is often used instead. The backing is also important as its behavior under stress also contributes to the performance of the tape.

**Tack**

Tack is the force required to debond an adhesive after it has been bonded with low force for a brief time. Tack is also called “quick stick,” and the most common method is the uninstrumented “finger tack” – which is often the most important from a practical standpoint. Instrumented methods to characterize tack are numerous, but the most common are the rolling ball, loop tack, and probe tack methods. The rolling ball test (**PSTC-6**) is the least intuitive measure and the hardest to relate to actual use. A steel ball is rolled down an incline onto a tape of the adhesive at the bottom. The distance the ball travels along the adhesive before stopping is inversely related to its “tack.” The loop tack method (**PSTC-16**) takes a loop of tape, adhesive side

facing out, and brings it down onto a substrate, but not so far as to compress the loop entirely. The maximum bonding force is determined by the stiffness of the tape. The instrument then reverses and pulls the loop off of the substrate. The maximum force upon debonding is recorded as the loop tack value. The width of the loop is about 25 mm (1 in.) as is the width of the substrate, thus the contact area is roughly  $25 \times 25$  mm, and therefore loop tack is often reported in units of force/inch<sup>2</sup> or as force/inch width of tape. Probe tack is the most meaningful measure of tack. A cylindrical probe with a rounded edge is compressed briefly into the adhesive and removed (ASTM D-2975), much like one would do with their finger. The maximum force during removal is reported as the tack value. Probe tack is gaining popularity in usage with the advent of newer machines, such as the texture analyzer from Stable Micro Systems, which can measure the entire force displacement curve during the test.

Typically the tack level of the adhesive will increase with the thickness of the adhesive layer and show a maximum with testing temperature (see Fig. 2). Smoother substrates or those of higher surface energy show higher tack values.

## Peel

Peel resistance is a critical performance property (PSTC-101). The tape is bonded by first laying it down gently on the substrate, then pressing it twice with a standard weight roller (2 kg) moving at a standard speed (10 mm/s), and then allowed to stand for a specified time, which is commonly 20 min for initial peel and a week or more – perhaps at elevated temperature and humidity – for a measure of aged peel. The free end of the tape is gripped and the tape pulled off of the substrate at an angle by an automated tester with a load cell at a crosshead (grip) speed of 5 mm/s. Most common are peel tests conducted at 90° or 180° (most common; this is where the tape is peeled back on itself). The former generally yields higher peel values partly because at the same pull rate on the tape, the speed at which the peel front moves is twice as fast when pulled at 90° (this results because the bonded substrate is moved on a sled horizontally at the same speed as the crosshead moves vertically, in order to

**Fig. 2** Loop tack (N/25mm) versus temperature for a pressure sensitive adhesive based on a styrenic block copolymer

maintain the 90° configuration, whereas the substrate is fixed in the lower grip in the 180° test).

The peel test measures the work done on the entire tape. If the backing is stiff and elastic, such as polyethylene terephthalate (PET), no work will be done on the backing, and the peel force is unaffected. However, if the backing can also yield, such as aluminum, then the peel value will be increased in proportion to the work done. If the tape is curled or otherwise distorted after the test, then some work has been consumed in the backing. Even if the backing does not deform, its thickness can have an effect on the peel force since it changes the precise angle at the peel front which influences how the adhesive deforms and thus the work done on it. Peel increases with adhesive thickness, but not proportionately, provided that the whole adhesive layer becomes deformed during the test, which is usually the case. Peel also increases with peel rate until the peel becomes unstable and the force is no longer constant. This occurs as the peel rate crosses over the second maximum shown in Fig. 1. At this point a slip-stick behavior is observed and heard. With each “slip” of the bond, a snapping noise is emitted. The substrate will usually have thin lines of adhesive residue, equally spaced, remaining after the test from each sticking period during peel. Further increasing the peel rate increases the spacing of the stick lines and further lowers the average peel force.

As shown in Fig. 1, uncrosslinked adhesives can exhibit two maxima in peel force with peel rate. At slow peel rates, they will fail cohesively. When pulled sufficiently fast, their failure becomes adhesive, and the peel force drops but then rises with peel rate – as with crosslinked adhesives – until falling again when slip-stick failure occurs. Commercial styrenic block copolymer-based adhesives can exhibit high peel force cohesive failure at standard test speeds when bonded to high-energy substrates like polished steel.

## Shear

The shear holding power of pressure sensitives is low in comparison to other adhesives due to their softness and low strength. Thus, they are limited to low load applications. Failures can occur within the adhesive itself (cohesive failure) or through peel initiated by stress concentrations at the corners of the bond. Pressure sensitives are normally tested in static shear – fixed load – whereas most structural adhesives are tested in dynamic shear, fixed deformation rate (see ► Chap. 19, “Failure Strength Tests”). Two types of fixed load tests are most common: (1) time to failure at fixed load and temperature and (2) temperature of failure at fixed load and temperature ramp rate (known as the SAFT – shear adhesion failure temperature). The first of these gauges whether the bond can resist persistent loads in use, whereas the second provides a measure of the maximum use temperature. Shear bonds are made on clean polished stainless steel – identical to that used in peel and tack tests. The overlap depends on the test and customer requirements. The PSTC standard (PSTC -107) is 12 × 12 mm. The panel is tilted at a slight angle (2°) off of the vertical and away from the tape, to eliminate peel at the bottom edge of the tape (see Fig. 3). However, there are always peel stresses at the top edge of the tape. While shear loads are normally reported in units of force/area, the specific configuration of

**Fig. 3** Shear holding test with  $12 \times 12$  mm overlap bond (Reproduced with permission from the Pressure Sensitive Tape Council)

the bond is very important since it affects the magnitude of the stress concentrations and peel forces at the top edge of the bonded area. As much as an eightfold difference in shear hold time has been observed for the same nominal load/area by simply changing the dimensions of the overlap. This is much the same situation as with structural bonds, where doubling the length of a lap shear bond will not double the dynamic strength (failure load/bonded area). As with any adhesive test, failure analysis is the starting point for understanding how to improve the bond.

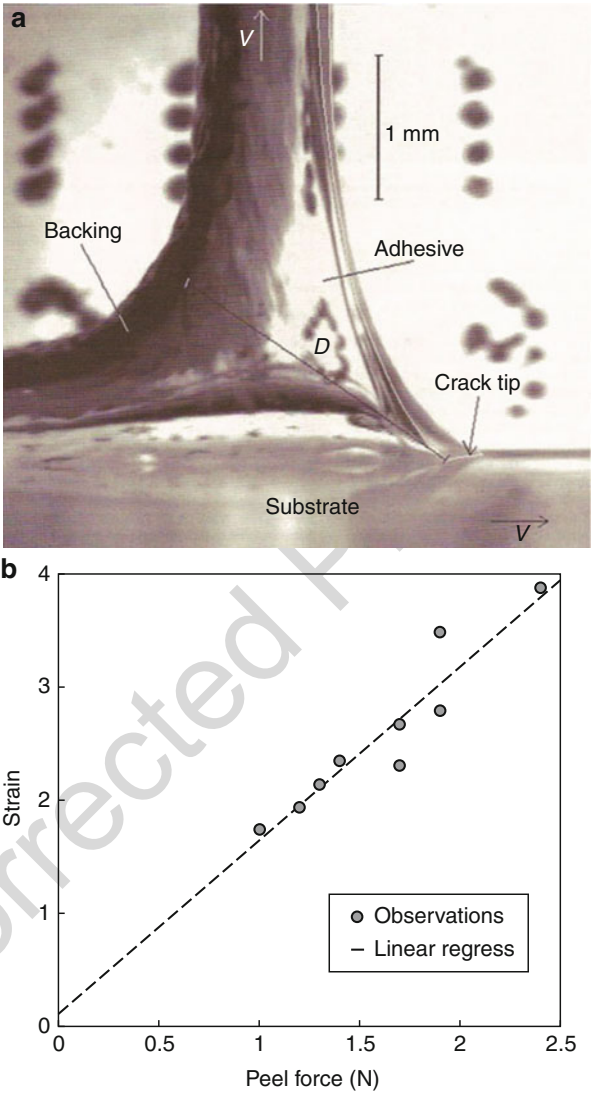

Typically, with lightly crosslinked materials, the shear failure is cohesive. This is also the case for physically crosslinked materials such as styrenic block copolymers, particularly at elevated temperatures. However, as the cohesive strength of the PSA increases and/or as the resistance to peel adhesion falls, the mode of failure will tend to switch to adhesive, normally initiated as a delamination from the substrate at the corners of the tape. As the delamination grows and the stress builds, failure can be rapid and catastrophic with the debond crack traveling interfacially, alternately along the substrate and the backing interface.

Thicker bonds fail more easily in shear whether adhesive or cohesive. For cohesive failure this is undoubtedly due to the narrower gap through which the adhesive is flowing. For adhesive failure, it is presumably due to an increase in peel forces at the top of edge of the bond.

### 15.2.5 Rheological Tests

The work consumed in deforming the adhesive (and backing) determines the peel force and shear resistance of the adhesive. Detailed observations of adhesive

**Fig. 4** (a) Side view of PSA tape being peeled at 90°. Note the extensive tensile deformation of the adhesive at the crack tip (Reproduced with permission from Christensen et al. (1998), copyright Elsevier). (b) Adhesive deformation (strain) measured optically versus recorded peel force (Reproduced with permission from Christensen et al. (1998), copyright Elsevier)

deformation during peel have shown that the adhesive is deformed in tension at the peel front (see Fig. 4a) and that the level of deformation can be as high as 1,000%. The peel force is directly proportional to the degree of deformation (see Fig. 4b). Thus the large deformation properties are critical to performance. Unfortunately, to measure the large deformation properties requires extensive testing since separate samples are needed for each test. Where this has been done, and the properties have then been used for finite element analysis of the peel process, good models have been generated. From a practical standpoint, such extensive testing and modeling are more burdensome than simply running the actual performance tests themselves.

Therefore, many have sought instead to correlate the low deformation, linear elastic, behavior of the adhesive with performance. With such tests, a single sample can be used to collect a vast quantity of data. These efforts have been very successful but still have their limitations, and pitfalls, inherent in the assumption that linear elastic properties can be used to predict nonlinear elastic properties.

In this section, the concepts of viscoelasticity and linear elasticity are introduced. Then the common rheological tests conducted on pressure sensitives are described, followed by examples of how these tests are used in practice.

**Linear Elasticity and Viscoelasticity**

As mentioned above, the tensile properties of pressure sensitives dominate their peel performance. The tensile stress-strain curve on pressure sensitives has a shape similar to pure rubber (see Fig. 5). The linear elastic region is the low strain region where stress is proportional to strain (the proportionality constant is the modulus), and the material will recover fully when the stress is released. Beyond this point, the slope first decreases substantially with strain, or effectively the adhesive softens. This softening blunts the cracks that form on debonding and enables the high strain necessary to obtain high peel by fibrillation of the adhesive. At sufficiently high strains, the adhesive again hardens as the molecules become completely stretched to the limit of their covalent bonds. The strain range over which linearity is maintained will vary greatly with temperature and strain rate. Ordinarily the linear region is below 0.05% in the glassy state (low temperature), a few percent in the rubbery region, and below 30% in the melt or flow region (see Fig. 6 and explanation below). These deformations are all far below what the adhesive experiences during peel.

The measurement of the linear elastic properties is normally done through oscillatory measurements where strain, frequency, and temperature are controlled.

**Fig. 5** Tensile stress ( $\sigma$ ) versus strain ( $\epsilon$ , in %) for a styrenic block copolymer based adhesive (Reprinted with permission from Hu and Paul (2009), copyright Taylor and Francis)

**Fig. 6** Modulus and tan delta versus temperature for a typical styrenic block copolymer-based adhesive (Reprinted with permission from Hu and Paul (2009), copyright Taylor and Francis)

If the material behaves perfectly elastically, then the stress recorded is in phase with the applied strain. If the material has no elasticity, but instead behaves perfectly viscously, then the recorded stress will be proportional to the strain rate, which is  $90^\circ$  out of phase with the applied strain, peaking where the strain is 0 in each sinusoidal cycle. Pressure sensitives are viscoelastic materials, and thus the recorded stress will peak in each cycle somewhere between  $0^\circ$  (in phase) and  $90^\circ$  (out of phase) with the applied strain. The tangent ( $\sin/\cos$ ) of this phase angle  $\theta$  is a measure of the relative viscous to elastic contributions to the adhesive's stress response. When a material approaches, its Tg "tan delta" (tangent  $\theta$ ) increases. The temperature at which tan delta reaches a maximum is very commonly defined as the material's Tg. The in-phase contribution to the stress ( $\text{maximum stress} \times \cos \theta$ ) provides the elastic modulus once divided by the applied strain. These experiments are normally conducted with parallel plate rheometers, and thus it is the elastic modulus in shear,  $G'$ , which is measured. The out-of-phase contribution to the stress ( $\text{maximum stress} \times \sin \theta$ ) yields the shear loss modulus,  $G''$ , when divided by strain. Note that these calculations are only valid in the linear elastic region where stress is assumed to be proportional to strain, and thus a single constant of proportionality (modulus) defines the material's response.

From such simple oscillatory measurements, a wealth of information is obtained. By scanning the temperature, a plot such as Fig. 6 is recorded. From this it can be determined: (1) the material should be tacky at room temperature ( $G'$  is below the

**Fig. 7** Styrenic block copolymer – based adhesive with various levels of UV-crosslinking: none ( $\diamond, \diamond$ ), low dose ( $\blacksquare, \square$ ), and high dose ( $\blacktriangle, \triangle$ )

299 Dahlquist criterion of  $3 \times 10^6$  dynes/cm<sup>2</sup>), (2) about 10 °C is the minimum tem-  
 300 perature at which the material will exhibit tack (very close to the T<sub>g</sub>), (3) the material  
 301 will begin to flow at about 105 °C (this is where tan delta = 1 ( $G'' = G'$ )) and thus  
 302 above this temperature it will behave more like a liquid (viscous) than a solid  
 303 (elastic)), and (4) if the T<sub>g</sub> has been optimized to maximize peel at the use  
 304 temperature (i.e., could the T<sub>g</sub> be increased without the peel becoming zippy?).  
 305 Comparing such curves is very useful. For example, the level of cure is easily gauged  
 306 by the magnitude of the modulus at elevated temperatures (see Fig. 7). When new  
 307 materials are added to the formulation or substituted for others, the effects on T<sub>g</sub> and  
 308 the rubbery plateau modulus are readily apparent. From rubber-elasticity theory, the  
 309 relationship between the  $G'$  in the rubbery region (see Fig. 6), the volume fraction of  
 310 polymer ( $V_p$ ), and the molecular weight between entanglements for the pure poly-  
 311 mer ( $M_e$ ) is

$$G'(\text{rubbery plateau region}) \sim V_p^2 / M_e \quad (2)$$

312 With multiphase materials, such as adhesives based on block copolymers, a  
 313 temperature scan is a sensitive although indirect gauge of morphology. The temper-  
 314 ature scan is also a useful fingerprint for a particular adhesive which is extremely  
 315 valuable for quality control.

**Fig. 8** Elastic ( $G'$ ) and loss ( $G''$ ) moduli and their ratio ( $G''/G' = \tan \delta$ ) versus frequency at 25 °C for a styrenic block copolymer-based adhesive. Constructed via time-temperature superposition

Frequency scans are also useful. These are conducted at several temperatures and then via time-temperature superposition can be extrapolated to very low and high frequencies as was done in Fig. 8. This same type of data can be converted to a series of temperature scans at different frequencies as shown in Fig. 9. From this curve it can be determined that at a peel rate of about 100/s, the adhesive will become zippy and the peel force will drop at room temperature (this occurs at approximately the frequency at which the material becomes glassy at the temperature of the peel test). Another common use of the frequency curve is to look at the ability of the adhesive to damp vibrations at various frequencies. Tan delta is a direct measure of this capability.

Stiffness values at low frequencies have also been used as a relative measure of creep resistance for adhesives. A better way of gauging creep resistance is by direct measurement. Direct measurement has the advantage of extending the data beyond the linear elastic region, which is the region of interest when adhesive failure in creep is a possibility. Such measurements are made by applying a fixed stress and monitoring the strain. An example of the data obtained is shown in Fig. 10. The slope of the curve after the initial strain is a measure of the creep viscosity. The flatter the curve, the higher the creep viscosity. Upon removing the stress, the recovery of strain should mirror the creep viscosity. Notice that the strain values can reach several hundred percent in this test, which is far beyond the linear elastic region and more representative of the scale of deformation in the shear hold test.

**Fig. 9** Tan delta versus temperature at  $10\times$  frequency intervals from 0.1 rad/s (■) to 100 rad/s (▲) via time-temperature superposition for a general purpose tape adhesive based on styrenic block polymers

### 15.2.6 Optimizing Performance: General Principles

There is often much confusion about what determines adhesion. The word adhesion intuitively seems to imply some measure of molecular interactions across an interface. Whereas, in practice we are referring to some measure of the overall bond strength. How important are the molecular interactions in comparison to the adhesive's bulk properties? Obviously both are quite important. The same acrylic PSA tape can yield peel forces that differ by several multiples depending on the substrate to which it is bonded (see Table 1). For pressure sensitives it is normally assumed that the peel force is proportional to both the level of specific interactions across the interface and some function of the adhesive's rheological response to peel:

$$\text{peel force} \sim \text{specific interactions} \times \text{rheological function} \quad (3)$$

The strength of the interfacial bond determines at what stress the substrate lets go. The higher this stress, the more work can be done on the adhesive before it debonds. The more the work done on the adhesive, the higher the peel. Because pressure sensitives have  $T_g$  values below their application temperature, there is substantial mobility within the adhesive. Thus there is an opportunity for specific interactions between the adhesive and substrate to build over time. A few acid groups attached to the polymer, for instance, can serve this purpose on metals and

**Fig. 10** Creep and recovery for two styrene block copolymer-based hot melts (SHM) with different levels of diblock and triblock, but the same total amount of polymer. A higher level of triblock dramatically improves the creep resistance (Reprinted with permission from Hu and Paul (2009), copyright Taylor and Francis)

glass. A few basic groups can help build adhesion to polyvinyl chloride. Epoxy or silane groups can build adhesion to glass through covalent bonding. Two part systems such as isocyanate-cured materials can do the same. Ingredients within the adhesive, such as tackifiers, can partially solvate substrates such as plastics and thus help the adhesive to form a diffuse interface with it.

As noted earlier there is often a conflict between the capability of the adhesive to wet out the substrate completely and rapidly and its capacity to resist shear. This dependency follows the form indicated in Fig. 11. As the adhesive becomes stronger through physical or chemical crosslinks, the tack will first increase, until the molecular weight exceeds the capability to relax on the tack time scale (1 s for wet-out). Since the adhesive is normally given much longer to wet out prior to peel testing (typically 20 min for initial peel values and a week for ultimate values), adequate wet-out is achievable even with a much stiffer, lower tack adhesive. The increased stiffness with crosslinking will normally translate into increased peel, until the level of extensibility of the adhesive is reduced. Thus the peel force will peak at a higher level of crosslinking than the tack. Shear increases continuously with crosslinking provided the failure is cohesive. However, at a sufficiently high level of crosslinking, the mode of failure will switch to adhesive – or peel-initiated failure. At this point shear will fall with increased crosslink density just as the peel does.

Considering only the bulk adhesive properties, the ideal pressure-sensitive adhesive would have a broad molecular weight distribution with a fraction at very high

**Fig. 11** Tack, peel, and shear versus crosslink density of the adhesive

375 molecular weight but lightly crosslinked. Such a material will be highly extensible  
376 but unable to flow. It will provide rheological loss over a broad spectrum of  
377 relaxation times and thus be resistant to flow on various time scales  
378 (or alternatively temperatures). The  $T_g$  of the adhesive should be selected such  
379 that it is sufficiently below the lowest temperature/deformation rate it will experience  
380 in use. In later sections, how these principles translate into specific adhesive design  
381 and are reconciled with processing and interface issues will be discussed.

## 382 15.2.7 Other Characterization Methods

383 Beyond performance testing, there are a number of very useful ways of character-  
384 izing adhesives to better aid in their design. These methods have been used to gauge  
385 the uniformity of the adhesive, its morphology, specific interactions across inter-  
386 faces, and the mechanics of debonding at the peel front. These methods will not be  
387 described in detail.

388 Crosslinked adhesives are frequently characterized by conventional solvent-  
389 swelling methods. The adhesive is placed in a suitable solvent where it swells and  
390 would dissolve if not for chemical crosslinks. This is often the solvent from which it  
391 is applied. The amount the material swells is an inverse measure of the crosslink  
392 density and proportional to its extensibility. The soluble fraction is also then col-  
393 lected, dried, and weighed. For conventional acrylics about one third of the material  
394 remains soluble after crosslinking.

395 Adhesive morphology can be imaged using newer atomic force microscopes.  
396 This method has revealed the tendency for certain tackifiers to separate over time. It  
397 has also been used to study blends, as shown in Fig. 12. As the technique is further  
398 developed, its use in pressure sensitives is expected to expand. This method can

**Fig. 12** Atomic force microscopy (AFM) image of a pressure sensitive containing a blend of incompatible block copolymers. One of the block copolymers forms a separate macrophase, within which its hard and soft phases are evident as *light* and *dark* co-continuous domains

easily spot surface segregation. A cruder traditional method for analyzing surface segregation is attenuated total reflectance infrared spectroscopy. This technique often reveals some level of surface segregation of lower molecular weight materials such as tackifiers and can be used to spot transfer of silicone release resins to the adhesive surface.

Methods for characterizing specific interactions are few. Contact mechanics has been applied using the JKR (Johnson–Kendall–Roberts) methodology with some success using acrylic PSAs (Garif et al. 2002). This method involves bonding and debonding the materials at a very slow rate such that rheological loss can be ignored. Academic labs are applying it to characterize bioadhesion in particular. While collaborations with industry have borne fruit, it has not been adopted as an in-house technique. More common in industry is computer modeling of specific interactions.

Of most impact over the past decade has been the application of instrumented probe methods with direct visualization of the interface (Creton and Shull 2009). This simple technique has been used to study the tensile debonding process that occurs at the peel front. Using this method, the importance of the adhesive's ability to cavitate to form fibrils and for these fibrils to remain adhered to the interface while being highly extended has been solidly established. The dependence on adhesive composition and the substrate interface has been studied as well. These studies have demonstrated the validity of probe methods to characterize both tack and immediate peel in one test. The peak force upon probe removal is used as a measure of tack (similar to the normal probe tack measurement), whereas the area under the force displacement curve (a measure of the work of debonding) is a measure of peel resistance at short bonding times. The use of such methods in industrial labs is

**Fig. 13** Instrumented probe test using a Texture Analyzer to record force versus time during debonding for a styrenic block copolymer (SBC) – based adhesive (dark lines) and a solution acrylic adhesive (gray lines) at thicknesses of 50 µm and 125 µm

gaining momentum. Stable Micro Systems offers an inexpensive instrument for this purpose and a variety of probe materials. (Visualization of the debonding process is not offered.) These devices are now in widespread use. An example of the data generated is shown in Fig. 13.

### 15.3 Backings and Release Liners

During adhesive development it is common to use polyethylene terephthalate (PET) film as the backing. This rigid plastic film has normally been corona treated to eliminate surface contaminants and increase the surface energy of the film. Adhesive failure from the backing, known as “transfer,” fails to give information about the adhesion to the substrate of interest. If substrate adhesion is very strong, it may be necessary to apply the adhesive directly to the backing in solvent or the melt state to ensure strong adhesion and avoid transfer. PET has the advantages of a  $T_g$  above room temperature, a high level of crystallinity, and high modulus. The high  $T_g$  and crystallinity help to prevent migration of the adhesive into the backing that would affect the adhesive properties. The high modulus of this backing film makes it rare for it to deform permanently in a peel test, and thus it will not contribute to the work done in peeling. For these reasons it is an ideal backing for measuring the properties of the adhesive itself.

While some applications use PET backings, most use less expensive materials such as oriented polypropylene (OPP), polyvinyl chloride (PVC), paper, and aluminum foil. The most common issue with backings is migration. PVC backings are heavily plasticized. These plasticizers are often compatible with acrylic and rubber

**Fig. 14** Structures of common release layers

adhesives. In the former, they tend to reduce the peel values, while in the latter they tend to destroy the cohesion by attacking the styrene domains. OPP and other olefin films are normally unplasticized; however, they can absorb tackifiers and oils from adhesives. Papers too can absorb these materials leading to not only a change in adhesive properties but also an increase in the transparency of the paper due to this “staining” by the adhesive. Primers or coatings on the backing have been used to block migration.

Unbacked, two-sided tapes can be adhesive alone or more commonly two adhesive layers with a central core reinforcement layer of paper, fabric, or foam. These are commonly called “transfer tapes” and are used in a variety of product assembly applications in industry and around the home.

The release layer is ordinarily a vinyl carbamate or a silicone (see Fig. 14). The primary requirements for good release are (1) the complete incompatibility between the adhesive and release layer and (2) the lack of specific interactions or covalent bonding across the interface. For cured silicones, the likely presence of some unreacted groups such as acrylate ends (UV cured) or hydrosilane (Si-H) groups (hydrosilylation cure) must be considered. The side chains of the vinyl carbamate release coatings are uniform in length which allows them to crystallize to a high degree. This high level of crystallinity ensures that the adhesive does not interpenetrate, so long as the temperature of the tape remains below the melting point of the crystals. Silicones are quite different. They are amorphous and very low in  $T_g$  which provides a smooth and noiseless release even when removed rapidly. The immiscibility of silicones with common adhesives prevents interpenetration without the necessity of crystallinity. Silicone PSAs (not discussed in this chapter) require a different release material; ordinarily fluorosilicones are used to achieve immiscibility between the adhesive and the release layer.

Crystalline vinyl carbamate release coatings are commonly called “low adhesion back-size coatings” or LAB, because they are used almost exclusively on the back side of the backing to allow self-wound tapes to release smoothly (Kinning and Schneider 2002). Silicones provide release at lower force levels and with less noise. They are applied neat or from solvent and are heat or UV cured on the support (paper, PET, or polyethylene-coated paper primarily) to create a release liner.

The level of release can be increased by using additives which co-cure with the silicone and raise its  $T_g$ . By using such a “tighter” release liner on one side with a “lighter” release on the other, a transfer tape will selectively release from one liner, after which it can be applied to a substrate, and then have the other release liner cleanly removed.

In the vast majority of tape and label applications which use a release liner, the adhesive is applied to the release liner and then nipped to the backing. This method does not optimize adhesion to the backing but does prevent its exposure to heat (from hot adhesive or subsequent solvent/water removal). The release liner is normally quite stiff because of its paper or PET support layer and is more resistant to heat than many backings (most liners have already been exposed to the oven cure of the silicone layer). In addition, the silicone layer is mirror smooth which yields a correspondingly smooth exposed adhesive layer for the tape or label.

---

## 15.4 Acrylics

In contrast to common rubbers, the entanglement molecular weight,  $M_e$ , of most acrylics is sufficiently high that without dilution they meet the Dahlquist criterion discussed earlier ( $G' < 3 \times 10^6$  dynes/cm<sup>2</sup>,  $10^5$  Pa) and exhibit tack. With little or no crosslinking, the neat polymers form a pressure-sensitive adhesive with some cohesion. To obtain adequate cohesion, it is common to use polar monomers which can form hydrogen bonds and usually also some level of crosslinking. (Acrylics are also discussed in ► [Chap. 14, “Adhesive Families”](#).)

### 15.4.1 Monomer Composition

Acrylic pressure-sensitive polymers consist mainly of a “soft” monomer with a low  $T_g$  and high  $M_e$ . The three most common soft monomers are butyl acrylate, iso-octyl acrylate, and 2-ethylhexyl acrylate. All three have a  $T_g$  below  $-40^\circ\text{C}$  and an  $M_e$  above 15,000 Da; see Table 2. When polymerized on their own, they meet the Dahlquist criterion at room temperature and well below. To increase peel, often a “hard” monomer is incorporated. These are high  $T_g$  monomers, and most are low  $M_e$ . By moving up the  $T_g$  of the overall polymer, these hard monomers increase the viscous loss and thus the peel force, much in the same way as increasing the rate of peel. In addition, the lower  $M_e$  hard monomers, such as MMA, also increase the stiffness of the adhesive which further increases the peel force. Polar monomers are invariably incorporated to increase cohesive strength through intermolecular hydrogen bonding and to increase the potential for specific adhesion with the substrate. These polar monomers are also generally “harder” (higher  $T_g$ , lower  $M_e$ ) than the soft monomers and so increase the peel in a similar manner. A wide variety of monomer blends are employed in practice to suit various applications. However, in its simplest form, a good pressure-sensitive adhesive is made from 95% of a soft monomer and 5% of acrylic acid with light crosslinking as described below.

**Table 2** Acrylic monomers and their T<sub>g</sub>, M<sub>e</sub>, and typical weight percent addition into an acrylic pressure-sensitive adhesive

		Monomer	T <sub>g</sub> (°C)	M <sub>e</sub> (Da)
<b>Soft monomers</b>	<b>70–90%</b>	2-ethyl hexyl acrylate	–65	35,000
		n-butyl acrylate	–50	17,000
		Iso-octyl acrylate	–70	
<b>Hard monomers</b>	<b>0–30%</b>	Methyl methacrylate	105	5,000
		Methyl acrylate	9	11,000
		Vinyl acetate	32	11,400
		Styrene	100	18,000
		Vinyl neodecanoate	–3	40,000
<b>Polar monomers</b>	<b>3–10%</b>	Acrylic acid	106	
		2-hydroxy ethyl acrylate	–15	
		N-vinylpyrrolidone	180	

## 15.4.2 Molecular Weight and Solvents

The vast majority of acrylic pressure sensitives are polymerized by free radical polymerization. Emulsion, solution, and neat polymerization are in widespread practice. Emulsion polymerization is the least expensive. While this method enables very high molecular weight polymers, usually lightly crosslinked, the necessity of surfactant in the formulation to create the emulsion results in adhesives with less water resistance and generally less heat resistance than those made in solution or neat form. The surfactant creates an obstacle to complete coalescence of the emulsion particles. Various techniques, such as polymerizable surfactants, have been employed to mitigate this issue. Nonetheless, homogenous films are never obtained starting from emulsions, and superior performance is delivered by solution acrylics which do form homogenous films and are devoid of surfactants.

A further disadvantage of emulsion-based systems is the difficulty of drying them. The high heat of vaporization of water makes it impractical to dry films above 50 µm since inordinately long dryers would be required. Such thick films, common in industrial tape applications, are not required for the majority of labels or graphic films. Here emulsion acrylics, coated to about 25 µm, find wide use.

The molecular weight of solution acrylic polymers is limited by the need to coat the adhesive, which requires a viscosity less than 10,000 cP, and the desire to minimize the amount of solvent that must be evaporated. Solid levels are normally kept above 20%, with 40–50% typical. Molecular weight is determined by the same factors which control any free radical polymerization. Thermal initiators are most common, such as azo and peroxide types. Polymerization can be done under pressure, allowing independent temperature control, but is more commonly done under reflux. Solvent choice is therefore critical for fixing the temperature of polymerization. Polymerization is normally done at a solids level above that of the final product. The polymerization solvents are chosen based on the desired reflux temperature, the solubility of the polymer, and their effects on polymer viscosity,

**Fig. 15** Gel permeation chromatography (GPC) trace of a typical solution acrylic polymer in dimethyl acetamide. The number average molecular weight,  $M_n$ , is 58 kDa, and the weight average molecular weight,  $M_w$ , is 312 kDa, based on polystyrene standards and using the integration points and baseline as shown. The molecular weight at the peak detector response is indicated

MW (through their tendency toward chain transfer), their health and safety profile, and their effect on the coatability of the final solution. A typical polymerization solvent would be a blend of ethyl acetate and heptane or isopropanol. The concentrated polymer solution is then diluted to achieve the desired stability and coating performance. Most solution acrylics are crosslinked via their acrylic acid groups using metals such as aluminum or titanium. These metals are incorporated into the adhesive in chelated form. To ensure shelf stability, extra chelation agent is often added to the mix, such as 2, 4-pentanedione. To minimize intermolecular hydrogen bonding in the solution and thus reduce viscosity, isopropyl alcohol is added. Toluene is also sometimes added to prevent bubbling on drying due to its higher boiling point which prevents the film from forming a solid skin as the more volatile solvents (ethyl acetate and heptane) are removed.

To consume the last traces of monomer, a final shot of initiator is often added at the end of the polymerization. This last step produces a small portion of very low molecular weight polymer. The final polymer often has a bimodal molecular weight distribution with a number average degree of polymerization of only about 40,000 Da but a weight average of four to eight times higher; see Fig. 15. This broad molecular weight distribution is beneficial as it provides a wide range of relaxation times and therefore viscous dissipation over a broad range of temperatures/peel rates. This breadth of relaxation times is evident in the dynamic mechanical temperature scan. As shown in Fig. 16, solution acrylics have a high tan delta, i.e., a large portion of its response to stress is viscous, over a very broad temperature range in comparison to a typical rubber-based PSA.

### 15.4.3 Crosslinking

To obtain an adequate level of shear and clean removal from substrates, some level of crosslinking is necessary. With water-based adhesives, this is accomplished by

**Fig. 16** Comparison of  $G'$  and  $\tan \delta$  ( $G''/G'$ ) versus temperature for a styrenic block copolymer (SBC) – based PSA, a solution acrylic PSA, and an emulsion acrylic PSA (Reprinted with permission from Hu and Paul (2009), copyright Taylor and Francis)

using a portion of difunctional monomer and thus crosslinking during polymerization or by post-adding a crosslinker just prior to coating such as a polyisocyanate or most often a polyaziridine. The former reacts with alcohol groups on the polymer and the latter with acid groups. These same crosslinkers can be employed with solution acrylics to produce covalently bonded polymers. However, in most applications a one-part system is preferred. For these, metals are used, most commonly titanates and aluminum acetylacetonate (acac). The metal's ligands evaporate on drying liberating the metal to chelate with the acid groups and/or hydroxyl groups of the polymer. These metal oxygen crosslinks are labile at very high temperatures, whereas covalent crosslinks are not.

Another way to covalent crosslinks from a one-part system is to use electron beam or ultraviolet light radiation, by adding such a curing station at the end of the coating line. The need for inerting and the high capital cost of electron beam have driven the decision to favor UV curing.

Alternatively, neat polymerization is practiced in-house by several tape makers, using a complex UV-initiation process (Martens et al. 1980). Typically the monomer syrup is applied and polymerized very slowly under nitrogen using black lights. Slow polymerization provides high molecular weight – higher than can practically be obtained via solution polymerization. Some portion of difunctional acrylate is

included to provide a very low level of covalent crosslinking. This method provides a covalently crosslinked structure with outstanding shear hold. However, it is not practical to remove all traces of residual monomer, and thus such tapes are only suitable for industrial use.

The issue of residual monomer can be avoided, by using preformed and purified reactive oligomers such as epoxy or urethane diacrylates. This method has the advantages of formulation flexibility and low viscosity and the ability to be coated by a wide variety of methods including screen printing. However, these systems typically trade off pressure-sensitive properties for these processing advantages. To form an infinite network from such lower molecular weight precursors invariably results in a more tightly crosslinked network. Extensibility and thus viscoelastic loss are compromised, and peel, tack, and hold are reduced. In some cases excellent properties are obtained, but then over only a narrow temperature range. Such oligomer-based formulas have had success in removable labels and other low performance applications.

Nonetheless, the industry is moving toward 100% solid systems, driven by environmental considerations and the much lower capital and operating costs of such systems. By moving from liquid systems based on oligomers to solid hot-applied systems, the crosslink density can be lowered, and the performance of the pressure sensitive is significantly improved. Formulation techniques can further mitigate the difference between 100% solid UV-cured hot melts and conventional solution acrylics.

Photoinitiators are necessary for UV cure systems in order to initiate chain extension and/or coupling of chains. There are various types of photoinitiators to choose from based on whether cure follows free radical or cationic chemistry (see Figs. 17 and 18). The photoinitiators shown are formulated into the system; however, they can also be chemically bound to the base polymer (see Fig. 19).

**Fig. 17** Photoinitiators for free radical UV cure

**Fig. 18** Photoinitiators for cationic UV cure

**Fig. 19** Polymer bound photoinitiator

A common commercial set-up is a slot-die hotmelt coater equipped with UV lights across the web just prior to lamination. There are a number of UV light choices available on the market today including microwave, arc, and LED. The microwave and arc systems contain lamps with broad spectral output including H bulb, H+ bulb, and D bulbs. LED bulbs by contrast exhibit a single narrow emission peak. It is important to match the photoinitiator UV absorption spectrum with the output from the UV light(s) in order to get maximum cure at the lowest dose.

A final consideration for UV cure is how Beer's law impacts the UV cure process. Photons are absorbed as they move through the film, and the intensity of the light is diminished, decreasing exponentially through the depth of the film. For this reason, UV free radical cure is usually limited to a thickness of about 5 mil (125  $\mu\text{m}$ ).

Thicker coatings can be obtained using UV-initiated cationic cure. In cationic cure, the UV light triggers the photoinitiator to form a super acid which in turn starts the cationic polymerization of cyclic ethers such as epoxides and oxetanes. These

reactive species do not couple and extinguish themselves like free radicals, or react with oxygen, but rather remain active until water or other basic impurities are encountered, or side reactions occur. Thus cationic polymerization can continue after the UV light source is removed, which is referred to as dark cure. Very thick pressure-sensitive films can be cured using cationic chemistry.

## Tackification

While tackifiers are not required to achieve pressure sensitivity in acrylic polymers, they are used to improve tack and peel, with some sacrifice in shear (see Table 1). Tackifiers have a higher  $T_g$  than the base polymer and much lower molecular weight, typically below 2,000 Da. These materials increase the  $T_g$ , pushing it toward room temperature and thus increasing the viscous loss and consequently the peel and tack (see Fig. 20 and Table 1). However, this comes at a sacrifice in low temperature performance. Tack is increased at room temperature because despite the higher  $T_g$ , the dilution of the entanglements softens the adhesive providing improved wet-out. The higher  $T_g$  increases the resistance to debonding in the tack test much as it does in peel. However, this can be carried too far. As the level of tackifier is raised further, eventually the  $T_g$  becomes too high and the adhesive too stiff. Tack will drop and then, at a somewhat higher level of tackifier, peel will drop as slip-stick behavior begins.

**Fig. 20** Dynamic mechanical properties versus temperature for untackified (acrylic A: ■, □) and tackified (acrylic B (tackified A): ▲, Δ) acrylic polymers. Adhesive properties are in Table 1

The loss in entanglement density upon tackification decreases the shear adhesion failure temperature and the hold at elevated temperatures (see Table 1). Hold at room temperature may also decrease, as it does for acrylic B in Table 1, but may not always due to the counterbalancing influence of the increase in Tg.

The most common reason tackifiers are added is to improve the adhesion to nonpolar plastics; see Table 1. Rosin ester tackifiers added at 15–30% will normally increase the peel several fold on polyethylene and polypropylene surfaces. For more polar surfaces, terpene phenolic or styrene phenolics are added. Tackifiers are discussed in more detail in the section on rubber-based adhesives below. Acrylics are compatible with only a narrow range of commercial tackifiers. Tackifier dispersions are available for water-based adhesives.

## 15.5 Rubber Based

The words “rubber” and “tackifier” imply physical effects materials can display. They are not linked directly to any specific chemical structures. “Rubbery” materials are defined by ASTM (D1566) as those which will have less than 50% permanent set after 1 min when recovering from a strain of 100% applied for 1 min. This is a physical, not chemical, definition. Any lightly crosslinked polymeric material (through physical or chemical crosslinks) of sufficient molecular weight to withstand a 100% deformation, and with a matrix phase Tg below room temperature (to allow rapid deformation and recovery), is a rubber (Rubbers are also treated in chapters ► “Adhesive Families,” and ► “Sealant Families”). Conventional “natural rubber,” if degraded to very low molecular weight and uncrosslinked, is not a rubber anymore but a liquid. Liquid rubber is an oxymoron, but one in common usage. From a historical perspective, rubbers were made from crosslinked polydienes (polyisoprene or polybutadiene) via sulfur crosslinking primarily, and so these early polymers – and butyl as well (polyisobutylene) – are often referred to as “rubber” even when they are not in this state.

In contrast to acrylics, the Me of all the low Tg rubber monomers are below 10,000 Da (see Table 3). Thus the polymers must have their entanglement density reduced to exhibit tack. This reduction in entanglements is accomplished by diluting the high molecular weight base polymer with materials that are less entangled or incapable of entanglements. These diluent materials can include low MW oligomers

**Table 3** Tg and Me of monomers in common rubbers

	Tg (°C)	Me (Da)
Isobutylene	−30	9,000
Ethylene propylene	−55	1,700
Ethylene butylene	−55	1,700
Isoprene	−60	7,000
Butadiene	−85	1,700
Styrene	100	18,000

of the base polymer itself (“liquid rubbers”), but more commonly are tackifiers and oils. These additives will be discussed in more detail below.

### 15.5.1 Natural Rubber

The rubbers in common use for pressure-sensitive adhesives are natural rubber and styrenic block copolymers. Natural rubber, cis-polyisoprene, is obtained as a latex from the rubber tree. To render it processible, it is degraded by shear, dissolved in solvent, and formulated with tackifiers and sometimes curing agents such as sulfur or phenolic resin (Eaverarts and Clemens 2002). The level of tackifier is about the same as the amount of rubber in the formula. Similar to the acrylics, the molecular weight distribution is broad, which provides adhesion over a broad range of temperatures/shear rates. However, unlike acrylics, these materials do not have polar groups attached to the polymer and consequently do not build adhesion to polar surfaces to the same extent. Due to their unsaturation, natural rubbers also have poor thermo-oxidative stability and so are not used in durable applications such as graphics. They find application instead for temporary bonding as masking and medical tapes.

### 15.5.2 Styrenic Block Copolymers

Styrenic block copolymers consist of high Tg polystyrene end blocks coupled to soft, low Tg mid-blocks made primarily of polybutadiene or polyisoprene. The end and mid-blocks are miscible with one another in solution or at high temperature but are sufficiently different in polarity that they phase separate upon drying or cooling. The hard styrenic end blocks thus physically crosslink the soft mid-blocks at their ends, providing them with heat and creep resistance.

Styrenic block copolymers are synthesized by anionic polymerization (Jagisch and Tancrede 1999). The high Tg polystyrene end blocks are polymerized first, followed by polymerization of the soft, low Tg mid-block. Next these diblocks are either (1) further polymerized with styrene or (2) reacted with a coupling agent to link two or more of these diblocks together. Normally 2 or sometimes 4 diblocks are linked; however, as many as 8–12 have been combined to produce so-called “star” polymers. The first process, called “sequential polymerization” can produce pure triblock copolymers for maximum strength and temperature resistance. The second process, coupling, is never 100% complete, so some diblock is always present. Heat resistance and strength are somewhat compromised, but peel and tack generally are increased by the presence of diblock. The amount of diblock can reach as high as 80 or even 100% if the polymer is high in styrene content and molecular weight. The upper limit for a particular starting diblock is set by the need to provide the final polymer in a readily dispersed form, either free-flowing pellets or a friable crumb. These forms permit the polymers to be dissolved or masticated quickly during the compounding of solvent-based or hot melt adhesives, respectively. By contrast,

**Fig. 21** Polymer property versus molecular weight, where Me is the molecular weight at which the polymer chains become mechanically entangled (Reprinted with permission from Paul (2002), copyright Elsevier)

conventional non-blocky rubbers come in bales of about 20 kg each which the adhesive manufacturer must break apart using specialized equipment before blending with the other adhesive ingredients, and even then these conventional rubbers require extended mixing time. Thus a key advantage of the styrene block copolymers over conventional non-blocky rubber polymers is the ease of manufacturing adhesives from them.

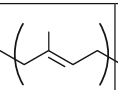

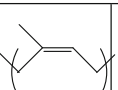

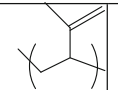

The polymerization of styrene anionically produces an atactic block. The typical end-block molecular weight for polymers used in pressure sensitives is below the 18,000 Da entanglement molecular weight of polystyrene (see Table 3). Thus the softening point of these polymers is less than that of pure polystyrene. Like the tackifiers and oils discussed below, the polystyrene end blocks are in the oligomeric region where properties still depend on molecular weight (see Fig. 21).

The soft block monomers are primarily isoprene and butadiene. These diolefins can each polymerize in one of three ways: (1) trans 1,4 addition, (2) cis 1,4 addition, or (3) across a terminal double bond to produce a pendant vinyl side chain (1,2 or 3,4 addition for butadiene or isoprene, respectively), as described in Fig. 22. The typical proportions of each and their Tg and Me (where available) are also shown. These proportions are easily varied by changing the polymerization solvent or adding complexing agents. The level of “vinyl” in the butadiene block is normally increased from 10% to 30% if this block is subsequently to be hydrogenated, otherwise the mid-block is prone to crystallization.

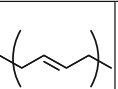

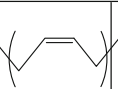

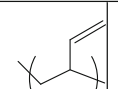

Styrene-isoprene-styrene (SIS) is the most common base polymer for pressure sensitives. The higher Me of isoprene versus butadiene permits higher levels of polymer to be used while maintaining adequate softness to meet the Dahlquist criterion. In addition, the overall polymer is higher in molecular weight for the same solution or melt viscosity. The lower solubility parameter for isoprene versus butadiene means that good phase separation between the hard and soft domains is

				For typical wt.%
	trans 1,4	cis 1,4	"vinyl" 3,4	
Typical wt. %	20	73	7	
Tg pure (°C)	-66	-71	20	-60°C
Me (Da)	NA	NA	NA	7,000

				For typical wt.%
	trans 1,4	cis 1,4	"vinyl" 1,2	
Typical wt. %	50	40	10	
Tg pure (°C)	-83	-95	-10	-85°C
Me (Da)	NA	2,900	1,700	1,700

**Fig. 22** Tg and entanglement molecular weight, Me, for isomers of polybutadiene and polyisoprene, and for typical average isomeric compositions in styrenic block copolymers (Reprinted with permission from Paul (2002), copyright Elsevier)

achieved at lower weight percentage of styrene. The lower styrene content of the adhesive produces a softer adhesive or alternatively enables additional polymer to be incorporated while maintaining tack. Peel and creep resistance benefit from the higher overall molecular weight and higher polymer content obtainable with SIS. Nonetheless, through careful formulation excellent pressure sensitives are made from SBS. These formulas have the advantage of being generally less expensive and significantly more thermo-oxidatively stable.

Hydrogenation of SIS and SBS produces SEPS (ethylene-propylene mid-block) and SEBS (ethylene-butylene mid-block), respectively. These saturated mid-blocks have relatively low Me values, similar to butadiene (see Table 3). Pressure sensitives based on SEPS and SEBS are generally inferior to those based on SIS and SBS in terms of peel, tack, and shear. However, formulations adequate for many applications have been developed. These polymers are used in removable applications such as for sanitary napkins which must adhere to undergarment fabrics and for attaching inserts into magazines or credit cards into mailers. Their superior thermo-oxidative stability and capacity for holding high levels of diluents are their key advantages in these and their other niche applications.

**15.5.3 Tackifiers and Oils**

Without dilution both natural rubber and styrenic block copolymers are stiffer than the Dahlquist criterion and therefore have no tack. Tackifiers gained their name

because of their capacity to render materials tacky when added. Tackifiers and oils are lumped to together in this section because they serve the same basic purposes in adhesive formulation:

- Reduce the entanglement density
- Lower the viscosity at a given solids level
- Adjust the  $T_g$
- Improve wet-out at a molecular level

Both materials achieve these ends because they are amorphous and of sufficiently low molecular weight that they are unentangled. Where they differ is that oils are of low  $T_g$ , comparable to the soft phase of the base polymer, and tackifiers are of higher  $T_g$  than the base polymer. Together, they are used to optimize the full set of properties for a given application, including optimizing the formulation  $T_g$  and cost. The cost of most tackifiers is below that of most polymers, while oil is invariably the least expensive ingredient.

The range of commercial tackifier choices is extensive and growing. They are derived from trees or petroleum. From trees (stumps, sap, citrus oils, or pulpwood) are derived rosin and terpene monomers (see Figs. 23 and 24). From petroleum are derived various aliphatic monomers (principally piperylene and dicylopentadiene)

**Fig. 23** Abietic acid, the largest component in most rosin acids

$\beta$ -Pinene

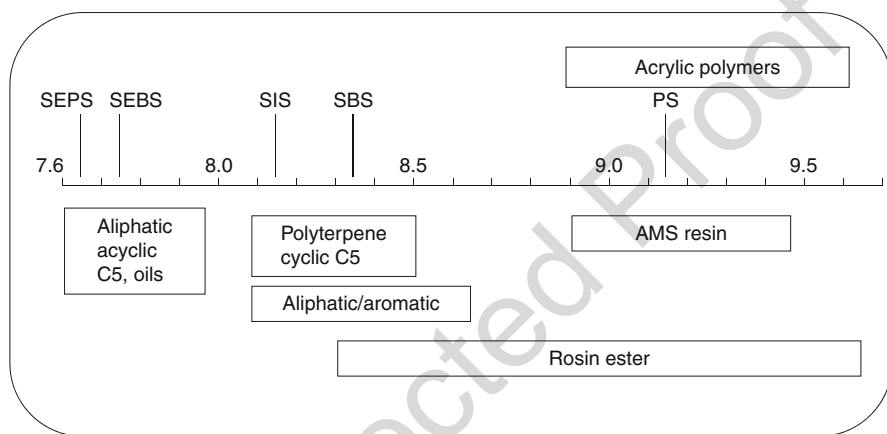

Dipentene (limonene)

**Fig. 24** Terpene monomers

**Fig. 25** Vinyl monomers in the  $C_8 - C_{10}$  feed stream which polymerize to “ $C_9$ ” resins

**Fig. 26** Solubility parameters of common tackifiers and polymers (Reprinted with permission from Hu and Paul (2009), copyright Taylor and Francis)

and aromatic monomers (see Fig. 25), and phenol. These materials are polymerized or copolymerized to obtain the desired polarity and Tg. More detailed descriptions are available elsewhere (Paul 2002). Rosin is the only material that can be used as a tackifier without modification. However, it is normally esterified with glycerin or pentaerythritol. As shown in Fig. 26, rosin esters offer the broadest range of compatibility. They are one of the few tackifiers compatible with acrylics. The excellent solvency power of rosin esters is likely why they are so effective in improving the adhesion of acrylic pressure sensitives to polyolefins. The more polar terpene phenolics and alpha-methyl styrene phenolics improve specific adhesion to polar surfaces and dilute entanglements with less of an effect on heat resistance due to their capacity for strong hydrogen bonding with the acrylic ester groups.

For styrenic block copolymers, the tackifier is normally chosen to be either mid-block (soft block) or end-block selective. For SIS, SEBS, or SEPS, the mid-block selective tackifiers are primarily aliphatic materials. For SBS, higher polarity is needed for the mid-block. Tackifiers composed of up to 30% aromatic

monomers are used. Rosin ester can be used with any of these polymers but in all cases is not entirely mid-block selective. A portion of the rosin ester will be incorporated into the styrenic end block leading to a decrease in softening point but an extension of the adhesive's open time. More details can be found in Hu and Paul (2009). The level of mid-block tackifier in PSAs based on styrenic block copolymers is very high, often more than half the formula and twice the amount of rubber.

The end-block selective tackifiers are usually added at a low level, 3–10%, to reinforce the end block. In a formulation with 30% polymer, containing 20% styrene, there is only 6% of the end-block phase. By adding 5% of end-block resin, this minor phase is reinforced, becoming more creep resistant. End-block tackifiers with  $T_g$ 's close to that of the polymer end block or higher are chosen to ensure the softening point is not compromised. Usually, for a given tackifier type, a range of softening points are offered, differing only in molecular weight not chemical composition. The higher the molecular weight, the higher the softening point ( $T_g$ ) since tackifiers are oligomeric materials and thus they are on the upward sloping portion of Fig. 21.

Oils, like tackifiers and styrenic end blocks, are oligomeric materials with molecular weights below Me. The majority of oils used in practice are petroleum derived with molecular weights between 300 and 600 Da. The higher the molecular weight, the higher the  $T_g$  and the lower the solvency power. These are hydrofinished to eliminate all but traces of aromatics, which are converted to cycloparaffins. The amount of linear, branched, and cyclic fractions of the oil depends primarily on the petroleum source. The more cyclics, the higher the  $T_g$  and solvency power and the less tendency to crystallize (Paul 2002). Low MW polyisobutylene oligomers are sometimes used in place of petroleum-derived oils. The amount of oil used in adhesives based on styrenic block copolymers ranges from none to as much or somewhat more than the rubber content. Typically oil is present at from 50% to 100% of the level of rubber.

In acrylic adhesives, plasticizers are rarely used. Conventional oils are incompatible due to their low polarity. A variety of other polar plasticizers are compatible such as phthalates, adipates, trimellitates, benzoates, and phosphates.

---

## 15.6 Summary

For a material to be tacky and thus pressure sensitive, it must be sufficiently soft (the Dahlquist criterion of  $G' < 3 \times 10^6$  dynes/cm<sup>2</sup> ( $10^5$  Pa) on a time scale of 1 s). Some polymers are sufficiently unentangled that they can meet this criterion without dilution. Acrylics based primarily on high Me, low  $T_g$  monomers such as butyl acrylate, 2-EHA, or iso-octyl acrylate, are in this class. Styrenic block copolymers and natural rubber are not and require dilution with tackifiers and/or oils. To qualify as a pressure-sensitive adhesive – a solid material and not merely a pressure-sensitive liquid – some minimum level of cohesion is required for clean peel and

adequate hold. This cohesion is obtained in acrylics through the use of hydrogen bonding monomers and also usually crosslinking, either covalently or by metal complexation of acrylic acid groups. Natural rubber also requires crosslinking, usually through sulfur, but styrenic block copolymers (SBC) rely only on the physical crosslinks provided by their high  $T_g$  end blocks which phase separate on cooling. However, this characteristic compromises the temperature resistance of SBC-based adhesives ( $SAFT \leq 110^\circ C$ ) in comparison to acrylics, where  $SAFT$  values can often reach above  $150^\circ C$ .

Optimization of properties generally involves trade-offs between tack, peel, and shear. Because peel and tack involve deformation of the adhesive on a relatively fast time scale,  $\sim 0.01$  s, raising the  $T_g$  of the matrix phase tends to improve both properties, up to a point. Once the failure becomes slip-stick, i.e., the material behaves rigidly during debonding, the average peel and tack drop. Tack drops first, because the time scale for initial wet-out is much shorter – 1 s versus typically at least 20 min for peel samples. The level of peel depends on the work that can be done on the tape.

To maximize the work done, the adhesive must hold onto the substrate strongly, i.e., the strength of the interaction with the substrate is critical. The work done on the adhesive depends on the force required to deform it (the level of viscous dissipation at a given strain rate) and the distance over which it is deformed (the extensibility of

**Fig. 27** Dynamic mechanical properties versus temperature for tackified solution acrylic (acrylic B:  $\blacktriangle$ ,  $\triangle$ ) and a solution rubber adhesive, also tackified, based on styrenic block copolymers ( $\blacksquare$ ,  $\square$ ). Adhesive properties are listed in Table 1

the adhesive) as the peel front passes through. Thus peel is optimized with a strong interface, a high level of viscous loss as the adhesive is deformed, and a high level of extensibility (maximizing the total work done on each area of contact). Any permanent deformation of the backing also contributes.

Shear resistance increases with  $T_g$  (particularly the room temperature shear holding power), the level of crosslinking, and the polymer molecular weight, until again, failure occurs interfacially starting from the stress concentrations at the top edge of the tape. At this point the peel resistance dominates.

With acrylic adhesives the viscous dissipation of energy input, as characterized approximately by  $\tan \delta$ , is high over a much broader range of temperature than with rubber-based adhesives. Thus acrylics are chosen where a wide range of temperatures are expected. On the other hand, the sharper  $T_g$  and greater extensibility of rubber-based adhesives provides the highest levels of peel at an optimum temperature. This sharpness in  $T_g$  also contributes to their higher tack (see Fig. 27 and Table 1).

The selection of an adhesive for a specific application often hinges on the level of durability required. Untackified solution acrylics are chosen where durability is paramount.

## Abstract

Selection of the correct adhesive for an application can be a daunting task due to the many types commercially available, ranging from different chemistries through different forms to almost a continuum of material properties. It is critical therefore to take a logical approach to this task and apply deselection criteria wherever possible. The needs of the final application are paramount and often a

detailed review of the requirements can provide the engineer with some key selection needs or constraints which in turn may enable large groups of adhesives to be eliminated from consideration at an early stage in the process. It is also important to appraise aspects related to manufacturing, in terms of product volume, handling issues, curing equipment, dispensing equipment, etc. An apparently perfect adhesive with suitable mechanical properties may not be suitable for the application for one or more reasons such as not being able to be dispensed easily/rapidly enough, having a curing temperature that is too high for the substrate to tolerate, curing too fast for a large area joint etc.

Although the initial adhesive selection process is “only” a desktop exercise, the need to be efficient and identify only those candidates with the greatest property match requires that this activity be given a high level of importance. Almost every application will require a bespoke approach at some level and this will necessitate practical testing and trials to be carried out to verify suitability. Selection of unsuitable adhesives at the outset can be very costly in the long run.

---

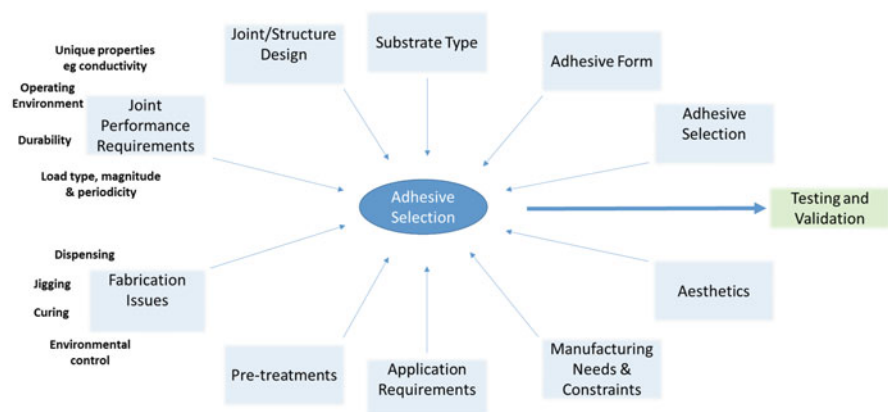

## 16.1 Introduction

A quick search online or via textbooks in the library shows that there are many types of adhesives available to use, ranging in type from simple paper bonding adhesives to high-performance aerospace materials. Indeed if the reader considers the fact that in some cases the same generic adhesive will be sold under license to different suppliers or will be based upon common formulations, then there are probably hundreds if not thousands of adhesive products available worldwide to choose from. The situation is further complicated by the fact that the same adhesives can often be classified in several different ways; the main classifications being:

- Chemistry – epoxy, acrylic, polyurethane, etc.
- Form – two part (2K), single part (1K), paste, film, tape, etc.
- Function – wood bonding, metal bonding, multipurpose, rapid cure, etc.
- Cure type – room temperature (RT) cure, UV cure, moisture cure, pressure sensitive, etc.
- Specific property – high strength, electrically or thermally conductive, toughened, heat resistant, etc.
- Part name or number – VHB PSA, ESP110, Scotchweld DP8005, etc.

So it is not surprising to find the same adhesive being described as an RT curing two-part epoxy, as a metal bonding paste adhesive, Araldite 2015, or some other combination. Indeed it may well be that the standard titles do not convey or assist with the specific nature of the application in mind. Such a situation has the potential to make selection of the correct adhesive for the task in hand a potentially challenging activity. However, if the user follows a logical set of choice paths, then the task can be simplified considerably, Fig. 1. Key factors to consider include:

**Fig. 1** Primary influencing factors to consider when selecting an adhesive

- Joint performance requirements in terms of load type, magnitude, and periodicity; operating environment; unique properties (e.g., electrical conduction, low shrinkage); durability; etc.
- Joint/structure design
- Pretreatment type which often affects durability
- Substrate type(s), i.e., metal, polymer, ceramic, etc.
- Adhesive form
- Application requirements
- Manufacturing needs/constraints
- Aesthetics
- Cost
- Fabrication needs (dispensing, jigging, curing, environmental control, etc.)

As will be seen, it is important to understand from the outset what the key selection parameters are. Quite often the apparent key parameter can be superseded by another less obvious requirement. An example of this could be the physical form of the adhesive, i.e., whether it is a paste or a film which may turn out to be more important than the original selection parameter such as the mechanical strength of the joint. Both single-part paste and film adhesives can provide high strength joints, but while using a standard high strength paste, adhesive may be simpler and relatively cheaper per unit volume. Accurate rapid placement of the adhesive is critical to the manufacturing process which may require a significant amount of additional capital investment in terms of automated metering and dispensing. In contrast, a precut sheet of film or tape adhesive, although materially more expensive, is easy to handle and extremely quick to place in position prior to curing thereby potentially lowering costs while maintaining performance. Another example could be the need to identify adhesives that cure very slowly so that a large joint area can be bonded before the adhesive starts to gel or harden, over bond strength or cost.

The key parameters described above are often interrelated and it is therefore very important to stress that adhesive selection is often an iterative process where the first question must relate to what is required of the structure and the associated joints. This in turn will allow the engineer to start defining limits/requirements for the potential adhesive candidates. Often, whole families of adhesives can be eliminated early on in the process due to a single property such as pot-life duration, temperature of cure, shrinkage, or substrate type (Lees 1984). It is rare though, for there to be only one type or even only one specific product for an application. The inherent diversity of adhesives and the creativity of the chemists/formulators normally ensure a wide palette of adhesives from which to choose.

---

## 16.2 Joint Performance

When asked to design a structure or device, the engineer will normally always want to consider performance as a key initial selection criterion, but it should be remembered that “performance” is an umbrella term that covers many factors including:

- Mechanical strength – ultimate failure load, working load, toughness, etc.
- Loading conditions – static, impact, fatigue, intermittent peak, etc.
- Environmental tolerance – heat, cold, chemicals (acids, bases, solvents, gases, etc.), radiation, mechanical erosion, etc.
- Durability – prediction (how strong, how long?)
- Structural properties – conduction (thermal, electrical), self-repair, structural stability, etc.

Mechanical strength must not be oversimplified. The need for a strong joint can be subjective as there are adhesives which will provide very high bond strengths but at the cost of very low strain to failure values (e.g.,  $<0.05\%$ ). So while a headline peak failure load value may be impressive, say 40 MPa, the joint may well be very brittle and fails catastrophically when the peak load is exceeded with little or no indication. In contrast, a joint made using a toughened adhesive may be shown to fail at 20 or 25 MPa but at 5% strain, thereby demonstrating a much higher energy absorption capacity and a greater resistance to damage, especially with respect to impact loading. Such properties will significantly affect the types of applications for which an adhesive may be used. In the case of the first example (high strength and low strain to failure), it may be best suited to aerospace applications whereas the toughened system (lower strength and high strain to failure) is much more likely to be the adhesive of choice for an automotive application.

Loading conditions can be regarded as an extension of mechanical strength in that the form and type of load that the joint is designed for will also affect adhesive choice. Very high static loading conditions will require adhesives with high creep

resistance whereas “softer” more elastomeric adhesives will be better suited to fatigue cycling.

The core chemistry of an adhesive will have the largest effect on the environmental resistance of the adhesive. Epoxy-based systems are extremely tolerant of a wide range of chemicals either by resisting their uptake or by allowing free diffusion through the polymer structure whereas cyanoacrylates have a lower tolerance to water exposure. Polyurethanes and to a lesser extent toughened acrylics will start to thermally degrade above 160 °C while there are epoxies that will survive continuous exposure to temperatures of 250 °C or greater and some cyanate esters or aromatic polyimides systems which can be used continuously in environments of 320 °C or more. The majority of adhesives are chemically cross-linked rendering them stable but irreversible in structure but there are some which are not cross-linked, termed thermoplastics, which can be remelted or reformed. Examples of thermoplastic adhesives include hot-melts, cyanoacrylates, and polyvinyl acetates (PVA). Although limited in terms of temperature and chemical solvent tolerance, they do offer the benefit of reworkability and recyclability, useful green credentials in a modern world.

Probably the most common and important question that arises in the engineer’s mind when selecting an adhesive is how long will the adhesive joint last and will it be as strong in 5 or 15 years as it is at the start? Absolute life prediction of a bonded structure is still some way off and the adhesive is only one component within the joint. It should be remembered that the term “joint” refers to a system including the substrates (often termed adherends), the adhesive, and the surface pretreatment(s), or a primer or adhesion promoter applied to the substrates prior to bonding. The joint will only be as strong as the weakest link and if the pretreatment is inappropriate or the substrate has low cohesive strength, then the ultimate performance of the joint will have little to do with the adhesive selected. In the majority of cases, the stability of the modern adhesive will be sufficient to last at least as long as the substrates. Studies of bonded steel joints which had been aged in a marine environment have shown that in some instances the steel substrate corrodes much more quickly than the rate at which the adhesive degrades. See Part F “Durability,” for more information.

Almost all adhesives are complex mixtures, where the base resin will dictate many of the underlying properties, but which are modified to a greater or lesser extent by varying amounts and types of additives. Such components can increase toughness, reduce shrinkage, speed up or slow down cure rates, change rheology, change structure, provide new properties such as conduction (thermal/electrical) or self-repair, or simply reduce costs by acting as a simple bulking agent. Small amounts of highly specialized chemicals can enhance adhesion or increase tolerance to surface contamination.

It is hoped that the reader will now have an understanding that adhesive selection based purely upon performance can be daunting, but if a key, perhaps very specific parameter, can be identified such as electrical conductivity, then the adhesive selection process can be made much simpler.

### 16.3 Joint Design

The design of a joint can have a significant effect upon the type of adhesive that can be selected for two key reasons. The first and the most important being the way in which load passes through the joint, i.e., a joint which will see significant levels of peel and/or cleavage will require a toughened system that is resistant to such loads whereas high levels of shear or tension may be better addressed with a more rigid system. More information is given in Part E “Joint Design.” The other reason relates more to the way in which the joint requires to be assembled. If the joint is very large in size, then the adhesives selected will have to have a working life prior to cure (often termed as pot life) that is sufficiently long to allow for the application time especially if this is a manual operation. Examples would include either very slow cure mixed materials or single-part adhesives where cure is initiated by a controllable external source such as heat or radiation. This method of assembly assumes that the adhesive is applied prior to the structure being assembled and that the adhesive is of a form that will not move or migrate to any extent once applied, i.e., in a viscous liquid/paste or a solid state.

Some structures are better fabricated by applying the adhesive after the parts are brought together. In this case, the adhesive must be of sufficiently low viscosity that it can enter the joint area either through gravity/capillary action or by pumping.

### 16.4 Pretreatments

Critical to the success of an adhesive bonding operation is the type of surface pretreatment that is used. If the pretreatment (or lack of it) is not matched to the application and the substrate(s), then it is extremely likely that the joint will be compromised in a number of ways including initial strength, durability, environmental resistance, and substrate damage. As described in more detail in Part B “Surface Treatments,” there is a wide range of surface pretreatments from which to choose, each having distinct attributes, in particular being compatible with the substrate and ideally also with the adhesive.

Basic pretreatments are highly generic and very substrate/adhesive nonspecific; they typically include degreasing, washing, and abrasion, although care must be taken with selecting the correct abrasive medium for metallic materials to avoid the potential for contamination and possible galvanic corrosion, i.e., steel shot should never be used on lighter alloys (aluminum, magnesium, etc.). However, more complex pretreatments based upon chemical processes (etching, oxide growth, chemical conversion, etc.) and energetic physical processes (plasma, flame, corona, and laser) can be substrate specific. The final state of the pretreated surface may have an effect upon the type of adhesive that is selected in terms of adhesion properties such as wettability, mechanical interlock, polar attraction, chemical reaction, etc. Furthermore, if a primer or adhesion promoter is also used, then the likelihood of specific adhesive compatibility increases significantly. Examples include silane systems, often called coupling agents, where the silane molecule has two sites of

different chemical reactivity, one for reaction/interaction with the substrate surface and the other which can chemically react with the adhesive resin. It is therefore important to match the silane reactivity to the adhesive/substrate chemistry for the highest levels of adhesion. The most common type of silane reactivity is based upon the epoxide group. In the case of primers, it is also advisable to select similar chemistries where possible.

## 16.5 Substrate Type

The type of substrate or adherend that is required to be adhesively bonded may have an effect upon the type of adhesive to select for the task. This is especially true for thermoplastic polymers where either the adhesive may have a detrimental effect upon the polymer such as crazing, swelling, or in some cases dissolution or there may be an incompatibility that renders the adhesive incapable of bonding. Examples of the detrimental effects would be the use of some types of acrylic-based adhesives with polycarbonate or polystyrene where both crazing and dissolution are common or cyanoacrylates for acrylic systems where crazing often called fogging can be an issue. Incompatibility is especially relevant when trying to bond low energy polymers such as fluoropolymers (e.g., polytetrafluoroethylene [PTFE]) or the polyolefins (polyethylene and polypropylene). In the case of fluoropolymers, only specific surface pretreatments can be used to achieve any type of adhesion whereas polyolefins can now be bonded with some speciality-toughened acrylic systems.

In the case of metals, sensitivity is not quite so marked, although some adhesives in the anaerobic class are sensitive to the presence of certain metal ions, in particular copper which can act as a cure inhibitor. In contrast, the presence of other metal ions on the surface is essential for the curing process to occur at all and anaerobic adhesives will not work to bond together nonmetallic substrates. A simple selection guide is provided in Table 1.

All of the examples cited above have been specific to the chemistry of the substrate but the physical form can also have an effect, in particular porosity. Some adhesives are aqueous suspensions, e.g., poly vinyl acetates (PVAs), and others rely upon adsorbed moisture or ease of moisture transport to the bond-line for cure to occur, examples being single-part polyurethanes and silicones. In the case of PVA usage, it is important for either one or both of the substrates to be porous in nature, e.g., wood, paper, masonry, etc.

Extreme selection examples would be the ability to bond to materials in very nonideal conditions, e.g., wet/damp surfaces, underwater, or to very "contaminated" surfaces where oils are present. In such cases, the adhesives have been carefully formulated to address these requirements but the products are very specialized and come from limited sources/suppliers.

Another factor to consider relates to the mode of cure and the effect this may have on the substrate. The use of an ultraviolet (UV) curing adhesive on opaque materials is not going to be satisfactory as UV energy from the UV source can be absorbed or

blocked preventing the adhesive to cure within the joint where the adhesive is hidden.

There are probably two main adhesive classes which rarely exhibit substrate sensitivity: the two-part epoxies and the two-part polyurethanes; both rely upon internal curing mechanisms and do not contain solvent-like agents.

---

## 16.6 Adhesive Form

Adhesives are available in a wide variety of forms such as liquids of varying viscosity, pastes, semisolid films, and solids (powders, granules, chips, blocks, etc.). The form of the adhesive will dictate how the adhesive is dispensed/applied and the way in which the joint is designed and the structure manufactured (Table 2). For example, a low viscosity liquid is not easily applied to a joint oriented in an overhead or vertical position, whereas a paste adhesive would be a good choice. However, the same liquid system would be better suited to application over a large flat area or one which is very small and constrained with regard to access. Film adhesives are excellent for precise positioning in joints which are prepared to very high tolerance limits but are very poor for more variable structures where additional adhesive may be required to fill larger gaps or variations along the bond-line, whereas a paste adhesive would be much better suited for this application.

Another quite specific aspect relates to the use of adhesives in a film form such as pressure-sensitive adhesives or thermosetting systems such as epoxies. Such materials can appear to be quite expensive when compared to similar liquid/paste analogues, but there are many obvious benefits to using precut “dry” systems which can be easily handled and laid directly into the joint area before assembly. Often, especially in the case of pressure-sensitive systems, the adhesive can be supplied precut, ready for use with little or no wastage. Such properties enable the manufacturer to minimize assembly time, increase tolerances, and reduce rework which can have a significant effect on cost reduction thereby justifying the higher relative price of the adhesive used.

---

## 16.7 Application Requirements

Due to the inherent diversity of adhesives and potential for almost infinite formulations, these materials can offer a wide range of additional properties over the “simple” requirement to form a load bearing, structural joint. Such properties can include high compression strength, toughness, abrasion/erosion resistance, stiffness/elasticity, optical properties, anisotropic properties, tolerance to extreme temperatures (high and low), conductivity (thermal and/or electrical), dielectric properties, acoustic damping, chemical resistance, tolerance of contaminated surfaces, biocompatibility, bioactivity, etc. It may well be, therefore, that the initial requirement to select an adhesive to bond two substrates with a particular strength may be overridden by another more specific property such as one those listed above.

Indeed for some applications, the bond strength may be completely secondary to another function, e.g., a bioactive agent may be incorporated into an adhesive to ensure that rejection or infection are reduced/eliminated or for electrically conductive adhesives the level of resistivity may dominate the selection and ultimate function of the adhesive.

---

## 16.8 Manufacturing Needs/Constraints

Manufacturing requirements also have an impact upon the form of adhesive used, especially in terms of the number and size of products to be produced. The use of a single-part system will allow a simpler mode of dispensing to be employed, i.e., no mixing and subsequent replacement of mixing nozzles, but in turn such systems may be more restrictive with regards to curing time, i.e., they may cure very rapidly (cyanoacrylates) or they may require heat (epoxies) or radiation (acrylics). In contrast, a two-part system can be formulated to cure at different rates. If external curing stimuli such as heating or radiation is needed, then this can add to the total capital expenditure of fabrication although it may offer additional manufacturing control to the product assembly, i.e., assemble a number of separate products and then cure all of them at once using UV radiation. Alternatively adhesives can be selected so that they can be cured using a process normally assigned to another function (e.g., to cure a paint or other coatings). Examples of this include the ability to cure flange adhesives in car body structures at the same time as the paintwork is being cured or curing of electronic bonding adhesives on a circuit board during the solder reflow process.

Rapid cure systems are usually suited to small precision bond-lines such as medical or electronic products, whereas long cure time adhesives are used either for much larger structures where a large area has to be covered with adhesive before the two parts are brought together – a good example would be the assembly of a deck to the hull of a large yacht where the joint could be many meters in length – or where the joint is part of a more complex assembly and cure is required to be carried out at a later stage of the fabrication process.

If a small number of components are required to be adhesively bonded together, then it is most likely that the process will be manual in type as the cost of automation would not be justifiable. A key benefit of adhesive bonding is that it is fully scalable, enabling initial prototypes to be manually assembled, but as volumes increase, more and more of the bonding operations can be automated. See Part G “Manufacture” for more information on manufacturing.

---

## 16.9 Aesthetics

In some instances (bonding transparent materials or for visual impact), there may be a need for the adhesive to be seen as part of the structure, deliberately or otherwise. In such circumstances, care must be taken to select adhesives that have the correct

t.1 **Table 2** Adhesive selection based upon the form and processing conditions (Petrie 2007)

t.3	Type of adhesive	Common forms available				Solvent solution, emulsion

visual characteristics. This might be relatively simple such as using a water-clear adhesive to bond transparent plastic/glass or perhaps as a design statement as shown in the Lotus Elise chassis where the adhesive is now a characteristic blue color (it used to be orange). For such applications, the adhesive must be applied very carefully and the final cured bond must be made to be aesthetically acceptable, with attention given to ensuring that the form and profile of the edge fillet is even and defect free.

Where transparent joints are required, the choice of adhesives can be significantly reduced as fully transparent systems will not be able to contain much, if any, filler or additives. Such a constraint will limit properties such as rheology, toughness, thermal conductivity, etc.

---

## 16.10 Costs

Costs are always never far from a manufacturer's mind and as before, adhesives offer a number of choices. Ultimately, almost all adhesives are derived from oil products and are therefore subject to world oil price fluctuations, but some systems are inherently more expensive than others. However, while base feed-stock prices will have some effect, much more cost is associated with manufacturing activity, functionality, quality, and ultimately the markets for which they are destined.

Aerospace film adhesives demand specific specialized processing equipment, high performance, consistent high quality, and careful transport and storage requirements. The demands are ultimately defined by the end users but no adhesive manufacturer would want a substandard product on an aircraft. In order to deliver such a product, it has to be tested and assessed at each stage. All of this work has a cost which is ultimately passed on to the consumer. Other areas where performance is critical are the medical sector and electronics applications. The former requires a product of extremely high quality and often high purity whereas the latter may contain high value additives such as silver to ensure the highest levels of electrical conductivity. Due to the very precise nature of the applications described, adhesive volumes are not necessarily that high but the consequences of failure are, making the adhesives used, high value components.

In contrast, industry sectors where higher volumes of adhesive are used may demand lower costs with little compromise to quality; examples would include the automotive sector and shipbuilding. Tolerances are often much lower, although the structural needs are still great. In these areas, a greater design leeway is factored into the structure allowing for more adhesive to be used. The costs associated with the additional testing and properties required by the end users are offset against the higher volumes of adhesive sold with lower margins. There are also many other factors which can affect cost of an assembly; these include storage, handling, drying, degassing, or dispensing of an adhesive or the substrate, type of surface preparation and cost of associated materials used (e.g., primers), fixing and assembly of the joint, type of curing method used, and cost of labor for each of these steps.

### 16.11 Fabrication Issues (Jigging, Curing, Environmental Control, etc.)

To enable effective fabrication using adhesive bonding, a wide range of factors must be considered which relate to the process of creating the bonded joint, most normally within a manufacturing environment. Examples of which include some areas already covered previously, such as joint design and assembly needs and within those processes adhesives have to be suitable to either remain in situ when applied (thixotropic pastes) or flow into inaccessible areas when the joint is formed. They have to cure in a controlled fashion either from an internal chemical reaction (room temperature systems) or by some external stimulus such as heat or light.

Considerations also need to be taken with regard to the mechanical performance of the joint and the potential sensitivity the adhesive is to bond-line thickness (BLT). Some adhesives are much more tolerant of BLT than others and can be used within variable tolerances in some instances up to and even greater than 1 mm (e.g., epoxies and polyurethanes), whereas others benefit from very low BLT values/ranges in the order of 20–50  $\mu\text{m}$  (e.g., cyanoacrylates). To ensure that such BLT values can be attained, four strategies can be considered:

- Joint tolerance – depending upon the substrates to be bonded, careful design, machining, and alignment are critical in achieving consistent BLT values.
- Jigging/fixtures – external jigging and fixtures such as clamping, tailored frames, fasteners, etc. will ensure that the parts are held closely together with little or no chance of movement while the adhesive cures.
- Joint features – in tandem with joint tolerance and jigging is the inclusion of features within the joint area such as ridges or localized protuberances which will hold the joint apart to a specific tolerance.
- Internal adhesive components – a relatively simple approach to achieving BLT control is by selecting an adhesive that has an internal additive/filler of sufficient dimensions to limit the minimum value of BLT. Normally such fillers are added by the adhesive manufacturer but the end user can also add material such as glass beads (ballotini).

Joint tolerance limits can have a significant impact upon adhesive selection. Different adhesive types will respond to the above approaches in different ways. For example, epoxy adhesives show little shrinkage upon cure and therefore are relatively insensitive to additives or external joint factors, whereas toughened acrylic adhesives can exhibit considerable shrinkage ( $\sim 10\%$ ) and if the joint cannot move sufficiently to accommodate this, then local voids can be formed and residual stresses can be very high. Moisture curing systems (e.g., polyurethanes and silicoes) require a relatively large BLT to enable the movement of water vapor into the adhesive and a thin BLT will significantly inhibit or slow the rate of cure.

Adhesive choice can therefore be influenced by actual joint tolerance control and dimensions and where a cyanoacrylate or an anaerobic adhesive might be ideal (polymeric substrates or a threaded metallic joint, respectively), the measured bond

421 gap may be too large and an alternative adhesive such as a polyurethane or an epoxy  
422 may be better suited.

---

## 423 16.12 Other Sources of Assistance

424 Assistance with adhesive selection may in the first instance come from asking others  
425 who have more experience with specific adhesives or with adhesives in general.  
426 Typically such help will come from a variety of sources, the main ones being:

- 427 • Adhesive manufacturers/suppliers and trade bodies (direct but product-specific  
428 information)
- 429 • Consultancy organizations (direct but product-neutral, i.e., no product preference)  
430 including universities and research and technology organizations (RTOs)
- 431 • Online resources (indirect and both specific and nonspecific information,  
432 depending upon reference source)
- 433 • Reference books

### 434 16.12.1 Adhesive Manufacturers/Suppliers and Trade Bodies

435 Every adhesive product should have a technical datasheet (TDS) and must have a  
436 materials safety data sheet (MSDS) to comply with international regulations. How-  
437 ever, as suppliers often have a wide range of products all differing slightly in  
438 properties such as substrate preference, viscosity, bond strength, environmental  
439 tolerance characteristics, and even color in some instances, it is often quite difficult  
440 to determine which is potentially best suited to the application in hand. Looking at the  
441 data supplied in the TDS may be confusing and may not highlight the key property  
442 required. It is therefore extremely useful to discuss the application requirements  
443 directly with company representatives, either within the sales team or if possible  
444 with the technical group. In that way, valuable time can often be saved by allowing a  
445 rapid, targeted product selection to be made. Most reputable suppliers will only try to  
446 promote the best potential products for the application as it does their reputation no  
447 good to sell inappropriate materials. However, supplier guidance must be treated with  
448 caution in that the recommendations will be product/brand specific and will not  
449 always be completely unbiased, although communication is most often direct and  
450 free evaluation material is often provided. In some instances, suppliers may offer to  
451 carry out test trials and supply additional test data, especially if the application volume  
452 has the potential to be large resulting in significant adhesive consumption/sales.

453 Sometimes, when a particularly demanding or unique application is sought  
454 where specialist materials are used, identification of a particular adhesive  
455 manufacturer/supplier may not be easy. In this instance, the use of a trade body  
456 which represents many industrial players may be another option to consider. Trade  
457 bodies represent a wide number of companies, normally on a region or country basis.  
458 Additionally, they serve as useful feedback/information centers to flag up legislative

issues such as REACH, H&S, and other regulatory concerns which may have a direct impact upon the use of adhesives. Examples of trade bodies include:

- ASC (Adhesive and Sealant Council, North America) – [www.ascouncil.org](http://www.ascouncil.org)
- ASMAC (Adhesive and Sealants Manufacturers Association of Canada, Canada) – [asmac.net](http://asmac.net)
- BASA (British Adhesives and Sealants Association, UK) – [www.basaonline.co.uk](http://www.basaonline.co.uk)
- CATIA (China Adhesives and Tape Industry Association, China) – [www.cnaia.org](http://www.cnaia.org)
- DETIC (Association Belgo-Luxembourgeoise des Producteurs et des Distributeurs de Savons, Cosmétiques, Détergents, Produits d'Entretien, d'Hygiène et de Toilette, Colles et Produits Connexes, Belgium) – [www.detic.be](http://www.detic.be)
- FEICA (Federation Europeenne des Industries de Colles et Adhesifs, Europe) – [www.feica.eu](http://www.feica.eu)
- JAIA (Japan Adhesive Industry Association, Japan) – [www.jaia.gr.jp](http://www.jaia.gr.jp)
- KAIA (Korea Adhesive Industry Association, Korea) – [www.kaia.kr](http://www.kaia.kr)
- PACIA (Plastics and Chemical Industry Association, Australia) – [www.cas.com.au](http://www.cas.com.au)
- PSTC (Pressure Sensitive Tape Council, North America) – [www.pstc.org](http://www.pstc.org)
- TASA (The Adhesives and Sealants Association, India) – [www.tasaindia.org](http://www.tasaindia.org)
- VLK (Vereniging Lijmen en Kitten, Netherlands) – [www.vlk.nu](http://www.vlk.nu)

## 16.12.2 Consultancy and Academic Research Organizations

There are a wide variety of consultancy bodies, often called research and technology organizations (RTOs) and universities who can offer a range of services from simple adhesive searching and material screening activities through adhesive bonding trials to fundamental modeling and phenomenological studies and failure investigation. RTOs are more industry focused and are therefore more sensitive to the budget and timescale requirements of industry, but services will often be priced at a higher level than those offered by universities due to the specific nature of the work and the allocation of specific resource to the client's needs. Examples of RTOs include:

- AIMEN (Spain) – provides technological services and engages in R&D&i activities in different areas such as high performance materials, smart manufacturing, laser based manufacturing, laser-assisted manufacturing, micro and high precision manufacturing, environmental technologies – [www.aimen.es](http://www.aimen.es)
- AIRTO (UK) Association for Innovation, Research and Technology Organisations – assists members to network and engage collectively with government and policy makers in the UK's R&D landscape on matters of mutual interest, including research policy, innovation strategy – [www.airto.co.uk](http://www.airto.co.uk)
- BATTELLE (USA) – conducts research and development, manages laboratories, designs and manufactures products, and delivers critical services for its clients – [www.battelle.org](http://www.battelle.org)

- 498 • Cambridge Consultants (Global) – innovative product development in a wide  
499 range of industrial sectors including medical technologies, consumer products,  
500 industrial products, smart metering, defense and securing, wireless, semiconduc-  
501 tor, transport, and clean-tech – [www.cambridgeconsultants.com](http://www.cambridgeconsultants.com)
- 502 • ChemQuest Inc. (USA) – is an international strategic business management  
503 consulting firm specializing in paints, coatings, resins, polymers, adhesives, and  
504 sealants industries – [www.chemquest.com](http://www.chemquest.com)
- 505 • EARTO (EU) European Association of Research and Technology Organisations –  
506 a nonprofit international association established in Brussels to promote and  
507 defend the interests of RTOs in Europe by reinforcing their profile and position  
508 as a key player in the minds of EU decision-makers and by seeking to ensure that  
509 European R&D and innovation programs are best attuned to their interests –  
510 [www.earto.eu](http://www.earto.eu)
- 511 • Element – previously MERL Ltd (Global) – R&D, laboratory testing, and  
512 consultancy services on polymer materials for engineering systems and structures  
513 – [www.element.com](http://www.element.com)
- 514 • Fraunhofer (Bremen, Germany) Institute for Manufacturing Technology and  
515 Advanced Materials (IFAM) – undertakes research and development work in  
516 the following areas: shaping and functional materials and adhesive bonding  
517 technology and surfaces – [www.ifam.fraunhofer.de](http://www.ifam.fraunhofer.de)
- 518 • HORIBA MIRA (UK) Motor Industry Research Association – is an automotive  
519 engineering and development consultancy company headquartered near Nuneat-  
520 on in Warwickshire, United Kingdom. It provides product engineering, research,  
521 testing, information and certification services to the automotive sector – [www.horiba-mira.com](http://www.horiba-mira.com)
- 522 • ISQ (Portugal) – founded in 1965, ISQ is a private and independent company  
523 providing inspection, testing, training and technical consultancy – [www.isq.pt](http://www.isq.pt)
- 524 • NPL (UK) – National Physical Laboratory is a world-leading center of excellence  
525 in developing and applying the most accurate measurements standards, science  
526 and technology – [www.npl.co.uk](http://www.npl.co.uk)
- 527 • PA Consulting Group (Global) – offers technology development and technology  
528 consulting services across a broad range of sectors including life sciences and  
529 health care, consumer products, communications and electronics, public sector,  
530 defense, energy, and transport – [www.paconsulting.com](http://www.paconsulting.com)
- 531 • SATRA (UK) – is an independent research and testing organization established in  
532 the UK in 1919. It has technical facilities in Europe and China serving customers  
533 throughout the world and is considered a leading technical authority for footwear  
534 and leather – [www.satrapra.com](http://www.satrapra.com)
- 535 • Smithers RAPRA (Global) – world-leading independent rubber, plastic, and  
536 composite consultants providing services including testing, analysis, processing,  
537 and research for the polymer industry and industries using plastics and rubber in  
538 any component, product, or production process – [www.smithersrapra.com](http://www.smithersrapra.com)
- 539 • TWI Ltd. (UK) – Global leader in technology engineering with key expertise in  
540 the welding and joining of all types of materials. The ACS (adhesives, compos-  
541 ites, and sealants) section provides assistance to industrial members in all aspects  
542

of adhesive and adhesion-related matters including material selection, surface preparation, design, testing, and training – [www.twi-global.com](http://www.twi-global.com)

• VTT (Finland) – is the leading research and technology company in the Nordic countries – [www.vttresearch.com](http://www.vttresearch.com)

• WMG (UK) Warwick Manufacturing Group – WMG was founded by Professor Lord Kumar Bhattacharyya in 1980 to help reinvigorate UK manufacturing. From its inception WMG's mission has been to improve the competitiveness of organizations through the application of value adding innovation, new technologies and skills deployment, bringing academic rigor to industrial and organizational practice. Today, the Group has grown into an international role model for how universities and business can successfully work together – [www2.warwick.ac.uk](http://www2.warwick.ac.uk)

Universities often can offer highly technical or scientifically focused work and access to sensitive instrumentation, but sometimes their priorities in relation to delivery timescales are less well aligned to the needs of industry. Confidentiality can also often be an issue in that universities will see a high throughput of students and possibly staff making it harder to control and maintain confidentiality. This is due to the fact that academic institutions have two primary functions, i.e., teaching and research. In view of this, specific services to industry will have a lower priority unless a dedicated capability is created, such as spin-out consultancy services.

Both RTOs and academic organizations can offer considerable assistance to the end user, but care is often needed when determining who to go to. Where a decision has been made to invest in a long-term study of a particular area and time is not critical, looking to a university and/or perhaps funding a student for a doctorate or master's degree in that area may be the best solution. This approach may provide significant benefits to the company funding the work but the timescale will be in years and the work will be often limited to generic models as there will be a requirement for the student to publish in the open literature.

At the time of writing, universities with a significant track record in adhesives research include:

#### UK

- University of Birmingham, Department of Chemical Engineering (K Kendall – contact mechanics), School of Dentistry (W Palin – dentistry adhesives)
- University of Glasgow, School of Engineering (M Cowling – adhesive bonding of ship-related structures)
- Imperial College, London, Department of Mechanical Engineering (A Kinloch – fatigue and durability of adhesive joints, B Blackman – studies and testing of structural adhesives, A Taylor – nanocomposites research, F Guild – joint mechanics)
- Loughborough University, Department of Materials (G Critchlow – surface analysis, A Ansarifard – bonding to rubber, J Comyn – curing and cross-linking of adhesives and sealants)
- University of Nottingham, Faculty of Engineering (I Ashcroft – mechanics and stress analysis of joints)

- Oxford Brookes University, Department of Mechanical Engineering and Mathematical Sciences (A Hutchinson – wide variety of adhesive-related areas including civil structure repair, bonding, and sealing), Joining Technology Research Centre (J Broughton – analysis of bonded and sealed joints, structural repair, durability, timber bonding, R Adams – mechanics of adhesive joints)
- University of Oxford, Department of Engineering Science (R Adams – mechanics of adhesives joints)
- Strathclyde University (R Pethrick – dielectric studies of adhesive joints and their durability to water)
- University of Surrey Department of Mechanical Engineering Sciences (J Watts – surface analysis, A Crocombe – stresses in joints), Department of Physics (J Keddie – pressure-sensitive adhesion)

#### Europe

- Saarland University, Saarbrücken, Germany (W Possart – adhesion, adhesion)
- University of Alicante, Spain (J M Martinez – shoe industry)
- University of Bordeaux, France (E Papon – adhesives, M Shanahan – adhesion, fracture)
- Technical University Braunschweig, Germany (K Dilger – adhesives technology in industry)
- IFREMER, Brest, France (J Y Cognard – joint mechanics)
- University of Kaiserslautern, Kaiserslautern, Germany (PL Geiss – durability)
- Laboratoire Génie de Production (LGP) – Ecole Nationale d'Ingénieurs de Tarbes – France (J A Petit – electronics and durability)
- University of Porto, Portugal (LFM da Silva – joint mechanics)
- University of Turin, Italy (L Goglio – joint mechanics)

#### USA and Canada

- Virginia Tech, USA (D Dillard – joint mechanics)
- University of Akron, USA (E Sancaktar – adhesives)
- University of Toronto, Canada (J Spelt – joint mechanics)

#### Asia

- Hiroshima University, Japan (T Sawa – joint mechanics)
- Korea Advanced Institute of Science and Technology, Korea (D G Lee – joint mechanics)
- Tokyo Institute of Technology, Japan (C Sato – joint mechanics)

In contrast, if the research is time critical and/or commercially very sensitive, then a dedicated RTO may be the most appropriate solution. Such organizations have experience managing such industrial needs and will fully respect the confidentiality that often accompanies such activities. Some organizations often specialize in one

industrial sector or manufacturing activity, whereas others will be more broad-based. In some instances, it may be possible to obtain economic assistance from national or local government to fund specific topics.

### 16.12.3 Online Assistance

One of the most significant developments in recent years is the rise of the Internet and the wealth of information that can now be obtained from this ever-expanding resource. Virtually all adhesives companies and suppliers have an online presence where product information (MSDS, TDS, etc.) can be accessed and downloaded. Many companies also offer adhesive selection facilities, though the majority of these still take the format of a requirements form which needs to be filled in and sent to the technical team where a human response will be made in due course. While this is a pragmatic approach and may well result in contact being made with an adhesives expert who should be able to offer good advice, the advice will be company product biased. The end user will therefore have to make calls to a range of adhesive suppliers to ensure that a full market appraisal has been achieved. Alternatively, one can find a small number of web sites where the end user can learn more about adhesives and associated design issues from a more neutral stand point. In some instances, some rudimentary design elements can even be applied to provide an initial sanity check to determine whether a design or an adhesive choice has viability. Examples of such sites include:

- Adhesives Toolkit – originally a UK government-funded project designed to assist adhesives end users with most adhesives-related topics including selection, design, and test standards – [www.adhesivestoolkit.com](http://www.adhesivestoolkit.com)
- Adhesives.org – a web site developed and supported by the Adhesives and Sealant Council and ChemQuest; it provides many useful areas of help including supplier links, introductions to adhesives, and articles on markets and applications – [www.adhesives.org](http://www.adhesives.org)
- GlobalSpec – specialized vertical search information services, and e-publishing company serving the engineering, manufacturing, and related scientific and technical market segments. The web site provides searching facilities for key industrial adhesive suppliers with a wide range of links, mostly USA based – [www.globalspec.com](http://www.globalspec.com)
- Specialchem4adhesives – an informative web site which primarily serves the adhesives industry, but many of the articles on the site provide useful background reading for anyone wanting to become more informed on adhesives matters – [www.specialchem4adhesives.com/index.aspx](http://www.specialchem4adhesives.com/index.aspx)

### 16.13 Conclusion

Adhesive selection can be a complex and sometimes frustrating task, with so many products to choose from and an almost infinite range of properties at one's disposal. However, with a logical approach and following some straightforward principals as

outlined in this chapter, it is possible to arrive at a sensible number of candidates relatively easily. It is normally easy to adopt a deselection approach where one identifies and ranks key selection parameters and their limits. The critical selection path will rest upon those parameters and it is strongly advised that sufficient time is devoted to this initial task. The actual initial selection activity is essentially a desktop exercise, aided by personal experience, searching technology and a network of experts to draw upon. Once practical trials begin, timescales and resource start to escalate rapidly and selection of the wrong adhesive(s) can be costly. It should also be mentioned that when comparing published adhesives data from different suppliers, care must be taken to check how the data was derived as the units used for each data set may be different or the joint strength may be obtained from tests on different substrates with different surface conditions or aging data reported may have been obtained in different environments.

Finally, it must be stressed that in virtually every new case where adhesives are to be employed, there will be sufficient differences to make it necessary for at least some practical trials to be carried out. The results made come out as predicted but it is better to reinforce confidence and minimize risk. Full details of the types of testing that can be carried out are discussed in Part D and also in Part F.

Books provide an excellent starting point to become acquainted with the very diverse world of adhesives and adhesion-related phenomena, but due to the rapidly changing world in terms of industrial takeovers, etc., books will rarely be able to provide the most up-to-date information on specific adhesive products. Direct contact with suppliers, experts/consultants, and use of the Internet are currently still the best ways to keep on top of adhesive selection when it comes to identification of specific products.

The range of reference books available to the reader is very large. Some are very generic while others are highly specialized.

**Abstract**

A number of physical properties are relevant and important for characterizing adhesives, providing insights into the underlying behavior of the base polymer(s) as well as the effects that fillers, additives, and other factors may play on the behavior of the uncured adhesive, and also the quality and performance of bonded joints that may result. Characterizing these adhesive properties, interpreting the results, and understanding the implications provide important insights for assuring quality control, for improving bond performance, for assessing the relative merits of adhesive options for a given application, and for understanding the polymer more completely. This chapter addresses several

relevant physical properties of bulk adhesives, including viscosity, density, and stress-strain behavior. Methods of characterizing these properties are discussed, along with insights for interpreting these quantities and their implications for polymeric adhesive systems.

## 17.1 Introduction

The formation of satisfactory adhesive bonds normally involves the adhesive being applied in or changed to a liquid state to enable it to flow and wet the adherends, and then become a solid to resist loads associated with the service conditions (The exception being pressure-sensitive adhesives, which do not undergo the liquid to solid transition, but their high compliance is sufficient to wet the substrate (Dahlquist criterion), and their stiffness, strength, and energy dissipation capabilities are sufficient to resist removal.). Characterization of physical properties over this range of states from liquid to solid, as well as of a function of time, temperature, and often other factors, is of critical importance for formulating and selecting adhesives, optimizing fabrication techniques, and predicting performance. Excellent sources on a wide range of physical properties of polymers are available, including Ferry (1980), Osswald and Menges (1995), van Krevelen (1997), Rubinstein and Colby (2003), Ward and Sweeney (2004), and Mark (2007).

Density is a common physical property of interest, and although unlikely to be the determining factor in adhesive selection, density is an important indicator of the nature of a polymer, including chemical family, morphology, and filler or void content. While other physical properties such as moduli can vary over several orders of magnitude, density variations are typically much more subtle. While relatively simple methods are sufficient to characterize polymer density for some purposes, more precise methods are sometimes needed to ascertain quantitative attributes of the polymer in question. This chapter will review some of the methods for characterizing both liquid and solid polymer density and also some of the information that can be gleaned about a given material from careful density measurements.

Modulus and viscosity are two other important physical properties, representing the limiting idealizations of solid and liquid behavior. Recognizing their inherent viscoelastic nature, a particularly important aspect of any polymeric material is the time scale involved for the various transitions that occur. The time dependence of inorganic materials usually arises through the involvement of a very limited number of atoms, in mechanisms associated with the movement of dislocations as well as of bulk and grain boundary diffusion. For polymeric materials, however, time dependence is often associated with the complex movement of very large macromolecules or portions thereof, especially when flow of the liquid or uncured adhesive is involved. Depending on the scale of motion, a very wide range of characteristic times can be involved, ranging from short times associated with a limited number of atoms (e.g., crankshaft motion or the rotation of a side chain) to very long times required for entire molecules to slide or reptate past one another in a cooperative manner (Ferry 1980; Rubinstein and Colby 2003). Any one transition mechanism

can be considered to have an associated characteristic time,  $\tau$  (though the behavior may be spread over a number of decades). In considering the response of these time-dependent materials in light of experimental methods used for characterization, a useful concept is the Deborah number (Goodwin and Hughes 2000) defined as:

$$D_e = \frac{\tau}{t} \quad (1)$$

where  $t$  is the time of an experiment. For  $D_e \gg 1$ , the experiment may not adequately capture the time dependence of the respective transition, which occurs at much longer times than the experimental window. When  $D_e \ll 1$ , the experiment also may fail to capture important time-dependent deformation, which occurs much faster than the measurement capabilities of the instrument. When the Deborah number is on the order of unity, however, a well-designed experiment can capture this portion of the time-dependent behavior. Accelerated characterization techniques, such as the time temperature superposition principle (TTSP), can be employed to capture behavior that might otherwise be missed. TTSP involves the use of elevated temperature characterization to accelerate the polymer response into the experimental window, for predicting long-term response that is not experimentally feasible, or decelerate rapid polymer response to quantify very short time response not otherwise measurable in the test equipment (Ferry 1980; Rubinstein and Colby 2003) (► Chap. 18, “Thermal Properties of Adhesives”). Recognition of this viscoelastic response, including the use of appropriate experimental and interpretation techniques to properly characterize this behavior, is required. Because the characteristic times of complex polymeric materials often span many orders of magnitude, typical stress-strain behavior often exhibits significant rate dependence and viscosity experiments are complicated by the elastic component of seemingly liquid-like materials. With this as a background, characterizing viscoelastic materials from both the solid and liquid perspectives can be approached by addressing two different but related methodologies, both of which are discussed herein. Both approaches can, in principle, capture manifestations of the same viscoelastic nature of polymeric behavior, though in practice TTSP or other means are required to elucidate the full range of time-dependent mechanical properties.

## 17.2 Density

The *density* of a material, defined as the mass divided by the volume, is an important material property:

$$\rho = \frac{m}{V} \quad (2)$$

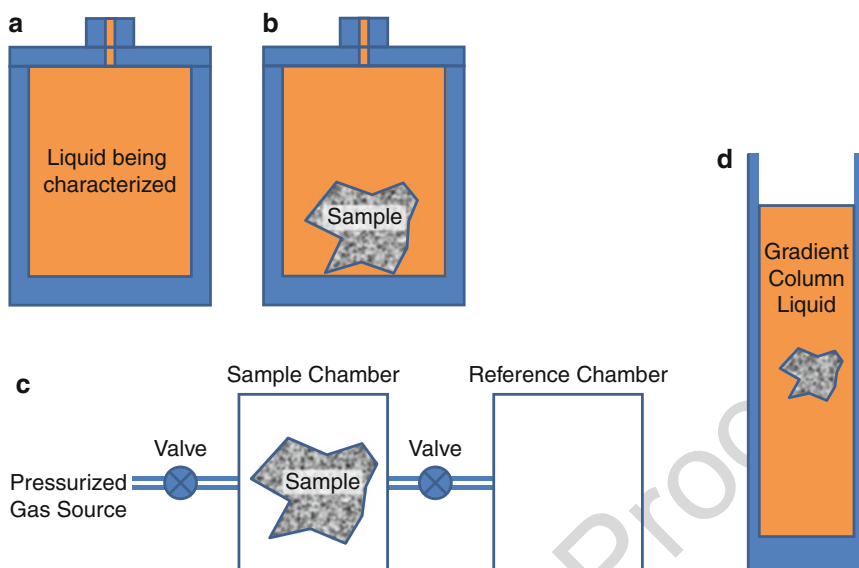

*Specific volume* is the reciprocal of the density. *Relative density* is the ratio of the density of a material to that of a reference material; for *specific gravity*, the reference material is water (Often the reference is water at 4 °C, when its density is greatest.) (Kholodovych and Welsh 2007). *Bulk density* is used to characterize the density of discretized forms of adhesives such as pellets and powders, where packing results in

large amounts of voids. Density typically decreases with increasing temperature and increases with pressure, although the latter dependence is very weak over commonly encountered pressures, except for foamed, pelleted, or granular forms of a material. *Physical aging* of glassy amorphous polymers is used to describe the time-dependent densification toward the equilibrium configuration.

Density may be measured through several means. In the direct measurement approach, the mass of a regular-shaped object is measured and the volume is calculated from known dimensions. This method is easily extended to liquid adhesives by determining the additional mass of a liquid used to fill a container of known volume. Indirect methods, useful for any solids, but especially for objects of irregular shapes, involve the use of a fluid or gas and include the volume and mass displacement techniques. In the volume displacement method, the amount of a fluid displaced by immersion of an object of interest provides a volume for the density calculation. This volume may be measured by the rise of the fluid in a graduated cylinder or the effluent from a container filled to the brim. The mass displacement method is based on Archimedes principle, which states that the buoyant force is the difference between the weight of an object measured in air and measured when immersed in a liquid of known density. Since the buoyant force is equal to the weight of the liquid displaced, one can determine the density of the object if the density of the liquid is known. Density columns have also been used to characterize polymer density, utilizing discrete or continuous gradients. A sequence of immiscible liquids, for example, will stratify into discrete layers, a popular classroom demonstration. Precise measurements can be obtained when polymer samples are allowed to drop to an equilibrium position in continuous gradient columns resulting when two miscible liquids with different densities are mixed under carefully controlled conditions (ASTM-D1505-03 2003).

Although seemingly a simple measurement, accurate density measurements require considerable care, especially since significant changes in formulation, processing, morphology, and physical aging, which, may of interest, typically result in relatively small changes in density. Thus, density is not particularly sensitive for reflecting a range of differences, so considerable precision is often required for meaningful quantitative studies. The density of polymeric samples, as well as fluids used for the indirect methods and even the containers in which such measurements are performed, are temperature dependent, so careful temperature control may be needed. Since mass is typically measured in air, the buoyant force of air should be recognized and included for precise density determinations. Voids or porosity within the polymer liquid or solid sample can significantly affect the measured density, as can the presence of bubbles on the walls of containers in the volume displacement method. Buoyant bubbles can also form around polymer samples when they are weighed in a liquid or dropped into a density column, effectively reducing their apparent density. Furthermore, the fluids used in the indirect methods should be chosen so that they have minimal interaction with the polymer samples. Measurements of displaced fluids flowing from a full container are complicated by surface tension of the fluid, so small mouths or capillary tubes are desired for escaping effluent. Considerable variation in reported densities can be found in

**Fig. 1** Illustrations of several methods to determine specimen volume or density: (a) pycnometer for liquid samples, (b) pycnometer for solid samples, (c) gas pycnometer, and (d) density gradient column showing sample suspended in liquid

the literature for a given polymer, due in part to the methods and equipment used, the skills of the operator, and whether appropriate corrections were made for buoyancy and other factors. Much of the variation, however, may be due to real differences associated with molecular weight, purity, processing conditions, physical aging, and the thermal, chemical, and mechanical history of the samples (Kholodovych and Welsh 2007). For porous materials, the measured density will depend on the method used and the nature of the porosity. If all pores are open to the outside and a gas is used to probe volume, the density of the polymer itself is obtained; if volume is directly measured from linear dimensions, the total volume of the foamed or porous material is obtained. When some pores are not open to the outside, or when the gas or liquid does not penetrate or wet the pores completely, intermediate values of density are obtained. Additional details on several popular methods (illustrated in Fig. 1) for determining polymer density are given in the following section.

### 17.2.1 Experimental Methods for Polymer Density Measurements

In practice, a pycnometer can be used to measure the density of liquid polymers by placing them in a cup of known volume and mass. A cover containing a capillary through which the overflow can pass for removal is typically added. Since both the volume of the cup as well as the density of the liquid adhesive are temperature dependent, accurate readings require that temperature be carefully controlled for the

test. The standard cup can be filled with a liquid adhesive that is below the desired test temperature. Then the cup and adhesive are heated to the temperature at which the density is to be determined, and the mass is determined after the excess overflow is wiped from the overflow orifice (ASTM-D1875-03 2003).

Pycnometers can also be used to measure the displacement of a gas or fluid from a container of fixed volume when a solid sample is added. Fluid-based pycnometers typically involve accurate mass measurements of the container when filled only with the fluid and when the sample is added. Knowing the density of the fluid and the mass of the polymer sample, one can then determine the density of the polymer sample. Commercial units are available, although standard laboratory equipment can also be used. Because the density of the fluid may be quite temperature dependent, care must be used to control temperature and use the density of the fluid at the test temperature, and care is also needed to avoid bubbles attached to the sample or container walls.

Gas pycnometers are popular because they avoid wetting and bubble issues. Because of this, they work well on materials with porosity and on granular and powdered materials, as well as on materials that might absorb, be dissolved in, or otherwise be affected by fluids used in fluid pycnometers. In constant volume gas pycnometers, a fixed amount of pressurized gas is introduced into a chamber containing the sample. A valve is then opened to permit this volume of gas to expand to fill a second or reference chamber as well. In a properly calibrated system, the pressure difference for the gas in the first chamber and then in both chambers, coupled with Boyle's law, allow one to measure the volume of the sample (ASTM-D6226 2005).

Continuous density gradient columns can be built and are commercially available. When a sample is dropped into the column, it will fall until it reaches the region of the column containing the same density. From the equilibrium position of the material and its relation to reference floats, the density can be accurately determined (ASTM-D1505-03 2003; ISO-1183-1:2004 2004). Organic solvents or salt solutions can be used to form the gradient column, but the liquids should be chosen so that they will easily wet the sample but not swell or dissolve the sample (Kholodovych and Welsh 2007).

## 17.2.2 Factors Affecting Polymer Densities

Polymer densities range significantly for common polymers, from as low as 0.6 g/cm<sup>3</sup> for thermoplastic polybutylene to 2.28 g/cm<sup>3</sup> for polytetrafluoroethylene (Kholodovych and Welsh 2007). Obviously, the atomic mass of the elements present in a molecule will affect the density, as well as their respective atomic radii. Thus, hydrocarbon polymers tend toward the lower range of density, whereas molecules containing large molar fractions of the halogens have larger densities. Density is affected by the relative rigidity of the molecule and the size and flexibility of side chains, which affect chain conformations and the resulting density.

## Crystallinity

Since the crystalline phase of a semicrystalline polymer is typically packed more efficiently, its density may be as much as 15% higher than the density of the corresponding amorphous region (Kholodovych and Welsh 2007). van Krevelen (1997) suggests that the density of a semicrystalline material,  $\rho_{sc}$ , may be estimated by

$$\rho_{sc} = \rho_a(1 + 0.13x_c) \quad (3)$$

where  $\rho_a$  is the density of the amorphous material and  $x_c$  is the degree of crystallinity, but the accuracy depends on the actual density difference between amorphous and crystalline regions, which can vary somewhat (Kholodovych and Welsh 2007). Density measurements have been useful for ascertaining the degree of crystallinity, but are complicated by the precise density measurements required to detect changes in crystallinity and the need to know the density of the crystalline and amorphous states, which can be difficult to determine in materials that are naturally semicrystalline. X-ray scattering differential scanning calorimetry (DSC), and other experiments provide capable alternatives for measuring polymer crystallinity, and are often preferred.

## Fillers and Foamed Materials

In addition to density variations among neat resins, significant density variations arise when these resins are formulated to contain fillers, which are often heavier inorganic materials, such as silica, calcium carbonate, aluminum, or even silver for electrically conductive adhesives. Where filler and polymer densities are considerably different, the density of the composite material can be used to determine filler content quite accurately, provided no voids are present. Voids will reduce the apparent density of a polymer, regardless of whether intentionally added or unintentionally introduced through the mixing process. Lower density adhesives can be produced when foaming agents are included or for syntactic foams containing microballoons. Foamed adhesives can provide lower weight, reduced stiffness, lower thermal conductivity, reduced coefficient of thermal expansion, altered response to ultrasonic energy, and flame retardant and ablative properties. These and other physical characteristics are often directly related to the density, making it an important quantity for estimating other physical properties (Gibson and Ashby 1999).

## Temperature Dependence

As with gases, the densities of solids and liquids also depend on the temperature and pressure at which measurements are made. Polymers expand more with temperature than most other engineering materials, having coefficients of thermal expansion that may be an order of magnitude larger than common metals, and as much as two orders of magnitude higher than some ceramics. In light of this, the density of polymers is significantly more temperature dependent. Dimensional changes associated with linear and volumetric expansion coefficients of materials arise from the asymmetry of the energy well associated with atomic spacing. Stronger interatomic forces, such as seen in ceramics and metals, typically result in deep energy wells with steep walls

and small coefficients of thermal expansion. The intermolecular forces between polymer molecules are typically weaker secondary interactions (e.g., van der Waal's or hydrogen bonding), resulting in shallow energy wells with considerable asymmetry about their equilibrium separation distance. Further complicating dimensional changes and their effect on polymer density, unlike gases, glassy solids in particular are often characterized in nonequilibrium thermodynamic states, resulting in a time dependence of density as well.

In understanding the role that temperature, pressure, and time have on polymers, the partitioning of volume within a polymer is important to understand. The majority of the space within a polymer is *occupied volume*, corresponding to the volume occupied by the individual atoms. The remainder of the space is *free volume*, an important quantity that significantly affects many of the physical, mechanical, and dielectric properties of a polymer, and is discussed further in ► Chap. 18, “Thermal Properties of Adhesives.” Polymers contain significantly more of this unoccupied space than other materials because the macromolecular chains have much more limited degrees of freedom than individual atoms due to the required continuity of the backbone, the bulky nature of side chains, steric hindrance, and other factors. For materials such as metals and ceramics, which do not contain significant amounts of unoccupied volume, the temperature dependence of density is quite small, with expansion corresponding primarily to expansion of the occupied volume associated with increasing atomic spacing. In polymers, however, the expansion of the free volume with temperature is much more significant, and in fact can be the dominant portion of polymer thermal expansion with temperature. Because the mobility of polymer chains requires free volume, the properties of polymers change significantly with temperature, especially about transition regions such as the *glass transition temperature*,  $T_g$ , which is the temperature at which molecular mobility changes dramatically as the polymer goes from glassy to rubbery behavior. Interestingly, this important transition occurs at fractional free volumes of about 2.5% for many polymers (Ferry 1980). In essence, once any polymer has about 2.5% fractional free volume, the molecules will have enough mobility to transition from glass-like to liquid-like (for very low molecular weights) or rubber-like (for high molecular weights with chain entanglements or in cross-linked systems) properties. Figure 2 shows the specific volume (reciprocal of density) as a function of temperature for a typical polymer, showing (specific) occupied, free, and total volume (Kovacs 1964). The expansion of free volume is seen to be responsible for a significant portion of the increase in total volume. Furthermore, there is a rapid increase (often about threefold) in the coefficient of thermal expansion, and because of its dominant effect, the total volume, as one passes through  $T_g$  (Ferry 1980). In light of this, the density of polymers is seen to be considerably more temperature dependent than metals and ceramics, and even more so for polymers above their glass transition temperature. Useful discussions of the temperature dependence of polymer density can be found in Ferry (1980) and Orwoll (2007).

Density measurements associated with temperature changes can often be measured through either volumetric or linear dilatometry, noting that the volumetric coefficient of thermal expansion is three times the linear coefficient of thermal

**Fig. 2** Illustration of total, free, and occupied specific volume in a polymer showing a  $T_g$  for samples cured at finite and infinitesimally slow rates

expansion. The latter is often measured in instruments such as thermal mechanical analysis (TMA) equipment that are fabricated with low expansion materials and carefully calibrated to correct for instrument dimensional changes. Additional methods to measure CTE and the associated stress-free temperature and residual stress state are discussed in ► Chap. 22, “Special Tests.” Mercury dilatometry is briefly discussed in ► Chap. 18, “Thermal Properties of Adhesives”; this can be useful to examine first-order (e.g., melting) and second-order (e.g.,  $T_g$ ) transitions in polymers, as well as explore physical aging and kinetics of equilibration in temperature jump experiments.

### Pressure Dependence

While doubling the pressure of an ideal gas will double the density according to Boyle’s law, pressure has much less effect on the density of solids and liquids, including polymers. Since the occupied space is filled with atoms whose size is barely affected by practical pressures, changes in density in polymers are often more associated with changes in the free volume. Free volume does contract when pressure is applied (Ferry 1980) and can reduce mobility and retard viscoelastic relaxations (Knauss and Emri 1987). The compressibility of polymers is very low, however. Even rubber, which is often referred to as “incompressible” (because elastomers deform in shear so much easier than volumetrically), is two orders of magnitude more compressible than steel. Thus, polymer density variations due to pressure are typically significant only when relatively high pressures are encountered in highly constrained configurations (Lai et al. 1992; Yu et al. 2001; Dillard et al. 2008; Tizard et al. 2012) or with foams or other products containing a significant fraction of voids. More detailed discussions of the pressure dependence of density can be found in Ferry (1980) and Orwoll (2007).

### Time Dependence

Although not often considered, density can be a time-dependent property in non-equilibrium systems such as amorphous regions of polymers below their glass transition temperature ( $T_g$ ), which is discussed in more detail in ► Chap. 18, “Thermal Properties of Adhesives.” In the rubbery region, a change in temperature or hydrostatic stress state results in a nearly immediate change in volumetric strain and density. For the case of a glassy polymer, however, the restricted mobility means that a portion of the response will be delayed, requiring convolution integrals to properly characterize the material’s behavior (Christensen 1982) and conveying the importance of the prior thermal and mechanical history on measurements of density. Of specific interest for density measurements is the process of physical aging associated with the gradual densification of a glass toward the equilibrium state (Kovacs 1964; Struik 1978). When an amorphous polymer is cooled from a cure or processing temperature through the glass transition temperature, the polymer density increases at a relatively constant rate until reaching  $T_g$ , below which the temperature dependence weakens significantly, as shown in Fig. 2 in terms of the specific volume. The polymer is unable to continue densifying along the liquidous line because of the reduced mobility (Matsuoka 1992; Shaw and MacKnight 2005). The liquidous line, however, remains the equilibrium configuration toward which molecular motion tends. The deviation from the equilibrium state explains why the Williams-Landel-Ferry (WLF) relationship for thermal shift factor breaks down below  $T_g$  (Struik 1978). Over time, the polymer will slowly continue toward the equilibrium configuration, as illustrated in Fig. 3. Upon heating, the polymer expands until it reaches the vicinity of  $T_g$ , where a step-like increase in volume can occur. Such behavior is a mechanical manifestation of the enthalpic anomalies that occur in DSC characterization of polymers (► Chap. 18, “Thermal Properties of Adhesives”). Physical aging usually occurs fairly slowly, often in a logarithmic time fashion (Struik 1978). Density measurements can be affected by physical aging, with

**Fig. 3** Illustration of physical aging as the reduction in excess free volume with aging time

volumetric changes occurring most rapidly right after being cooled from above the glass transition temperature. By heating physically aged materials above their glass transition temperature, polymers can be rejuvenated, in that physical aging can effectively be erased (Kovacs 1964; Struik 1978). When cooled, the density and other physical properties can return to the original values encountered when the polymer was first made, unless chemical or other degradation has occurred. Dropping the temperature below  $T_g$ , however, will restart the physical aging clock and its associated time dependence.

## 17.3 Viscosity

Viscosity is a very important property of adhesives, especially in their uncured fluid state, providing information that is of significant importance for mixing, pumping, and dispensing purposes (see Part G Manufacture), as well as for more fundamental understanding of the polymer itself. Relatively simple viscosity measurements can also be useful as a relatively sensitive metric for quality control, indicating changes in formulation, processing, and aging. More sophisticated techniques can provide important insights into the chemical structure, time and temperature dependence, and other properties, providing fundamental understanding of the polymer and allowing for accurate predictions of flow in complex systems. This chapter outlines some of the basic information relevant to viscosity as applicable to adhesive materials, but more detailed discussions should be examined for a thorough treatment of viscosity and the more comprehensive field of rheology (Bird et al. 1987; Larson 1988; Macosko 1994; Goodwin and Hughes 2000; Berker 2002; Han 2007).

### 17.3.1 Newtonian Behavior

The concept of viscosity is credited to Newton, who observed that the resistance to deformation of a fluid is proportional to the rate of change of deformation (Macosko 1994). Just as the elastic modulus is associated with the resistance of a solid to deformation, viscosity is a measure of a fluid's internal resistance to flow or deformation rate. *Viscosity* is defined as the ratio between the shear stress and the shear strain rate:

$$\eta = \frac{\tau}{\dot{\gamma}} \quad (4)$$

where  $\tau$  is the shear stress and  $\dot{\gamma}$  is the time rate of change of the shear strain,  $\frac{dv}{dy}$ , where  $v$  is the velocity and  $y$  is the coordinate perpendicular to the velocity, as illustrated in Fig. 4. Viscosity has traditionally been reported in poise or centipoise, but the SI units are *Pascal · seconds* [ $\text{Pa} \cdot \text{s}$ ], where  $1\text{Pa} \cdot \text{s} = 10\text{poise} = 1000\text{centipoise}$ . Viscosity as defined above is also referred to as the *absolute viscosity*. A related quantity, the *kinematic viscosity*, traditionally reported in Stokes,  $1\text{Stoke} = 10^{-4}\text{m}^2/\text{s}$ ,

**Fig. 4** Illustration of fluid element being sheared by a velocity difference

**Fig. 5** Illustration of several types of viscosity measurement configurations: (a) coaxial cylinder, (b) parallel plate, (c) cone and plate, and (d) capillary

is the absolute viscosity divided by the density of the fluid, resulting in a quantity that is particularly useful when relating viscous to inertial forces.

Viscosity may be physically measured in a number of ways. Some of the simplest and oldest methods rely on the time required for a given amount of liquid to flow from a chamber through an orifice or capillary. Such methods remain popular for quality control evaluation of materials because of their simplicity and ease of use. Some techniques span a range of applied pressures as the pressure head drops with flow, while in other tests, a constant pressure is applied. Steady-state flow methods work on the basis of applying a constant velocity difference across a known gap, and often involve the use of a rotating cylinder, plate, or cone. The torque required to maintain flow at this rate is measured and used to characterize the viscosity. A third primary method is the use of oscillatory methods to characterize the dynamic or complex viscosity. This method is seen as a bridge to the characterization of solid materials, which are often tested in a similar fashion. These methods, several of which are illustrated in Fig. 5, are described briefly in the following sections.

### Steady-State Rotation Rheology

Steady-state shear flow behavior can be measured with rotational equipment operating at prescribed angular velocities. The cone and plate configuration is commonly used (Han 2007), resulting in a relatively uniform shear rate within the test section

provided the angle between the cone and flat plate is relatively small (on the order of several degrees). Couette or concentric cylinder, Mooney, and double gap configurations have also been used (Goodwin and Hughes 2000). A variety of commercial instruments are available to characterize viscosity using this approach, many with interchangeable spindles to allow one instrument to be useful over a wide range of polymer viscosities.

### Capillary and Slit Rheometry

A number of rheometers have been developed based on flow through an orifice or capillary. Simple viscometers based on flow through a capillary involve flow of a fixed volume of fluid from a container. Instrumented versions include plunger-type capillary rheometers, in which a piston is used to force a fluid through a capillary. An inert pressurized gas can also be used to achieve the desired flow. Essentially, the pressure difference between the plunger and exit can be used to determine the relationship between the shear stress and strain rate at the walls of a capillary of known diameter and length. Corrections for end effects are often required to account for entrance losses, effectively lengthening the capillary by some fictitious distance, as can be determined with Bagley plots. Continuous-flow capillary rheometry allows one to not only measure the shear viscosity but also obtain the normal stress differences within a steady-state shear flow (Han 2007). Flow through a slit rather than a capillary has also been used, offering some advantages for certain situations (Han 2007).

### Dynamic or Complex Viscosity

In addition to their viscous properties, real liquids often exhibit elastic properties as well, meaning that if the applied stress is suddenly removed, stored elastic energy remains and can drive a partial recovery of the deformation. This combination of viscous and elastic behavior constitutes the class of viscoelastic materials. The limiting cases of solids and liquids correspond with materials that have either high or low Deborah numbers, the dimensionless ratio of characteristic material time to the time of the experiment. The time dependence of solid-like materials can be characterized through transient tests such as relaxation, in which the relaxation of stresses after a fixed strain is suddenly imposed; creep, in which the time-dependent strain is measured after a constant stress is suddenly imposed; and ramp tests, in which either stress or strain is increased at a constant rate (see ► Chap. 34, “Creep Load Conditions” in 1st edition). Characterization of the relaxation modulus and creep compliance can be made through either relaxation tests or ramp strain loading conditions, or through creep or ramp stress loading, respectively. Alternatively, linear viscoelastic behavior is often characterized through small strain, steady-state oscillation experiments, often using commercial dynamic mechanical analyzers (DMA), as also discussed in ► Chap. 18, “Thermal Properties of Adhesives.” Assuming a shear loading mode, the imposed stress and the resulting strain are given by the real parts of the complex shear stress,  $\tau^*(i\omega)$  and complex shear strain,  $\gamma^*(i\omega)$ , as:

$$\begin{aligned}\tau(t) &= \Re[\tau^*(i\omega)] = \Re[\hat{\tau} \cdot e^{i\omega t}] \\ \gamma(t) &= \Re[\gamma^*(i\omega)] = \Re[\hat{\gamma} \cdot e^{i(\omega t - \delta)}]\end{aligned}\quad (5)$$

441 where the carat denotes the amplitudes of the shear stress or strain,  $\omega$  is the angular  
 442 frequency of oscillation,  $i = \sqrt{-1}$ , and  $\delta$  is the phase lag of strain behind stress. The  
 443 complex shear modulus of viscoelastic materials can be defined in terms of the ratio of  
 444 complex stress to strain and expressed as a combination of storage and loss shear moduli:

$$G^*(i\omega) = \frac{\tau^*(i\omega)}{\gamma^*(i\omega)} = G'(\omega) + iG''(\omega) \quad (6)$$

445 If one approaches the constitutive characterization from the perspective of mea-  
 446 suring the viscosity rather than the modulus, however, replacing the complex strain  
 447 by the complex strain rate, the analogous complex viscosity is obtained:

$$\eta^*(i\omega) = \frac{\tau^*(i\omega)}{\dot{\gamma}^*(i\omega)} = \eta'(\omega) - i\eta''(\omega) \quad (7)$$

448 where  $\eta'$  is the in-phase component corresponding to the viscous contribution to the  
 449 dynamic viscosity and  $\eta''$  is the out-of-phase or elastic contribution. (The negative  
 450 sign in Eq. 7 arises to maintain a nonnegative value of  $\eta''$ .) One can easily go back  
 451 and forth between the dynamic modulus and viscosity using:

$$\begin{aligned} \eta'(\omega) &= \frac{E''}{\omega} \\ \eta''(\omega) &= \frac{E'}{\omega} \end{aligned} \quad (8)$$

452 The loss tangent can be defined as the ratio of loss to storage components in either  
 453 designation:

$$\tan \delta = \frac{\eta'(\omega)}{\eta''(\omega)} = \frac{G''(\omega)}{G'(\omega)} \quad (9)$$

## 454 **Extensional or Elongational Viscosity**

455 Capillary, rotational, and dynamic methods mentioned above are used to characterize  
 456 the shear viscosity of liquids. Extensional viscosity is also of significant interest,  
 457 including applications relevant to adhesive dispensing processes such as blade and  
 458 curtain coating (Goodwin and Hughes 2000). Beyond the scope of this chapter,  
 459 extensional characterization is discussed in sources such as Macosko (1994),  
 460 Goodwin and Hughes (2000), and Han (2007).

## 461 **17.3.2 Non-Newtonian Behavior**

462 Although Newtonian behavior is a useful starting point for many systems, more  
 463 complex behavior is very common, especially in formulated adhesives that  
 464 often have high solids content, contain fillers and flow controllers, or consist of

high-molecular-weight hot-melts. When materials are non-Newtonian, it is appropriate to refer to the measured viscosities as apparent viscosities in recognition of the more complex rate-dependent behavior.

### Shear Rate Dependence

Non-Newtonian behavior results when a material's viscosity varies with the imposed strain rate. Use of rotational viscometers described above have been advocated to address this issue for adhesives, wherein the rotational speed is varied from lowest to highest and back to lowest speed, all without stopping the instrument (ASTM-D2556-93a 2001).

Over a significant range of relevant shear rates, many polymers exhibit a simple power-law dependency of the form (Berker 2002):

$$\eta = m\dot{\gamma}^{n-1} \quad (10)$$

where  $m$  is known as the consistency index and  $n$  the power-law index. Such materials are referred to as Ostwald-De Waele fluids. For cases where  $n > 1$ , the material is referred to as dilatant, whereas for  $n < 1$ , the behavior is called pseudoplastic. In spite of the popular shear thickening example of the increasing viscosity with shear rate in corn starch and water dispersions, dilatant behavior is less common, applying principally to systems containing close-packed particles. Pseudoplastic behavior, on the other hand, is widely observed in many polymer products including adhesives. This shear thinning behavior is important for sag control of paints, coatings, adhesives, sealants, and even ketchup. The Bingham plastic fluid, represented by a viscous dashpot in parallel with a Coulomb (sliding or yield) element, can be thought of as a limiting case of a pseudoplastic material, in which a yield stress must be exceeded before viscous behavior is observed. Figure 6 illustrates Newtonian and non-Newtonian behavior, including pseudoplastic, dilatant, and Bingham response.

Caution is needed in using the power-law relationship of Eq. 10, however, as it cannot model the extreme rates, such as encountered near walls, for example (Berker 2002). Non-Newtonian behavior can be represented by a number of other representations that incorporate limiting values of viscosity at low shear rates, such as the Zaremba-Fromm-DeWitt (ZFD) model, which can be expressed as (Han 2007):

$$\eta(\dot{\gamma}) = \frac{\eta_0}{1 + (\lambda\dot{\gamma})^2} \quad (11)$$

where  $\eta_0$  is the limiting viscosity at zero shear rate and  $\lambda$  is a time constant. Forms that capture both the low and high shear rates include models such as the three-parameter Oldroyd, the four-parameter Carreau, and the five-parameter Elbirli-Yasuda-Carreau models, the latter of which is given by (Berker 2002):

$$\frac{\eta - \eta_\infty}{\eta_0 - \eta_\infty} = [1 + (\lambda\dot{\gamma})^a]^b \quad (12)$$

**Fig. 6** Illustration of non-Newtonian fluid behavior as well as a Bingham plastic fluid

**Fig. 7** Representations of pseudoplastic or shear thinning material response

where the rate-dependent viscosity,  $\eta$ , is given in terms of the limiting viscosities at zero shear rate,  $\eta_0$  and “infinite” shear rate,  $\eta_\infty$ . Here,  $b$  is the slope of the power-law region of the behavior, and  $a$  characterizes the width of the transition from Newtonian to the power-law region. Figure 7 illustrates the common shear thinning behavior of many polymeric melts, solutions, and dispersions, along with limiting values that might be encountered.

**Time Dependent non-Newtonian Behavior**

Another common aspect that complicates the characterization and analysis of viscosity is time-dependent behavior. As a material cures, for example, the viscosity

**Fig. 8** Effect of shearing time and recovery time on viscosity of rheopectic and thixotropic fluids

will change dramatically, making viscosity a useful metric in characterizing chain extension, crosslinking and other chemical structural changes. Other types of time dependence are also seen, however, and are associated with the length of time that a material has been sheared. For *rheopectic* materials, the viscosity increases over time with stirring or other forms of shearing. Examples of this include printer inks and body armor. *Thixotropic* materials exhibit a decrease in viscosity with shearing and is often observed in gels, colloids, clays, and drilling muds. For both of these time-dependent behaviors, there is typically a gradual recovery to the original viscosity if the shearing is stopped for a period of time. Figure 8 schematically illustrates such behavior.

### 17.3.3 Material Dependence

#### Dilute Solution Viscosity

To understand polymer structure, polymers are often dissolved in appropriate solvents, allowing molecular weight or degree of polymerization to be determined from dilute solution viscosity. The *relative viscosity*,  $\eta_{rel}$ , is the ratio of solution viscosity to that of the solvent. The *specific viscosity*,  $\eta_{sp}$ , is the ratio of the difference in solution and solvent viscosities divided by the solvent viscosity. These dimensionless quantities are often divided by the mass concentration of the polymer to obtain several additional terms that have units of dilution or volume per unit mass concentration: the *reduced viscosity*, which is ratio of the relative viscosity to the concentration; the *inherent viscosity*, which is the ratio of the natural logarithm of the relative viscosity; and the *intrinsic viscosity*,  $[\eta]$ , which is the common limiting value of the reduced (Huggins' definition) or inherent (Craemer's definition) viscosity at infinite dilution of the polymer. The intrinsic viscosity can be used to estimate molecular weight of a polymer through the Mark-Houwink equation. These solution viscosities are often measured with capillary viscometers.

**Fig. 9** Effect of molecular weight on viscosity, showing sharp transition at  $M_c$

### Molecular Weight Dependence

Viscosity is often strongly dependent on the molecular weight of the polymer. The zero-shear rate viscosity of many polymer melts has been shown to scale according to (Han 2007):

$$\eta_0 = \begin{cases} K \cdot M & \text{for } M \leq M_c \\ K \cdot M^{3.4} & \text{for } M > M_c \end{cases} \quad (13)$$

where  $K$  is a constant of proportionality,  $M$  is the molecular weight, and  $M_c$  is the critical molecular weight. Figure 9 is representative of such behavior. Since the transition appears to result from the onset of topological restrictions of chain movement, the process is often attributed to entanglement effects (Han 2007).  $M_c$  is believed to be related to the molecular weight between entanglements,  $M_e$ , through  $M_c \approx 2M_e$ , and appears to be the lower limit of molecular weight that can induce non-Newtonian behavior (Han 2007). Equation 13 can be extended to polydisperse polymers if  $M$  is replaced by the weight-average molecular weight,  $M_w$ .

### Dependence on Filler Content

Viscosity can depend strongly on fillers added to provide a range of mechanical, transport, electrical, magnetic, or other physical properties. The well-known Einstein-Guth relationship, for example, provides the viscosity of a dilute suspension of rigid spheres, obtaining the bulk or effective viscosity of a suspension as:

$$\eta_s = \eta(1 + 2.5\phi + 14.1\phi^2) \quad (14)$$

where  $\eta$  is the viscosity of the liquid and  $\phi$  is the volume fraction of the spheres. To be applicable, the initial liquid must behave in a Newtonian fashion and the concentration of particles must be very low (Han 2007). Other models have been

introduced to account for fillers that are not spherical but have other aspect ratios. At significant filler concentrations, the Guth and Gold equation and other relationships have been suggested, and yield phenomena are often observed (Goodwin and Hughes 2000). Extensions to nanocomposites have been reviewed (Han 2007).

### Temperature-Dependent Viscosity

For homopolymers, the Ostwald-De Waele power-law relationship may be extended to include temperature dependence as (Han 2007):

$$\eta(\dot{\gamma}, T) = K(T)\dot{\gamma}^{n-1} \quad (15)$$

where  $K(T)$  is the temperature-dependent consistency index. In addition to other forms cited earlier, the truncated power-law model can be used to capture the viscosity below some critical shear rate,  $\dot{\gamma}_0$ , below which the viscosity is not rate dependent (Han 2007):

$$\eta(\dot{\gamma}, T) = \begin{cases} \eta_0(T) & \text{for } \dot{\gamma} \leq \dot{\gamma}_0 \\ \eta_0(T)(\dot{\gamma}/\dot{\gamma}_0)^{n-1} & \text{for } \dot{\gamma} > \dot{\gamma}_0 \end{cases} \quad (16)$$

For many simple polymeric systems, thermal shift factors can be used to model the temperature dependence using:

$$\eta_0(T) = k_0 e^{(E/RT)} \quad (17)$$

where  $k_0$  is a pre-exponential factor,  $E$  is the shear flow activation energy,  $R$  is the universal gas constant, and  $T$  is the absolute temperature. The thermal shift factor can be expressed as the ratio of zero-shear rate viscosities at two temperatures:

$$a_T(T) = \frac{\eta_0(T)}{\eta_0(T_{\text{ref}})} \quad (18)$$

where  $T_{\text{ref}}$  is a reference temperature. For linear flexible homopolymers, Arrhenius and Williams-Landel-Ferry (WLF) relationships have been found useful as follows (Han 2007):

$$\log a_T(T) = \begin{cases} \frac{E}{R} \left[ \frac{1}{T} - \frac{1}{T_{\text{ref}}} \right] & \text{for } T > T_g + 100^\circ \text{C} \\ \frac{-C_1(T - T_{\text{ref}})}{C_2 + T - T_{\text{ref}}} & \text{for } T_g < T \leq T_g + 100^\circ \text{C} \end{cases} \quad (19)$$

where  $C_1$  and  $C_2$  are WLF constants (Ferry 1980) (also discussed in ► Chap. 18, “Thermal Properties of Adhesives”). Using the shift factor allows one to generate reduced shear rate or viscosity master curves spanning a wide range of rates and applicable for a range of temperatures by using the corresponding thermal shift factor plot. The master curve and shift factor plots are prepared with respect to the

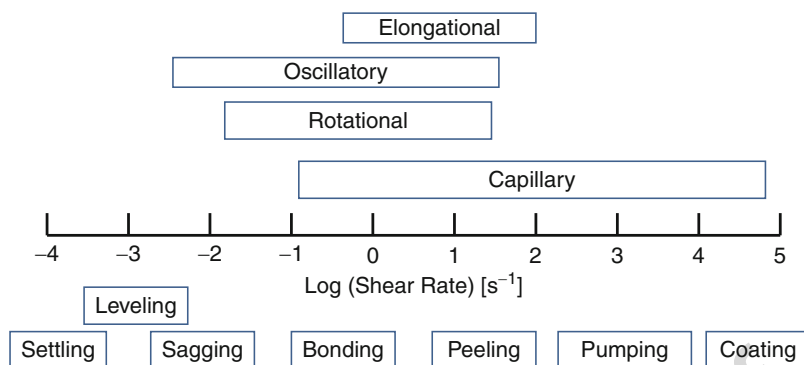

chosen reference temperature,  $T_{\text{ref}}$ . Although such techniques are often extended to more complex material systems, the accuracy or appropriateness of these relationships for such systems should be carefully examined.

### 17.3.4 Adhesive Viscosity Measurements and Applications

In addition to the general approaches for measuring viscosity discussed earlier in this chapter, certain methods have been standardized specifically for adhesive materials. ASTM D1084 (ASTM-D1084-08 2008) describes four different methods for viscosity measurements for self-leveling adhesives (eliminating thixotropic or plastic materials where rate of stirring and prior history affect the behavior). Method A involves the use of viscosity cups with orifices that are several millimeters in diameter. Using accurate temperature control, acceptable readings are obtained when 50 mL of sample flow through the orifice in 30–100 s. Method B involves the use of a Brookfield rotational viscometer in which spindles outfitted with a disk appropriate to the viscosity being measured are rotated within a container of the liquid being characterized. Torque measurements associated with given angular velocities can be used to determine viscosity. Method C is based on the use of a Stormer rotational viscometer in which the time required for a spindle (equipped with paddles and loaded by a constant torque) to turn 100 revolutions. Method D quantifies the time required for a fixed volume of adhesive to flow through a properly sized orifice in a Zahn viscosity cup, which can simply be dipped into the adhesive for filling.

The viscosity of an adhesive can change significantly when solvent or dispersant evaporates, when chain extension or crosslinking occur, or when other changes take place over time. This sensitivity makes viscosity measurements popular for assessing the detrimental effects of storage life (ASTM-D1337-96 2001) (see ► Chap. 36, “Storage of Adhesives” in 1st edition), for characterizing the allowable working life of an adhesive (ASTM-D1338-99 2001), and to determine the heat stability of hot-melt adhesives (ASTM-D4499-95 2001) using (ASTM-D3236 2001). These measurements detect changes that take place with aging.

All of these test methods obtain viscosities at relatively low shear rates, and because of the sensitive to temperature and solvent content, means are required to maintain the desired temperature and minimize solvent loss during testing. Such viscosities may be relevant for low speed mixing, pumping, and dispensing methods, but may be insufficient for higher speed processing conditions. More sophisticated viscosity measurements are most easily performed with more elaborate equipment that allows for imposing a wide range of flow rates in a carefully controlled temperature environment. Because of the strong rate-dependence of many formulated adhesives, it is important that one characterize the viscosity at the temperature and rate conditions that the adhesive will experience during flow through the dispensing equipment and application to the adherends. Processing and dispensing or application methods cover a wide range of effective shear rates, such as indicated

**Fig. 10** Approximate relative ranges of shear rates for rheometers (*above*) and polymer processing or adhesive applications (*below*)

in Fig. 10, which also suggests relevant rates of some of the viscosity measurement equipment discussed above.

## 17.4 Stress-Strain Behavior

While viscosity measurements are typically carried out on uncured adhesives that are still in their liquid state or on partially cured materials that can still exhibit flow, measuring the basic stress-strain behavior is one of the most fundamental tests conducted on polymeric adhesives in their cured or solid state. In their simplest form, these tests are intended for characterizing materials with very large Deborah numbers, where the time scale of the test is short compared to any relaxation times within the material, or for cross-linked materials tested at time scales much longer than their characteristic times. Just as with viscosity tests and because of the very broad characteristic time scale of typical polymers, however, stress-strain tests are often conducted in a manner that captures some of the inherent time dependence of the materials being evaluated.

The stress-strain behavior of a material provides important information relevant to its range of applicability. Load bearing applications may require certain stiffness or strength properties, the latter of which has been addressed in ► [Chap. 19, “Failure Strength Tests.”](#) For strain-controlled loading modes experienced by sealants, the modulus must be sufficiently low and the strain capabilities sufficiently high to provide adequate flexibility to meet the mechanical or thermally driven deformations. Due in part to the popularity of screw-driven test frames, most stress-strain characterization experiments have traditionally been carried out at a constant cross-head displacement rate, effectively straining the specimen at the desired rate. Results obtained are often quite rate- and temperature dependent, so care is needed in reporting these details.

Stress-strain behavior can be obtained with a variety of specimen configurations depending on the properties desired, the nature of the material being tested, and the available equipment. Perhaps the simplest and most common means to determine stress-strain behavior is in uniaxial tension, using either straight-sided or dogbone-shaped specimens. Straight-sided specimens are useful in some situations, especially if properties are only being measured to a fraction of the breaking strain and when appropriate extensometry equipment is not available. In such cases, the strain of straight-sided specimens can be estimated by dividing the crosshead displacement by the length of the specimen as measured between the grips. The aspect ratio of the specimens should be sufficient that end effects are negligible – suspended length-to-width ratios approaching 10 or more are preferred. Care should be used to make sure that specimen slippage within the grips does not affect strain measurements made in this manner. Where failure properties are important, waisted configurations, known as dogbone or dumbbell specimens, are favored for bulk polymer or adhesive samples. The higher stresses within the region of reduced cross section will typically induce failures within these regions, avoiding failures at the grips, as often occurs with straight-sided specimens. Engineering stress is characterized by dividing the applied axial force (typically measured by a load cell) by the original cross-sectional area of the specimen. Other stress metrics are also useful, including true stress, which is the applied load divided by the current cross-sectional area (Dowling 2007).

Strains can be measured by a number of techniques. The simplest technique is to divide the crosshead displacement by the gage length of the specimen, as mentioned before. Specimen slippage and load frame compliance can both affect the apparent strains determined through this method. Mechanical extensometers have been widely used, measuring a displacement over a given gage length and reporting the quotient as an average strain. Strain gages can be applied directly to specimens to measure strain, although the effects of reinforcement, local heating, and shear lag issues make these less appropriate for measuring strains on neat polymer samples. Optical techniques for characterizing strains are becoming increasingly popular. High resolution capabilities are available in the form of interferometric Moiré and other techniques, but for many applications, less resolution is acceptable. Optical methods have the advantage of being essentially noncontact techniques, a distinct advantage when working with small specimens that might be affected by the weight of a mechanical extensometer or the presence of their knife edges or contact points. Equipment based on several different principles is available. Examples include laser extensometers, which scan a laser beam along the length of the specimen to determine the location of two or more targets on the specimen. For uniaxial loading configurations, these methods normally report only the axial strains averaged over the distance between pairs of targets. Full field methods are also popular, including digital image correlation (DIC) techniques, which can provide measures of the full in-plane strain states across the specimen and, in three-dimensional systems, out of plane displacements as well. Such methods may require that the surface of the specimen be speckled with a paint or ink spray to provide a random pattern of features that can be tracked during the deformation process (Chu et al. 1985).

A number of metrics can be assessed from stress-strain behavior (Dowling 2007). Properties that are often evaluated include the modulus (initial modulus, or secant modulus evaluated to some specific strain), the yield stress, the yield strain, the ultimate strength, and the strain at break, as have been discussed in ► Chap. 19, “Failure Strength Tests.” The area under the curve, known as the modulus of toughness, has physical units of energy per unit volume, which are equivalent to force per unit area, the units of stress and modulus.

The initial modulus, ideally from the linear portion of the stress strain diagram, is known as Young’s modulus (or modulus of elasticity) for uniaxial tensile loading or shear modulus (or modulus of rigidity) for shear loading, assumes linear elastic behavior. This may be reasonable at rates much faster than the characteristic relaxation times of the material (i.e., glassy state) or at times much larger than these characteristic times (i.e., the rubbery state), provided the strains are small. Since polymeric adhesives are all time-dependent viscoelastic materials, however, the resulting modulus is, in general, a function of the rate of the test, as well as the test temperature and perhaps moisture or diluent content. Thus, modulus is a function of the test rate. The apparent linearity of the stress strain behavior breaks down as the strain rate approaches characteristic relaxation times of the material, resulting in nonlinear stress strain curves for even linear viscoelastic materials (Brinson and Brinson 2007). One particularly useful means to utilize the apparently nonlinear stress-strain response, resulting when time-dependent materials are characterized in constant strain rate experiments, is to obtain the viscoelastic relaxation modulus for either extension or shear, respectively:

$$E(t) = \frac{1}{\dot{\epsilon}} \frac{d\sigma}{dt} \quad G(t) = \frac{1}{\dot{\gamma}} \frac{d\tau}{dt} \quad (20)$$

where  $\sigma$  and  $\tau$  are the normal and shear stresses and  $\dot{\epsilon}$  and  $\dot{\gamma}$  are the imposed constant normal and shear strain rates, respectively. Since  $E(t)$  and  $G(t)$  are linear viscoelastic properties, the limits of linearity must be established through conducting tests at several rates or through other means (Brinson and Brinson 2007). Analogous forms for creep compliances can also be obtained for the less common loading cases of constant imposed stress rates (see ► Chap. 34, “Creep Load Conditions” in 1st edition). Equation 20 clearly illustrates that the stress-strain response for constant strain (or stress) rate loading is inherently nonlinear for viscoelastic materials, reminding practitioners of the complications that arise when the characteristic times of the material and test are of the same magnitude.

## 17.5 Conclusion

Many physical properties are of importance in the characterization, enhancement, and selection of adhesives for the wide range of uses that they enjoy. This chapter has highlighted just a few of these relevant properties and pointed reader to other sources for information. The density of polymers spans a relatively narrow range, and small

variations can provide significant insights into the behavior of a polymer. In formulated adhesives, density can provide information about the filler content or void content of liquid adhesives or solid parts. Viscosity is a very sensitive metric of a very important polymer property. A number of techniques have been developed to characterize viscosity over different viscosity ranges and shear rates. Viscosity is often significantly affected by temperature, shear rate, time of shearing, and other factors, so care is recommended in selecting appropriate viscosity measurement methods to provide behavior relevant to the applications being used. The stress-strain behavior of polymers, adhesives, and sealants is often important information for selecting and using adhesives. This chapter has provided a short section on several aspects of these tests to complement other related coverage in this book.

**Abstract**

The thermal properties of adhesives affect the rate of cure, whether the latter is by evaporation, cooling, or chemical reaction. In the latter case, cure may not go to completion in the sense that not all monomer is reacted, or may not be possible at all above a ceiling temperature. The heat of polymerization is a useful guide to what may happen.

The glass transition temperature of a cured adhesive is of critical importance in that although there are both sub-T<sub>g</sub> and super-T<sub>g</sub> adhesives, crossing T<sub>g</sub> in service is not acceptable. T<sub>g</sub> also has a role in latex adhesives forming cohesive films. Water plasticizes epoxide adhesives and so lower T<sub>g</sub>. Some adhesives are partially crystalline with a melting point T<sub>m</sub>.

Adhesives exhibit a mixture of viscous and elastic properties and obey the WLF equation. This indicates that the fraction of free volume at the glass transition is 2.5%.

Consideration is given to thermal conductivity and thermal expansion, and the breakdown of adhesives at elevated temperatures. Shelf-life and pot-life vary with temperature.

The main methods of obtaining thermal information on adhesives are reviewed; these are differential scanning calorimetry (DSC), dynamic mechanical thermal analysis (DMTA), and thermogravimetric analysis (TGA).

---

**18.1 Introduction**

Polymers are the major components of all adhesives and thus have a dominant influence on their properties. There is relatively little specific information in the literature on the thermal properties of adhesives; therefore, we must depend on the properties of the polymer to tell us about an adhesive. Examples are that polymethyl methacrylate can be used as a model for reactive acrylic adhesives, polydimethylsiloxane for silicone adhesives, and nylons for polyamide hot melts.

---

**18.2 Shelf-Life**

The period over which a packaged adhesive retains satisfactory properties is known as the shelf-life. Adhesives are based on organic chemicals, and provided they are kept in containers which exclude oxygen and UV-light; they have very long, perhaps indefinite, shelf-lives. Examples are epoxides, where resin and hardener are packed separately, hot melts, and adhesives which are solutions of polymers in organic solvents.

Exceptions include latex adhesives, reactive acrylics, and one-part epoxides. Freezing of latex adhesives causes the water phase to solidify and the particles to agglomerate irreversibly. Freeze-thaw stability can be improved by using carboxylate comonomers and adding antifreezes such as ethane diol or glycerol. Blackley (1997) has written a full account of this topic.

One-part epoxide adhesives contain resin and hardener, and can be supplied in the form of a film. The hardeners are such that high cure-temperatures are needed, and to slow down cure during storage and so lengthen shelf-life, such adhesives are stored at low temperatures where shelf-lives are between 6 and 12 months. The hardener dicyandiamide is insoluble in epoxides at low temperatures, but dissolves at cure temperatures; such adhesives are regarded as being completely stable below 40 °C.

Structural acrylic adhesives contain monomer, and cure is by a redox system which generates free radicals which cause cure by addition polymerization. Redox systems have two components, one being dissolved in the adhesive and the other in the hardener or “catalyst.” Once mixed, cure is rapid. Examples are cumene hydroperoxide and N,N-dimethyl aniline. Should the peroxide be in the adhesive, then it will slowly decompose to give free radicals, which will cause cure and eventually terminate the shelf-life, which is typically 12 months. Chemical reactions obey the Arrhenius relation (Eq. 1). Here  $k$  is the rate constant,  $A$  represents the total number of collisions between reacting molecules,  $E$  is the activation energy,  $R$  the universal gas constant, and  $T$  the absolute temperature.

$$k = A \exp(-E/RT) \quad (1)$$

Lowering temperature is thus a means to extend shelf-life.

Water vapor from the atmosphere is the curing agent for some silicone and isocyanate adhesives. Adsorbed surface water causes the cure of cyanoacrylates. Such adhesives are often packed in polyolefin containers which are naturally permeable to water. Hence, the passage of water through the container wall has the possibility to shorten shelf-life.

Hussey and Wilson (1996) have compiled some data which includes shelf-lives.

## 18.3 The Hardening (Curing) Process

At the time of application, an adhesive is a liquid, which is sufficiently mobile to wet the adherends. The process which follows is known as hardening or curing, and converts the liquid into a cohesive solid. Pressure-sensitive adhesives are an exception in that they remain viscous liquids. Hardening can be by loss of solvent, loss of water, cooling, or chemical reaction.

### 18.3.1 Hardening by Evaporation of Solvent or Water

The saturated vapor pressure of a liquid ( $p_o$ ) depends strongly on temperature according to Eq. 2, where  $\Delta H_e$  is the heat of evaporation,  $T$  the absolute temperature, and  $R$  the universal gas constant. Some values for water and for some solvents commonly used in adhesives are shown in Table 1.

$$d \ln p_o / d(1/T) = -\Delta H_e / R \quad (2)$$

**Table 1** Heat of evaporation of solvents

Solvent	$\Delta H_e/J\text{ g}^{-1}$
Water	2440
Acetone	534
Ethyl acetate	404
n-hexane	508
Tetrachloroethylene	242
Toluene	413

There is now much pressure from environmental and health and safety regulators to reduce or eliminate the use of solvents in adhesives, and the industry is responding by developing water-based systems to replace them. However, a fundamental problem is the low rate at which water evaporates because of its high heat of evaporation, which is about five times greater than for common solvents.

**18.3.2 Minimum Film-Formation Temperature of Latex Adhesives**

Latex adhesives consist of particles of polymers with diameters of the order of 1  $\mu\text{m}$  suspended in an aqueous medium. Surfactant molecules such as anionic soaps, which are adsorbed on the surfaces of the particles, maintain the particles in solution, and so stabilize the latex. Stabilization can also be gained by the presence of a soluble polymer in the aqueous phase which increases viscosity. The volume fraction of the phases is about 50%. Current adhesives include the latices of natural rubber, styrene-butadiene random copolymer, polyvinyl acetate, and its copolymers with ethylene and vinyl chloride. For any further information on polymer latices, the reader is directed to the three volumes of Blackley (1997).

Latex adhesives are applied to the substrate and the water is allowed to dissipate; this can be by evaporation, or in the case of porous substrates such as paper and wood, by passage into the adherend. To obtain a cohesive adhesive, it is necessary for the particles to coalesce, and this can only occur above a critical temperature (which is different for each latex) known as the minimum film-formation temperature MFFT; this is the lowest temperature at which the latex can form a film.

MFFT and glass transition temperature  $T_g$  are close but not identical. Brodnyan and Konen 1964 have measured and compared MFFT and  $T_g$  for a number of latices, and data are shown in Table 2.

A common viewpoint is that MFFT is usually lower than  $T_g$ , and this is due to plasticization by the dispersion medium, particularly water. This is contradicted by most of the data of Brodnyan and Konen, which show that MMFT exceeds  $T_g$ .

MFFT can be lowered by adding an organic plasticizer to the latex, or copolymerizing with a monomer whose homopolymer has a lower  $T_g$ . These phenomena are respectively termed internal and external plasticization and examples are the use of di-n-butyl phthalate, and the copolymerization of methylmethacrylate with ethyl acrylate (Protzman and Brown 1964).

t.1 **Table 2** Comparison of MFFT and Tg for some latex polymers

t.2	Polymer with molar ratios	MFFT °C	Tg °C	(MFFT – Tg) °C
t.3	Copolymer of styrene and n-butyl acrylate (75/25)	58	48	+10
t.4	Poly-n-butylmethacrylate	30	22	+8
t.5	Copolymer of styrene and n-butyl acrylate (55/45)	23	17	+6
t.6	Copolymer of methylmethacrylate and ethyl acrylate (50/50)	27	30	–3

**Fig. 1** Dependence of melt viscosity upon temperature for three EVA hot melt-adhesives. Data replotted from Park and Kim 2003. The adhesives contain 50% by weight of EVA with different melt-flow indices, which were ○ 100 g min<sup>-1</sup>, ● 180 g min<sup>-1</sup>, and □ 200 g min<sup>-1</sup>

133 **18.3.3 Hardening by Cooling**

134 Hot melt adhesives harden by cooling, and it is first necessary to heat them to a  
135 sufficient temperature for flow, and for wetting of the adherends. Melt-viscosity fits  
136 the Arrhenius equation. Data for some ethylene vinyl acetate copolymer EVA hot  
137 melts are shown in Fig. 1 (Park and Kim 2003). Hardening is a rapid process which  
138 is primarily controlled by the flow of heat from the thin bondline. However,  
139 crystallization may increase after cooling. There can be a problem in using them  
140 on metals, in that rapid cooling prevents adequate wetting.

141 **18.3.4 Hardening by Chemical Reaction**

142 Where the hardening of an adhesive or sealant proceeds by chemical reaction, the  
143 rate will increase with temperature in accordance with the Arrhenius equation.  
144 Such materials include epoxides, structural acrylics, cyanoacrylates, silicones, and

high-temperature adhesives. Hence, pot-life and cure time will show the following proportionality.

$$\log t \propto 1/T \quad (3)$$

Lapique and Redford (2002) used differential scanning calorimetry to measure rates of cure for the epoxide paste-adhesive Araldite 2014, finding E to be 34.6 kJ mol<sup>-1</sup>. The equation also applies to other time-dependent processes such as diffusion and viscous flow.

### Pot-Life

Pot-life is the time available between mixing an adhesive and its application and the concept applies to adhesives where two components are mixed shortly before use. Examples are two-part epoxides, some silicones, reactive adhesives for wood based on formaldehyde condensates, some isocyanates, and polysulfides. Polymerization commences on mixing and crosslinking occurs in all cases. Both processes cause viscosity to increase, and this will begin to hinder the wetting of the adherends. A critical point however is the gel-point, where the viscosity increases very greatly, due to the adhesive becoming completely crosslinked. The gel-time is thus the upper limit of shelf-life, but in practical terms, the latter will be significantly less than the former. For some isocyanate and acrylic adhesives, pot-life can be only a few minutes. Where cure is rapid, the reaction exotherm can cause heating which accelerates the cure process. Such an effect will depend on the ability of the assembly to dissipate heat.

An adhesive which cures rapidly will have a relatively short pot-life; a prolonged cure is related to a long pot-life. Hussey and Wilson (1996) have compiled some data which includes pot-lives.

Factors other than pot-life can affect the working time of an adhesive or sealant. Some silicones and isocyanates are cured by moisture which causes a skin to form on the surface, the thickness of which increases in proportion to the square root of time. Solvent-based adhesives can suffer from rapid evaporation which limits their ability to wet the substrates. Hot melt adhesives are prone to oxidative degradation at temperatures of application.

### Ceiling Temperature

For thermodynamic reasons, some adhesives may not cure at all above a critical temperature, which is known as the ceiling temperature, and may only partially cure at lower temperatures. This particularly applies to adhesives which harden by polymerization of monomers with C = C bonds, such as acrylates, methacrylates, and cyanoacrylates.

The free energy of polymerization  $\Delta G_p$  is related to the heat  $\Delta H_p$  and entropy  $\Delta S_p$  of polymerization by Eq. 4.

$$\Delta G_p = \Delta H_p - T\Delta S_p \quad (4)$$

**Table 3** Some Thermodynamic Parameters for Polymerization

Monomer	$\Delta H_p/\text{kJ mol}^{-1}$	$\Delta S_p/\text{J mol}^{-1} \text{K}^{-1}$	$T_c/^\circ\text{C}$
Methylmethacrylate	-55.5	$-117 \pm 6$	201
Methyl cyanoacrylate	-42		
Ethyl cyanoacrylate	-47, -53, -54		
n-Decyl cyanoacrylate	-69, -74		217
Ethylene oxide	-94.6		-86
Styrene	-68.6, -70, -73	-104	387, 400, 429
$\alpha$ -Methylstyrene	-37	-110	61

Heat is evolved on polymerization, so  $\Delta H_p$  is negative. When monomer molecules which can move independently are captured in a polymer chain, there is an increase in order and therefore a decrease in entropy. At equilibrium,  $\Delta G_p = 0$  so the ceiling temperature  $T_c$  is given by Eq. 5.

$$T_c = \Delta H_p / \Delta S_p \quad (5)$$

Entropy of polymerization does not vary widely for  $C = C$  monomers; it is usually in the range of  $100\text{--}125 \text{ J mol}^{-1} \text{K}^{-1}$  for liquid monomers. This is because in each case, the dominant factor is the loss of transitional freedom that occurs when a monomer molecule is incorporated into a polymer chain. Table 3 gives some values for entropy of polymerization.

In contrast, heats of polymerization do vary from monomer to monomer. One factor which is particularly important in causing monomers to have different values of  $\Delta H_p$  is steric hindrance in the polymer chain caused by larger substituent groups. Table 3 gives some values for heat of polymerization. Changes in heat, rather than entropy of polymerization, cause polymers to have different ceiling temperatures. Some ceiling temperatures are given in Table 3.

The heat of curing for a fast curing two-part epoxide has been measured as  $494 \text{ J/g}$  (Keller et al. (2016)). Samples in aluminum molds were heated at  $80$  or  $100^\circ\text{C}$ .

And those which were  $4 \text{ mm}$  thick at  $100^\circ\text{C}$  reached a peak temperature of  $176^\circ\text{C}$  in about  $30 \text{ s}$ . Samples  $3 \text{ mm}$  thick cured at  $80^\circ\text{C}$  showed a rise of about  $40^\circ\text{C}$  in the same time. These rises will not be typical of adhesive joints with thin gluelines, and would be reduced by the presence of fillers and conductive adherends.

### Kinetic Approach to Equilibrium

The polymerization process can be represented as

where  $M^*$  is a polymer chain with an end group which is an active center (free radical, anion or cation) and  $M$  is monomer.  $M^*$  appears on both sides of the equation, but there is the actual difference in that the one on the right contains one more monomer unit than that on the left.

209 The rate of the forward polymerization reaction is

$$R_p = k_p[M^*][M] \quad (6)$$

210 The rate of the reverse depolymerization reaction is

$$R_d = k_d[M^*] \quad (7)$$

211 Here,  $k_p$  and  $k_d$  are the respective rate constants. At equilibrium, the rates of  
212 forward and reverse reactions are the same, so that

$$k_p[M^*][M]_e = k_d[M^*] \quad (8)$$

$$K = k_p/k_d = 1/[M]_e \quad (9)$$

213 Here,  $K$  is the equilibrium constant and  $[M]_e$  is the monomer concentration at  
214 equilibrium.

215 The Arrhenius equation can be substituted for the rate constants in Eq. 9, giving

$$A_p \exp(-E_p/RT) [M]_e = A_d \exp(-E_d/RT) \quad (10)$$

$$T = (E_p - E_d) / (R \ln A_p/A_d + R \ln [M]_e) \quad (11)$$

216 Equation 12 follows from the fact that heat of polymerization is the difference in  
217 the activation energies of the forward and reverse reactions. Here,  $R$  is the universal  
218 gas constant.

$$T = \Delta H_p / (R \ln A_p/A_d + R \ln [M]_e) \quad (12)$$

219  $A_p$  and  $A_d$  are related to the total number of collisions between reacting mole-  
220 cules, and to the entropies of activation. This leads to

$$T = \Delta H_p / (\Delta S_p^\circ + R \ln [M]_e) \quad (13)$$

221 Here,  $\Delta S_p^\circ$  is the entropy change in the standard state.

222 What this means is that at temperature  $T$ , a polymerization will continue consum-  
223 ing monomer, until the monomer concentration falls to  $[M]_e$ ; it will then cease. At  
224 the actual ceiling temperature,  $[M]_e$  = the bulk concentration of monomer.  $T_c$  will be  
225 less if the monomer is diluted.

226 The data in Table 3 have been compiled from a number of sources, and most are  
227 for the conversion of a liquid monomer to an amorphous polymer. The exception is  
228 ethylene oxide where the polymer is semicrystalline; the heat and entropy of  
229 crystallization will contribute to the parameters for this monomer.

230 The data illustrate some matters which have already been noted. One is that the  
231 entropies for the  $C = C$  monomers are very similar. Another is that the addition of a  
232 methyl group to styrene leads to increased steric hindrance in the polymer, so

lowering  $-\Delta H_p$  and ceiling temperature. If the methyl groups were replaced by the larger phenyl group (to give 1,1-diphenyl ethylene), the monomer would not polymerise at all! The first three monomers in the table are used in adhesives, and the ethylene oxide ring reacts in epoxide adhesives, which can cure by addition polymerization when certain hardeners are used (e.g., tertiary amines).

### Curing by Reaction with Water Vapor

Moisture curing adhesives and sealants consisting of low molar mass polymers with specific end-groups, hardened by reacting with water from the atmosphere. The end-groups include acetate, ethoxide and butanone ketoxime on silicones, and isocyanates. Cure proceeds by a skin forming on the surface, which then grows in thickness, such that the depth of cure ( $z$ ) is given by the following equation (Comyn et al. 1998).

$$z = (2PpVt)^{1/2} \quad (14)$$

Here,  $p$  is the vapor pressure of water,  $V$  is the volume of sealant which reacts with a unit of water, and  $t$  is the time.  $P$  is the permeability coefficient of water in the cured material and this in turn is the product of the diffusion coefficient  $D$  and solubility coefficient  $S$ . Thus, Eq. 14 can be modified to Eq. 15, where  $r.h.$  is relative humidity.

$$z = (2DSp(r.h./100)Vt)^{1/2} \quad (15)$$

The dependence of the rate of cure on temperature is thus controlled by three heats, which are the heat of evaporation of water, the activation energy for diffusion, and the heat of solution of water in the cured material.

For water in a silicone with ethoxy end-groups,  $P$  was found not to obey the Arrhenius equation, and to decrease slightly as the temperature rose; this is shown in Fig. 2 (Ashcroft et al. 2009). This was ascribed to many of the water molecules not being dispersed in the adhesive, but being isolated in droplets or clusters. A similar situation occurs for some isocyanate-ended automotive windscreen adhesives (Ashcroft et al. 2009), and the main factor which causes cure rate to increase with temperature was the increasing vapor pressure of water. Figure 3 shows that the actual Arrhenius plot was linear for the overall cure process.

## 18.4 Thermal Properties of Cured Adhesives

### 18.4.1 The Glass Transition Temperature

At low temperatures, all polymers are in the glassy state, by which it is meant that they are relatively hard and inflexible. At some temperature, which is characteristic for each polymer, the material becomes soft and flexible, and so enters the rubbery or leathery state. This change is the glass transition, and it occurs at the glass transition temperature  $T_g$ .

**Fig. 2** Dependence of water permeability for three automotive windscreen adhesives upon temperature (Ashcroft et al. 2009)

**Fig. 3** Dependence of rate of cure upon temperature for three isocyanate-based water-reactive automotive windscreen adhesives (Ashcroft et al. 2009)

Most polymeric adhesives are amorphous rather than semicrystalline, and the glass transition is a property of the amorphous phase. It is caused by changes in molecular motion, such that in the glassy state the polymer backbone is not free to move in translation, but it is free to do so in the leathery state.

T<sub>g</sub> can be measured by thermal analysis, dilatometry and mechanical damping. Heat distortion temperature, brittle point, and softening point are closely related to

T<sub>g</sub>. For a given polymer, these three temperatures will be similar, but not usually identical, because of the use of different heating rates and the fact that the phenomena are pressure sensitive.

Sun et al. (2014) used DMA to measure the effect of heating rates on the T<sub>g</sub> of an epoxy adhesive. A heating rate of 0.5°C min<sup>-1</sup> gave a T<sub>g</sub> of 61°C, whereas at 10°C min<sup>-1</sup>, T<sub>g</sub> was 64°C.

Both glassy and leathery polymers are used as adhesives. Examples of the former are epoxides, phenolics, and reactive acrylics; rubber-based adhesives are examples of the latter. However, because of the large changes in mechanical properties, it is unacceptable for the glass transition temperature to exist in the same region of temperature in which an adhesive bond has to operate.

### Free Volume Theory

The free volume theory is a simple and effective means of accounting for T<sub>g</sub>. Free volume increases on thermal expansion, and once it reaches a critical amount, the backbone is free to move and the polymer is transformed into a rubber or leather.

Thus, the effect of pressure will be to reduce free volume and so increase T<sub>g</sub>. The chemical structure of a polymer affects its T<sub>g</sub>. Intermolecular forces are attractive and so reduce free volume. Polar groups cause polymer chains to be mutually attractive and so increase T<sub>g</sub>, while large nonpolar side chains tend to hold them apart and so lower T<sub>g</sub>. Table 4 shows the T<sub>g</sub> of polymethylmethacrylate (PMMA) to be 105 °C, but replacement of the ester methyl groups with 2-ethylhexyl lowers it to -50 °C. Poly 2-ethylhexyl-methacrylate is used in pressure-sensitive adhesives. Polymethyl acrylate has a T<sub>g</sub> of about 10 °C, but that of polyacrylic acid is much higher as intermolecular hydrogen bonds will reduce free volume. The sodium salt of the polyacid has a much higher T<sub>g</sub> of 230 °C, caused by the much stronger ionic attractions between chains. Starch is extensively hydrogen-bonded and so has a high T<sub>g</sub>. The polar carbon-chlorine bond in polychloroprene gives it a higher T<sub>g</sub> (-46 °C) than poly-*cis*-1,4-isoprene (c -70 °C), which closely resembles natural rubber. Crosslinking ties chains together so limiting molecular motion and increasing T<sub>g</sub>. The data in Table 4 are taken from a compilation (Andrews and Grulke 1999); some are T<sub>g</sub>s and others are brittle points and softening temperatures. In some cases, there are multiple entries.

Brittle points for some polyacrylates and polymethacrylates are shown in Fig. 4. At first, the brittle point falls as the number of carbon atoms in the side-chain (n) increases. The side-chains are alkyl groups which are nonpolar and flexible, and they act as internal plasticizers. A minimum temperature is reached when n reaches 8 with the polyacrylates and 12 with the polymethacrylates; beyond this, the brittle point rises and this is caused by partial crystallization of the side groups.

End groups introduce extra free volume, and hence T<sub>g</sub> falls as molar mass decreases. Often data fit Eq. 16, where T<sub>g</sub><sup>h</sup> is the glass transition temperature of very high molar mass polymer, M is molar mass, and A is a constant.

$$1/T_g = 1/T_g^h + A/M \quad (16)$$

**Table 4** Glass transition temperatures of some polymers and adhesives

Material	T <sub>g</sub> /°C
Polyacrylic acid	75,106
Polychloroprene	−46
Polydimethylsiloxane	−127
Poly-2-ethylhexylacrylate	−50
Poly <i>cis</i> -1,4 isoprene	−73, −70, −69
Polymethylacrylate	9, 10, 11, 19
Polymethylmethacrylate	105
Polypropylene (atactic)	−3 to −17
Poly sodium acrylate	230
Polystyrene	100
Polyvinyl acetate	32
Polyvinyl alcohol	85
Starch (dry)	165–185
Starch (humid)	95–135
Styrene-butadiene rubber	−61

**Fig. 4** Brittle points of poly-*n*-alkyl acrylates ○ and methacrylates ● (Data taken from Andrews and Grulke 1999)

In most cases, the T<sub>g</sub> of a random copolymer is between those of the corresponding homopolymers, and if T<sub>g</sub> is plotted against composition for the series of copolymers, it is a straight line or gentle curve linking the homopolymer T<sub>g</sub>s. In such cases, the Fox equation (Eq. 17, Fox 1956) is moderately successful in accounting for the T<sub>g</sub>.

$$1/T_g = w_1/T_{g1} + w_2/T_{g2} \quad (17)$$

Here,  $w_1$  and  $w_2$  are the weight fractions of the two components, and  $T_{g1}$  and  $T_{g2}$  are the glass transition temperatures of the homopolymers. The equation assumes that free volume contributions are additive. There are exceptions such as the copolymers of ethyl acrylate and vinylidene chloride. Here, the  $T_g$ s of both homopolymers are about  $-25^\circ\text{C}$ , while the equimolar copolymer has a  $T_g$  of about  $25^\circ\text{C}$ . Other copolymers show  $T_g$  minima (Comyn and Fernandez 1975).

Cured rubber-modified structural adhesives have a glassy matrix and a disperse phase of small rubber particles, which have a reinforcing action. Such materials have two  $T_g$ s, a higher one associated with the matrix and a lower one for the rubber particles. The  $T_g$  of the rubbery phase represents a lower temperature limit for these adhesives.

Block copolymers of styrene with either butadiene or isoprene are used in pressure-sensitive adhesives. These are three-block copolymers of type ABA where A are polystyrene blocks and B are polydienes. The two phases are incompatible, each phase having a separate glass transition temperature. The rubbery phase is continuous and the styrene phase consists of small particles 20–30  $\mu\text{m}$  diameter. The styrene content is generally above 25%. The  $T_g$  of the polybutadiene phase is about  $-80^\circ\text{C}$ , and it is about  $-50^\circ\text{C}$  for polyisoprene. The  $T_g$  of polystyrene is about  $100^\circ\text{C}$ , and this temperature must be exceeded in thermal processing. They are also used as thermoplastic rubbers.

The addition of a liquid to a polymer causes an increase in free volume and lowers  $T_g$ . Liquids have relatively high amounts of free volume; they might be present in adhesives by design or chance, examples of the latter being water and plasticizers. The phenomenon is generally known as plasticization, and may be quantified by the Fox equation, where  $w_2$  and  $T_{g2}$  are the weight fraction and  $T_g$  of the plasticizer. Pressure-sensitive adhesives generally have a low  $T_g$  and additives such as tackifiers have a high  $T_g$ .

### Dry and Wet Epoxides

The diglycidyl ether of bisphenol A DGEBA is widely used as a resin in epoxide adhesives. The three principal groups of compounds that are used to cure such epoxide adhesives are aliphatic amines, aromatic amines, and acid anhydrides. Cure with aliphatic amines occurs at lower temperatures than that with aromatic amines and acid anhydrides. This temperature difference is reflected in the  $T_g$  of the cured adhesive. Also epoxides cured with aromatic amines have higher  $T_g$ s than those with aliphatic amines, as the former have less flexible molecules than the latter. This is illustrated in Table 5 where DAPEE and TETA are aliphatic and DAB and DDM aromatic.

Brewis et al. (1982) measured heat-distortion temperatures  $T_d$  of a range of epoxide adhesives, both dry, after reaching equilibrium when immersed in water, and after a total of 10 months immersion. Their data which appear in Table 5 show that distortion temperatures are all initially lowered in water, but all increase on immersion for 10 months. The latter may be due to further crosslinking between

t.1 **Table 5** Heat distortion temperatures of some dry and wet epoxides

t.2	Hardener eqn	Equilibrium water absorption at 25 °C	Td/°C			Td depression/°C	
			Dry	Wet	10 Months	Actual	Fox
t.4	DAPEE	5.0	67	37	49	30	23
t.5	TETA	3.8	99	86	111	13	23
t.6	DAB	2.3	161	143	157	18	22
t.7	DDM	4.1	119	110	130	9	27
t.8	DMP	4.4	68	51	54	17	21
t.9	BF <sub>3</sub> MEA	2.3	173	155	18	22	

t.10 Hardeners are DAPEE = di(1-aminopropyl-3-ethoxy)ether, TETA = triethylenetetramine, DAB = 1,3-diaminobenzene, DDM = 4,4'-diaminodiphenylmethane, DMP = tris(dimethylaminomethyl)phenol, BF<sub>3</sub>MEA = borontrifluoride monoethylamine

360 unreacted groups in the water-plasticized adhesive. The actual changes after initial  
 361 immersion were compared with that predicted by the Fox equation. In some cases,  
 362 the two values are in reasonable accord. Except with DAPEE hardener, the actual  
 363 depression of Td is less than that predicted by the Fox equation; this can readily be  
 364 explained by some of the water not being molecularly dispersed in the resin and so  
 365 not plasticizing it, but instead being isolated in clusters.

366 Use of the Fox equation in this manner requires a value for the glass transition  
 367 temperature of water. This has been reported in the range –134 to –138 °C using  
 368 differential thermal analysis and other methods (McMillan and Los 1965, Sugisake  
 369 et al. 1968, Rasmussen and Mackenzie 1971).

## 370 18.4.2 Melting of Semicrystalline Polymers

371 While the glass transition is of very great importance in adhesives, crystalline  
 372 melting is not. This is because the polymers in most adhesives are totally amorphous,  
 373 which in turn is due to the lack of molecular regularity. Stereoregular polymers can  
 374 be made from vinyl and vinylidene monomers with the employment of organome-  
 375 tallic initiators, but these are not used when such monomers are converted into  
 376 polymers which are used in adhesives. The latter are atactic and examples are MMA  
 377 copolymers in structural acrylic adhesives, amorphous polypropylene, polyacrylic  
 378 pressure-sensitive adhesives, and polycyanoacrylates.

379 Adhesives which exhibit some degree of polymer crystallinity include EVA and  
 380 polyamide hot melts, polyvinylalcohol, polychloroprene, polyurethanes, polyureas,  
 381 and starch.

### 382 Ethylene Vinyl Acetate EVA Hot Melts

383 The melting point of low-density polyethylene is about 117 °C, and its degree of  
 384 crystallinity will depend on its thermal history. When copolymerized with vinyl  
 385 acetate, molecular regularity is diminished and there is a large reduction in degree of

crystallinity. EVA random copolymers containing up to 30% vinyl acetate are used. Further information has been provided by Eastman and Fullhart 1990. The thermal properties of an EVA hot melt adhesive with an aromatic hydrocarbon tackifier have been examined in detail by Park and Kim (2003).

### Polyamide Hot Melts

The melting points of polyamides are affected by the ability of amide groups to form hydrogen bonds. The melting points of some polyamides made from aliphatic diacids and diamines are plotted in Fig. 5. Melting point does not change smoothly as the number of methylene groups increases, and polymers with even numbers of carbon atoms are at the peaks of the zig-zag, because the number of intermolecular hydrogen bonds is greater. The matter has been detailed by Comyn (1997).

This is illustrated from diamines and diacids in Fig. 6, where four pairs of molecules are shown. In each case, there are a pair of polymer molecules, and the issue of concern is whether all the carbonyl and amine groups inside the pair are so placed that they can form a hydrogen bond  $>\text{CO} \cdots \text{HN}<$ . This happens for all the groups when all the carbon atoms are in even numbers, but in all the other cases in Fig. 6, only 50% can do so. This means that in Fig. 5 the peak temperatures are when there are an even number of carbon atoms in the diacid, and the tetramethylene diamine has higher melting points the pentamethylene. Similar trends occur with polyureas and polyurethanes, and smoothed plots are shown in Fig. 7, where the asymptote is the melting point of polyethylene. There is a reverse trend for aliphatic polyesters, which can be major components in polyurethanes. An explanation for this is the higher flexibility of the C-O linkage which so gives the molten molecules a

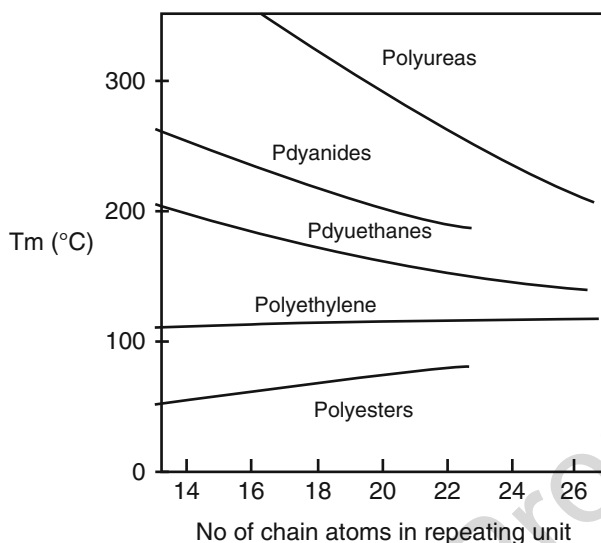

**Fig. 5** Melting points of polyamides formed from ● tetramethylenediamine, ○ pentamethylenediamine, and diacids (Comyn 1997)

**Fig. 6** Hydrogen bonding in polyamides derived from diacids and diamines

409 higher number of configurations, and so increasing the entropy of fusion. Melting  
 410 point  $T_m$  is controlled by the heat and entropy of fusion  $\Delta H_f$  and  $\Delta S_f$  by Eq. 18,  
 411 which is really a restatement of Eq. 5.

$$T_m = \Delta H_f / \Delta S_f \quad (18)$$

**Fig. 7** Smoothed plots of melting points of linear aliphatic heterochain thermoplastics

The use of mixed monomers in polyamide hot melts increases disorder, so lowering the extent of hydrogen bonding and melting point. Homopolyamides have melting points that are too high for hot-melt adhesives; for example, nylon 6 melts at 225 °C, nylon 66 at 264 °C, and nylon 12 at 180 °C. Their melt viscosities are also high for this particular application. However, copolymerization and terpolymerization give products with less regular structures and reduced levels of intermolecular hydrogen bonding, therefore yielding lower melting points. The polyamide terpolymers 6,6-6,6-10,6-6,12,6-6,6-12, and 6,6-9,6-12 are used for bonding textile fabrics, where they are resistant to washing and chlorinated dry cleaning solvents. Polyamide adhesives have been reviewed by Rossitto (1990).

### 18.4.3 Viscoelastic Properties of Adhesives

Polymers, and therefore adhesives, have a combination of the viscous properties of a liquid and the elastic properties of a solid. In a structural adhesive the elastic properties are dominant, whilst the viscous component is evident in pressure-sensitive adhesives.

#### Stress Relaxation

Viscoelasticity is manifest in creep and stress relaxation, which both depend on time and temperature.

If a constant strain is applied to a polymer at a fixed temperature, then the stress needed to maintain that strain will decrease with time. The time-dependent stress can be

**Fig. 8** Dependence of relaxation modulus upon time for polymethylmethacrylate, at temperatures between 40 and 135 °C (Comyn 1990, but original data from McLoughlin and Tobolsky 1952)

expressed as the relaxation modulus  $E(t)$ . The dependence of  $E(t)$  on time for PMMA at a number of temperatures is shown in Fig. 8. Using the principle of time-temperature superposition, the time range of the data in Fig. 9 can be extended both to longer and shorter times at any chosen temperature. According to this principle, any locus can be slid horizontally along the log (time) axis until it superimposes and extends its Neighbour; thus, data at a temperature below the reference temperature can be used to extend to shorter times, whereas data at higher temperature can be used to reach to longer times. The symbol for these shift-factors is  $\log a_T$ . This shifting has been done on the lines in Fig. 8 keeping 110 °C as the reference temperature, and the result is shown in Fig. 9.

The result of this operation is a single locus of  $\log E(t)$  against  $\log (\text{time})$  at a single temperature (here, 110 °C), which extends over a wider time range. A further consequence of time-temperature superposition is that plots of  $\log E(t)$  against temperature, at constant time, are similar in shape to those of  $E(t)$  against log (time).

**Fig. 9** Dependence of relaxation modulus upon time for polymethylmethacrylate, at 110 °C (Comyn 1990)

**Fig. 10** Dependence of relaxation modulus upon time for linear (continuous line) and crosslinked (broken line) polymers, showing four regions of viscoelastic behavior

For all amorphous polymers, values of  $\log a_T$  are an approximate fit to the following Eq. (19), which is widely known as the WLF equation after its originators Willams, Landel, and Ferry.

$$\log a_T = \frac{C_1(T - T_g)}{C_2 + (T - T_g)} \quad (19)$$

Here,  $C_1$  and  $C_2$  are empirical constants with the respective values of  $-17.44$  and  $51.6$ .

Figure 10 shows the modulus-temperature plot of a linear polymer, which has four regions of viscoelastic behavior. At the lowest temperatures, the material is a high-modulus glass. As temperature increases, it passes through the glass transition region and its modulus falls to that of a leathery material. It holds a stable modulus over a modest

region of temperature, but then enters a region of flow. The main difference between this case and that of a crosslinked polymer is that the crosslinks prevent the polymer from flowing.

A further empirical Eq. (20) due to Doolittle relates the viscosity of a liquid ( $\eta$ ) to its free volume. Here, A and B are constants and f is the fraction of free volume.

$$\log_e \eta = \log_e A + B/f \quad (20)$$

As stress relaxation is a manifestation of viscous flow, the WLF equation can also be applied to polymer viscosity, and comparison with the Doolittle equation shows that  $B/2.303 f = 17.44$ . If the value of B is unity, which is demonstrated by some of Doolittle's data, then the value of f is 0.025. This indicates that the free volume fraction at Tg of any polymer is 2.5%.

Further details of these matters have been given by Sperling (2006).

### Data for Adhesives

Brewis et al. (1982) reported the dependence upon temperature of the tensile modulus of the epoxide-polyamide adhesive FM1000, which has a Tg of 40 °C. Data which appear in Fig. 11 show typical viscoelastic behavior. The same authors (1983) showed similar data for an aliphatic amine-cured epoxide adhesive, which has a Tg of 65 °C. Changes in the strengths of lap-joints with increasing temperature fell in the same manner as the modulus and tensile strength of the adhesive, as in shown in Fig. 12.

**Fig. 11** Effect of temperature on the modulus of the epoxide-polyamide adhesive FM 1000 (Brewis et al. 1983)

#### 18.4.4 Thermal Conductivity of Adhesives

Adhesives are poor conductors of heat and electricity, but both can be increased by filling with powdered metals, especially silver. To increase thermal conductivity alone, metal oxide fillers can be used. The most effective of these is beryllium oxide, which is both toxic and expensive; aluminum oxide is a practical alternative. Some values of thermal conductivity are collected in Table 6.

Kilik et al. (1989) have measured thermal conductivities of a toughened epoxide adhesive filled with copper and aluminum powders. The effect of the size and shape of particles is less significant than the amount of filler used. Al-Samhan and Darwish (2005) showed that the thermal conductivity of an adhesive was increased from 1.06 to 1.81 W m<sup>-1</sup> K<sup>-1</sup> when filled with copper. Morriche et al. (2016) added graphene platelets of average thickness 6–8 nm to an epoxide cured with an aromatic amine which increased thermal conductivity by as much as 200–300%.

#### 18.4.5 Thermal Expansion of Adhesives

Unless polymers are the substrates, linear thermal expansion coefficients of adhesives are generally much greater than those of the materials being bonded. Some comparative data are shown in Table 7. When large areas are being bonded, these differences can lead to significant and damaging interfacial stresses as the temperature changes. Expansion coefficients of adhesives can be reduced by the addition of mineral fillers.

Expansion coefficients of polymers are greater in the rubbery state than in the glass. Some data appear in Table 8.

Metal cutting tools can reach very high temperatures (400 °C), and Al-Samhan and Darwish (2005) have used finite element stress analysis to examine the case of tungsten carbide tips bonded to a steel support. Here, the linear expansion coefficients were 12.1 × 10<sup>-6</sup> K<sup>-1</sup> for steel, 60 × 10<sup>-6</sup> K<sup>-1</sup> for the tip, and 40 × 10<sup>-6</sup> K<sup>-1</sup> for the adhesive. The use of cutting fluids much reduced the stresses.

Da Silva and Adams (2007) predicted advantages in using two adhesives in metal-composite double lap joints which had to operate over a temperature range of –55 to 200 °C, as might be the case in supersonic aircraft. A ductile adhesive was present to cope with low temperatures and a brittle adhesive for the high ones.

### 18.5 Breakdown of Adhesives

#### 18.5.1 Oxidative Degradation

Oxygen in the atmosphere generally attacks polymers. In many cases, the rate of attack, even at ambient temperatures, necessitates the use of stabilizing additives. Examples of adhesives that normally contain antioxidants are hot melts, those based on natural and synthetic rubbers, and pressure-sensitive adhesives.

**Fig. 12** Comparison of dependence on temperature of joint strengths with mechanical properties of the adhesive. ○ dry joints, ● joints stored for 1000 hours at 100% relative humidity and 50 °C. ■ adhesive modulus, □ adhesive tensile strength. The adhesive is DGEBA cured with DAPEE (Brewis et al. 1983)

**Table 6** Thermal conductivities of fillers and adhesives

Material	W m <sup>-1</sup> K <sup>-1</sup>
Silver	410
Copper	370
Aluminum oxide	34
Unfilled epoxide	0.7–0.26
Epoxide with 25% by weight of alumina filler	0.34–0.51
Epoxide with 50% by weight of alumina filler	0.51–0.68
Epoxide with 75% by weight of alumina filler	1.3–1.7
Epoxide with 50% by weight of aluminum	1.7–3.4

Although all polymers will degrade at elevated temperature in the absence of air, the rate of degradation is generally increased when there is a supply of oxygen. In adhesive joints, the supply of oxygen will depend on the oxygen permeabilities of

both the adhesive and the adherends, and on the distance that oxygen must diffuse in either of these. Metallic, ceramic, and glass adherends are impermeable to oxygen and therefore represent a complete barrier to it, but composites with polymeric matrices are permeable to atmospheric gases. However, the rate of oxygen diffusion into adhesives at elevated temperatures will probably be sufficiently high for impermeable adherends to offer little protection against oxidative degradation.

Oxygen is a diradical and can participate in polymerization and degradation reactions by acting as an initiator. Oxygen is absorbed by the polymer to form a hydroperoxide that subsequently decomposes to give radicals that then initiate degradation.

Figure 13 shows the amount of oxygen absorbed by a typical polymer in air as the temperature is raised. The pure polymer has a buildup period in which the hydroperoxide is formed, but this is absent in the polymer in which hydroperoxide groups have previously been added. In the presence of an antioxidant, there is a long induction period in which the stabilizer scavenges any free radicals. The end of the induction period marks consumption of the stabilizer. Oxidative degradation is a complex series of chain reactions. Karger-Kocsis et al. (1980) have demonstrated induction periods in the oxygen uptake of a number of hot-melt adhesives.

**Fig. 13** Oxygen absorption by a polymer

The excellent resistance to oxidation possessed by high-temperature adhesives such as polyimides, polyquinoxalines, and polybenzamidazoles is due to their high content of aromatic groups.

Polymers are also attacked by ultraviolet (UV) radiation. The combined effects of UV radiation and oxygen are particularly damaging. However, unless one adherend is transparent to UV rays, this is not a factor in the weakening of polymer adhesives.

## 18.5.2 High Temperature Limits of Adhesives

The temperatures at which different types of adhesives will survive in service for a period of 1 year will vary somewhat among particular materials, but the following general guidelines can be used. The upper limit for acrylates and cyanoacrylates is 80 °C, whereas epoxides cured with polyamides have a service limit of 65 °C. Epoxides cured with aliphatic amines have an upper limit of 100 °C, whereas this limit is 150 °C for those cured with acid anhydrides. The surface temperature is 200 °C for silicones and 260 °C for polyimides. Many of these adhesives can be exposed at higher temperature for shorter periods without detrimental effects.

Kadiyala and Bijwe (2016) employed high-temperature thermoplastic polymers as adhesives for steel. The polymers were polyethersulfone (PES), polyetheretherketone (PEEK), and polyetherketone (PEK). The latter pair was about 30% crystalline with respective melting points of 343 and 372C. Lap shear strengths were measured at temperatures of 25, 150, 225, and 300C, and strength retention at 300C was about 30% for PES, 65% for PEK, and 70% for PEEK. Degradation temperatures for all adhesives were about 440–450C. Reiss et al. (2015) measured mechanical properties of an amine-cured toughened adhesive at temperatures between 25 and 130C. Both modulus and tensile strength fell by about half and in a linear manner.

Rubbery adhesives and rubber-modified structural adhesives have lower temperature limits (the glass transition temperature). In many cases, the development of thermal mismatch stresses upon cooling will increasingly weaken joints.

### 18.5.3 Low Temperature Limits of Adhesives

Adhesives are used to bond an insulating layer to the steel hull of ships for transporting liquefied natural gas which has a boiling point of  $-161.5^{\circ}\text{C}$ . A two-part epoxide and a two-part polyurethane were examined at temperatures of  $23$  and  $-100^{\circ}\text{C}$  by Crocker et al. (2016). Tensile strengths for the epoxy at these temperatures were  $35$  and  $38 \pm 3$  MPa and  $8$  and  $37\text{--}71$  MPa, respectively. Coefficients of thermal expansion were much reduced at the lower temperature ( $82$  to  $38 \times 10^{-6}/\text{K}$  for the epoxide and  $121$  to  $48 \times 10^{-6}/\text{K}$  for the polyurethane).

### 18.5.4 Loss of Additives

Additives in adhesives can be there for a number of reasons, one of which is to act as a stabilizer. Tarragrosa-Coque et al. (2011) looked at the effect of temperature on the migration of low molar mass additives to the surface of a crosslinked styrene-butadiene rubber. The additives of interest were paraffin wax and zinc stearate, and the main tool of investigation was ATR spectroscopy. Below the melting point of paraffin wax ( $c67^{\circ}\text{C}$ ) the amount of this additive increased at the rubber surface. The wax was removed by sublimation at temperatures in the range  $80$  to  $120^{\circ}\text{C}$  and so exposed the zinc stearate. Above  $130^{\circ}\text{C}$ , both additives sublimated.

### 18.5.5 Thermally Reversible Adhesive

Aubert (2003) has described a thermally reversible adhesive rubbery adhesive ( $T_g = -40^{\circ}\text{C}$ ) where chains can be separated or linked in the Diels-Alder reaction between a furan and a maleimide shown in Fig. 14. Above  $90^{\circ}\text{C}$ , the links are broken, but the process is reversed on cooling.

## 18.6 Measurement of Thermal Properties

Differential scanning calorimetry (DSC) and dynamic mechanical thermal analysis (DMTA) are the favored methods to obtain thermal data and are described below, together with thermogravimetric analysis. Modern instruments will be linked to a computer both for control and data collection and processing. Historical methods to measure both  $T_g$  and  $T_m$  include dilatometry and the use of a torsion pendulum to

**Fig. 14** Reversible Diels-Alder reaction

measure damping. The practice of dilatometry involves containing the polymer in mercury in a sort of overgrown thermometer; it measures changes in volume.

### 18.6.1 Differential Scanning Calorimetry

Differential scanning calorimetry (DSC) examines how the heat capacity at constant pressure ( $C_p$ ) of a material changes with temperature. A sample is heated or cooled at a constant rate and changes in  $C_p$  are recorded. Rates can be in the range  $0.1\text{--}100\text{ K min}^{-1}$ .

A diagram of the scan of a semicrystalline adhesive is shown in Fig. 15. At low temperatures, the adhesive is in the glassy state and the slope of the line  $dH/dT$  gives its  $C_p$ . At the glass transition temperature ( $T_g$ ), the abrupt increase in slope is due to the higher heat capacity of the leathery adhesive. At a higher temperature  $T_m$ , the crystalline regions begin to melt, and a peak is observed due to heat being supplied to the sample, the area of which is measured in joules, and can give the degree of crystallinity of the adhesive. This requires the value of the heat of fusion of totally crystalline adhesive, which can only be obtained indirectly from the depression of melting point caused by diluents. Indium can be used as a calibrant for heat of fusion and synthetic sapphire for  $C_p$ .

If the sample is then cooled, it will eventually crystallize and the exotherm will be seen. This will be at a lower temperature than  $T_m$  due to supercooling. The area enclosed in the valley is related to the degree of crystallinity developed on cooling.

The cure of chemically reactive adhesives is exothermic and this permits DSC to follow cure, and also to measure the final to extent of cure. Kwon and Paik (2004) employed DSC to measure the extent of cure for an electrically conductive adhesive.

### 18.6.2 Dynamic Mechanical Thermal Analysis

Here, the sample is subjected to sinusoidal or other distortion at a fixed frequency and measurements are made over a range of temperatures. What is measured is stiffness and damping. The former is a measure of stored energy which is reported as

**Fig. 15** DSC thermogram for a semicrystalline adhesive, on heating followed by cooling

modulus; the latter is a measure of energy lost and is often reported as  $\tan\delta$ . The frequency range of commercial instruments is typically 0.001–1000 Hz and standard instruments have a temperature range of  $-190$  to  $400$   $^{\circ}\text{C}$  and heating rates are up to  $20$   $\text{K min}^{-1}$ . Samples can be maintained in inert gases, liquids, or humid air.

The diagram of a DMA record for a typical adhesive is shown in Fig. 16. It shows a loss peak centered on  $T_g$ . For adhesives which have two phases, such as block copolymers of dienes and styrene, both glass transitions are detected, one being about  $-70$   $^{\circ}\text{C}$  for the dispersed diene phase and the other at about  $100$   $^{\circ}\text{C}$  for the continuous polystyrene phase. Glass transition temperatures increase with frequency.

### 18.6.3 Thermogravimetric Analysis

Here, the sample is suspended from a balance and located in an oven. Weight changes are recorded as temperature increases. Its particular use is in observing thermal degradation of adhesives. Controlled atmospheres can be used. Typical temperature ranges are ambient to  $1000$   $^{\circ}\text{C}$  and heating rates  $0.1$ – $200$   $^{\circ}\text{C min}^{-1}$ .

An example is taken from the work of Xu and Dillard (2003). Data are for three epoxide adhesives made electrically conductive by the addition of about 80% by weight of powdered silver. They all begin to decompose at about  $400$   $^{\circ}\text{C}$ .

**Fig. 16** DMTA scan for a polymeric adhesive

## 18.7 Conclusion

Thermal properties of adhesives affect their behavior in a number of diverse ways. Firstly, cure processes, pot-life, and shelf-life depend on temperature. High temperatures can limit the lives of adhesives by causing chemical degradation, and in some cases by introducing stresses due to differences in thermal expansion. Glass transition is the most important temperature for an adhesive, in that it demarcates rubbery adhesives from rigid ones, and is something to be avoided in service.

intrinsic adhesive properties and are of limited use for design purposes. The prediction of the joint strength based on stress or strain limit criteria needs the adhesive stress–strain curve. In this chapter, the most important tests for the determination of the adhesive mechanical properties are described. Tests for the three basic loading modes – tension, compression, and shear – are discussed, indicating for each case the advantages and disadvantages. Reference is made to the corresponding standards according to the major standard-setting organizations such as the American Society for Testing and Materials (ASTM) and the International Standards Organization (ISO). Within each category (compression, tension, and shear), tests on bulk specimens and those on joints are compared. Recommendations to select the most suitable test are given, and it is shown that a reasonable relationship exists between adhesive properties measured in compression, tension, and shear.

---

## 19.1 Introduction

Failure strength tests are carried out for different purposes. During the formulation and development stage, manufacturers need to certify their products, and the commonly used tests are failure strength tests. These can be related to the application for which the adhesive is designed using loadings and adherends found in a particular application. Also, some manufacturers provide standard tests that are universal and can be used not only for qualitative but also for design purposes. In many cases, manufacturers provide limited information in the adhesive data sheet, and it is therefore necessary for the joint designer or the researcher to carefully test the adhesive properties. There is a wide variety of standard tests available in different countries (the USA, Britain, France, Germany, and Japan) that are also provided by many organizations at the international level, such as the International Standards Organization (ISO) and the European Standards (EN) Organization (da Silva 2012). Wherever available, adhesive testing standards from these organizations and others are given in this chapter.

When a complex joint is to be introduced in a structure, the ideal situation is to test that specific joint. However, this approach is very expensive. Before real joints or prototypes are built, the designer should first come up with a good prediction of the failure load based, among other things, on the basic mechanical properties of the adhesive. The basic properties can mean the elastic properties, such as Young's modulus and Poisson's ratio in case the analysis is linear elastic. However, for the more realistic theoretical methods that take into account the nonlinear behavior of the adhesive, the yield stress, the ultimate stress, and the failure strain are necessary. The stress–strain curve of adhesives is necessary for designing adhesive joints in order to compute the stress distribution and apply a suitable failure criterion based on continuum mechanics principles.

The tensile stress–strain curve on bulk specimens is generally the most common test used. This test is sufficient if the yield behavior of the adhesive is assumed to be of the von Mises type. However, it is known that adhesive yielding is better

described by more complex yielding criteria (Drucker and Prager 1952; Raghava et al. 1973; Dolev and Ishai 1981) (see ► Chap. 23 “Constitutive Adhesive and Sealant Models”) for which an additional test under a different loading condition is required. Shear tests are usually preferred because the compressive test is more difficult to perform. There are many test methods for the determination of failure strength data. They can be divided into two main categories: tests on bulk specimens and tests in a joint or in situ. Tests in the bulk form are easy to perform and follow the standards for plastic materials. However, the thickness used should be as thin as possible to represent the thin adhesive layer present in adhesive joints. Tests in situ more closely represent reality, but there are some difficulties associated with accurately measuring the very small adhesive displacements of thin adhesive layers. Moreover, the adhesive stress distribution is not perfectly uniform, and the failure mode may not be the same as that found in real joints. Another important point is that the adhesive strength measured in a joint depends on the surface preparation. This is not only critical for the short-term strength but even more so for the long-term strength, especially if aggressive environments are present. Also, there might be a region close to the interface with chemical and physical characteristics different from those of the bulk adhesive or adherend, leading to the formation of an interphase. There has been intense debate about the most appropriate method and whether the two methods (bulk and in situ) can be related. Some argue that the properties in the bulk form may not be the same as in a joint because the cure in the bulk form and the cure in a joint (thin film) may not be identical. In effect, the adherends remove the heat produced by the exothermic reaction associated with cure and prevent overheating. However, many studies have shown that the relation is reasonable, taking into account all the differences associated with each method (Jeandrau 1991; Lilleheden 1994; da Silva and Adams 2005). The truth is that there is no perfect test for the determination of failure strength properties. The designer needs to select the most appropriate test for a given application and understand what the results mean (Adams 1990).

---

## 19.2 Tensile Tests

### 19.2.1 Bulk Specimens

One of the most common types of tests for determining the strength properties of adhesives is the tensile test on bulk specimens. The specimens and the test methods are comparable to those used for plastic materials. The properties determined are intrinsic to the material: they are obtained under a uniform and uniaxial state of stress, with no influence of the adherends.

The manufacture of the bulk specimen is usually done by pouring or injecting the adhesive into a mold with the final shape (Fig. 1) or by applying pressure between plates (Fig. 2). The first method is suited to one-part adhesives that are relatively liquid. The mold can be open, but it can also be a closed cavity, in which case the adhesive needs to be injected (Fig. 1). When the adhesive is viscous, in the form of a

**Fig. 1** Tensile bulk specimens obtained by pouring

**Fig. 2** Bulk plates obtained by high pressure

film or of two components, the second method generally gives better results. If the adhesive is viscous or in film form, the pouring (or injection) phase is difficult or impossible. On the other hand, the mixing of two-part adhesives introduces voids. If the adhesive is liquid, the air bubbles can be removed by vacuum. If the adhesive is viscous, modern sophisticated machines that allow mixing at high speed under vacuum can ensure that the adhesive is void free. If the voids have been removed properly, the adhesive can be manufactured by pouring or injection. If not, the voids can be removed by high pressures. The technique described in the French standard NF T 76-142 works particularly well for producing plate specimens without porosity. It consists of curing plates of adhesive in a mold with a silicone rubber frame under a high pressure (2 MPa or 20 atm). The pressure is calculated using the dimensions of the silicone rubber frame. The technique, shown schematically in

**Fig. 3** French method (NF T 76-142) to obtain plates without porosity (da Silva et al. 2004)

Fig. 3, consists of placing in the center part of the mold a quantity of adhesive slightly greater than the volume corresponding to the internal part of the silicone rubber frame. There is a gap, at the beginning of the cure, between the adhesive and the silicone rubber frame. At the moment of the application of the pressure, this gap enables the adhesive to flow (until the mold is completely filled) and avoids gas entrapment. This technique is suitable for any type of adhesive, i.e., liquid, paste, or film. The plates are then machined according to the dimensions used for tensile testing or for other types of geometry (see Sects. 3 and 4). The geometry generally used for tensile specimens is the dog-bone-shape specimen according to standard EN ISO 527-2, which is represented in Fig. 4. Long specimens (Fig. 4a) are used for rigid adhesives (e.g., epoxies) where the displacements are small, whereas short specimens (Fig. 4b) are more suited for flexible adhesives (e.g., polyurethanes). The geometry described in ASTM D 638 (tensile properties of plastics) can also be followed. Alternatively, standard ASTM D 3039 (tensile properties of fiber-resin composites) can be used when working with supported film adhesives. It is important to specify the thickness of the plate because the adhesive properties will depend on it, especially if there are many voids in the specimen. The ideal method would be to work with very thin samples to reproduce the adhesive layer in a joint, but this is very difficult due to the high flexibility of the adhesive. Generally, a thickness of 2 mm is used; larger thicknesses can be used, but the exothermic reaction during the cure can cause adhesive burning in some adhesives. Round solid bar tension specimens have also been used by some authors (Grant et al. 2009). The specimens should be conditioned under controlled temperature and humidity because these factors influence the mechanical properties of the adhesive, especially for polyurethane adhesives. This is valid for any type of test.

The test consists in loading the specimen in a longitudinal direction until failure. The test speed generally used is 1 mm/min for the determination of Young's modulus, but higher rates can be used for failure testing. The strain rate of the adhesive measured in bulk should be similar to the strain rate the adhesive has in the joint, especially if the adhesive is close to its glass transition temperature ( $T_g$ ). The

**Fig. 4** Tensile specimens according to EN ISO 527-2 (dimensions in mm): **(a)** long specimen and **(b)** short specimen

**Fig. 5** Adhesive displacement measurement with clip gauges or strain gauges **(a)** and with an optical method **(b)**

temperature and humidity of the test should also be recorded. Small deviations from typical laboratory conditions (25 °C and 50% relative humidity) can cause an important variation in the mechanical properties, especially if the adhesive  $T_g$  is in that range. The load and the displacement are measured, which can then be used to determine the stress-strain curve. Measurement of the adhesive displacement is relatively easy using clip gauges or strain gauges (see Fig. 5a). However, whenever possible, it is recommended to use noncontacting devices to avoid any interference of the extensometer with the material behavior, especially for flexible and ductile adhesives. Optical (see Fig. 5b) or laser methods are widely used. Video extensometers are not accurate enough for strains below 1%. However, other methods based

**Fig. 6** Typical tensile stress–strain curve of an adhesive with the definition of the mechanical properties

on optical data treatment such as digital image correlation (DIC) enable one to measure strains below 1%. The displacement of the crosshead can also be used to estimate the adhesive strain. However, this requires a correction as the adhesive displacement in the calibrated area is not the same as that between the grips. For highly deformable adhesives, the crosshead displacement is good enough, especially for the nonlinear part of the curve.

A typical tensile stress–strain curve is shown in Fig. 6. The stress–strain curve can be used to determine Young’s modulus, the tensile strength, and the failure strain. There are several methods to calculate Young’s modulus. Standard EN ISO 527-2 recommends determining Young’s modulus between points at 0.05% and 0.25% strain. This range generally falls in the elastic range of structural adhesives. Table 1 shows Young’s modulus of different types of adhesives below  $T_g$ . Stiff adhesives are in the range of 4–5 GPa (e.g., epoxies or polyaromatics). Flexible adhesives for structural use such as polyurethanes are in the range of 0.1 GPa. For flexible and ductile adhesives such as polyurethanes, the material is nonlinear even for these small deformations. Other methods such as the secant modulus or the tangent at the origin may be used. For flexible adhesives such as polyurethanes, because the displacement rate is constant, there is time for the load to relax through the test. In order to avoid this phenomenon, a test under constant strain rate should be done.

The tensile and compressive properties were obtained in the bulk form, and the shear properties were obtained with the thick adherend shear test (TAST). ( $E$  Young’s modulus,  $\sigma_y$  yield strength,  $\sigma_t$  strength,  $\varepsilon_t$  tensile failure strain,  $\tau_y$  shear yield strength,  $\tau_r$  shear strength,  $\gamma_y$  shear failure strain,  $\nu$  Poisson’s ratio).

Poisson’s ratio can be determined provided the adhesive displacement is measured in the longitudinal and transversal directions. This property is very difficult to measure experimentally, especially in the elastic range. For polymers, Poisson’s ratio

*E* Young's modulus, *σ<sub>y</sub>* yield strength, *σ<sub>r</sub>* strength, *ε<sub>r</sub>* tensile failure strain, *τ<sub>y</sub>* shear yield strength, *τ<sub>r</sub>* shear failure strength, *γ<sub>y</sub>* shear failure strain, *ν* Poisson's ratio)

varies between 0.3 and 0.5. For temperatures below the glass transition temperature ( $T_g$ ), the value is close to 0.3. When the adhesive is above  $T_g$  or in the plastic region, Poisson's ratio is about 0.5. Table 1 gives the values for several adhesives. One way to determine Poisson's ratio is to deduce it from the measurement of Young's modulus and the shear modulus (see Sect. 5).

It is generally easy to find the yield stress of metals because there is usually a clear transition between elastic and plastic behavior. However, for polymers, the elastic region may not be linear, and it is difficult to find the value of the stress corresponding to the initial yielding. Various authors have proposed methodologies to find the yield stress. Young and Lovell (1991) state that the exact position of the yield point is very difficult to estimate, and so they define yield as the maximum point on the stress–strain curve. This procedure is valid when the adhesive behaves elasto-plastically. For strain-hardening adhesives, it is convenient to take the yield stress as the intersection of a line tangent to the linear elastic region and a line tangent to the nonlinear plastic region of the actual stress–strain curve, such as in the bilinear model (Hart-Smith 1973). The traditional 0.2% offset method may also be used for this effect for glassy polymers. Table 1 gives yield strength values for several adhesives. The strongest adhesive is in the order of 60 MPa. This is well below the yield strength of a low-strength steel, which is approximately 180 MPa. However, when loaded in shear over a large area, the adhesive can deform plastically the steel.

The strain to failure is highly dependent on the presence of defects such as voids and micro-cracks. In tension, once a crack is triggered next to a void, the specimen often fails there due to the high stress concentration. Generally, the strain to failure presents a very large dispersion, unless the manufacture is very well controlled. Table 1 presents values of the failure strain in tension and shear. Generally, adhesives are much more ductile in shear than in tension. For ductile adhesives, the difference can be of one order of magnitude. Stiff and strong adhesives have generally a limited ductility of the order of 1% or 2%, especially in tension. On the other end of the scale, failure strains of up to 300% can be obtained with polyurethane adhesives.

### 19.2.2 Axially Loaded Butt Joints

The tensile properties can also be measured with the adhesive in a thin layer between two steel substrates as in the butt joint (also called the “poker chip” test). There are two ASTM standards for this type of test. The first, ASTM D 897, uses short circular specimens made of metal or wood, and the second (ASTM D 2095) is more general and includes round and square geometries (Fig. 7). Other standards include ISO 6922, BS EN 26922, and BS 5350 – Part C3. A mold is presented in ASTM D 2095 for controlling the adherend alignment and adhesive thickness. The stress is obtained by dividing the load by the loaded area. Apparently, the stress state is of uniform tension. However, some authors (Adams and Coppendale 1977, 1979) have shown that the stress distribution is nonuniform due to the constraining effect of the substrates or slight misalignments. The lateral contraction of the adhesive does not occur

**Fig. 7** Butt-joint geometry (dimensions in mm) (ASTM D 2095)

**Fig. 8** Gauge length and displacements in the axially loaded butt joint

freely, which introduces additional radial and circumferential stresses, especially at the edges of the joint. In addition to the constraining effect of the substrate, misalignments can occur during fabrication or testing, which introduce bending in the adhesive.

The adhesive displacement can be measured by extensometers attached to the adherends, in which case a suitable correction is necessary. Taking the case illustrated in Fig. 8 and given by Adams et al. (1997), the extensometer displacement  $\delta$  is given by

$$\delta = \delta_1 + \delta_a + \delta_2 = \epsilon_1 d_1 + \epsilon_a d_a + \epsilon_2 d_2 = \epsilon_1 (d_1 + d_2) + \epsilon_a d_a \quad (1)$$

where  $\epsilon$  is the strain and  $d_1$ ,  $d_a$ , and  $d_2$  are defined in Fig. 8. If  $d_1$  and  $d_2$  are of the order of 1 mm and  $d_a$  (adhesive thickness) is of the order of 0.1 mm, then the displacements in the adhesive and in the adherend are of the same order. This correction is necessary for all the extensometers that measure not only the adhesive displacement but also the adherend displacement. This is a big disadvantage associated with adhesive joints and extensometers.

According to Adams and Cripps (1977), the elastic properties (Young's modulus,  $E$ , and Poisson's ratio,  $\nu$ ) can still be determined using this test. They defined a relation between the "apparent"  $E_a$  measured in the test and the real  $E$ . If the substrate is infinitely rigid in relation to the adhesive, the relation between  $E_a$  and  $E$  is given by

$$\frac{E_a}{E} = \frac{(1 - \nu)}{(1 + \nu)(1 - 2\nu)} \quad (2)$$

where  $\nu$  is Poisson's ratio of the adhesive. Another equation proposed by Kuenzi and Stevens (1963) gives Poisson's ratio of the adhesive, if the shear modulus of the adhesive is known, and the adherend elastic properties.

The stress-strain curve obtained with this test is not representative of the intrinsic adhesive behavior due to the adherend constraining effect described above and cannot be correlated with the adhesive bulk properties. An extensive study carried out by several laboratories and led by Centre Technologique des Industries Mécaniques from France (Jeandreau 1993) has shown that the reproducibility associated with this test is quite low, despite the use of a precise and specially designed extensometer.

### 19.3 Compressive Tests

This test is less common than the tensile or shear tests. Usually, it is assumed that the adhesive follows the von Mises model and, therefore, the compressive and tensile properties are the same. However, since adhesives depend on the hydrostatic stress component, the compressive strength properties differ from those obtained in tension. The ratio of the yield stress in compression to the yield stress in tension varies typically between 1.2 and 1.4 (Adams et al. 1997). There are various types of compressive tests on bulk specimens. The most common compressive test uses parallelepipedic (square or rectangular base) bulk specimens. The French standard NF T 51-101 recommends a square base (Fig. 9a), whereas ASTM D 695 (Fig. 9b) and ISO 604 use a rectangular base. In the case of ISO 604, the preferred specimens are  $50 \times 10 \times 4 \text{ mm}^3$  for modulus and  $10 \times 10 \times 4 \text{ mm}^3$  for strength. Cylinders can also be used and are 12.7 mm (1/2 in.) in diameter and 25.4 mm (1 in.) long according to ASTM D 695 (Fig. 10a). Gali et al. (1981) also used tubular specimens (Fig. 10b) with good results.

The specimen is placed between compressive plates parallel to the surface. The specimen is then compressed at a uniform rate. The maximum load is recorded along with stress-strain data. An extensometer attached to the front of the fixture is used to measure the adhesive displacement. The stress-strain curve is used to determine the properties of interest. Various authors have shown that Young's modulus in compression obtained by this method and that obtained with bulk tensile specimens correlate well. However, it is difficult to determine the failure stress and strain in

**Fig. 9** Bulk specimens for compressive testing using parallelepipedic specimens (dimensions in mm): (a) according to NF T 51-101 and (b) according to ASTM D 695

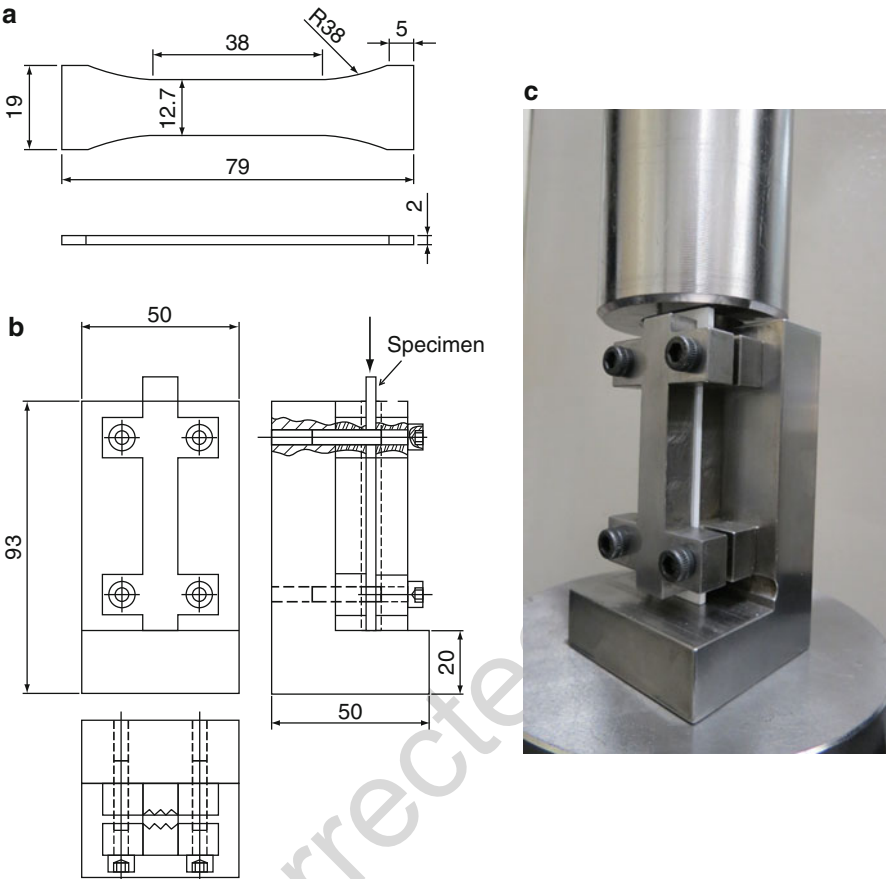

**Fig. 10** Bulk specimens for compressive properties using (dimensions in mm): (a) cylindrical (ASTM D 695) and (b) tubular specimens (Gali et al. 1981)

compression because the adhesive keeps deforming without breaking (Jeandreau 1993).

ASTM D 695 standard also describes a procedure using a plate specimen similar to the bulk tensile test (Fig. 11a). This method is valid only for rigid adhesives. However, special care must be taken to avoid buckling of the specimen, as shown in Fig. 11b. The machining of ends is particularly important to ensure they are smooth, flat, and parallel, with sharp and clean edges. Testing is done by placing a small specimen between the two blocks as shown in Fig. 11c and slowly compressing it until the point of fracture. Some of the results of this test include compressive strength, compressive yield strength, offset yield strength, and modulus of elasticity. Unpublished results by the author have shown that the values of the modulus

**Fig. 11** Bulk specimen for compressive properties according to ASTM D 695 (dimensions in mm): (a) specimen geometry, (b) blocks to avoid specimen buckling, and (c) loading jig

obtained with this type of test are comparable to those obtained using the bulk tensile test. The nonlinear part of the stress–strain curve should, however, be analyzed with caution because the two blocks used to avoid buckling might stiffen the adhesive.

### 19.4 Shear Tests

As with tensile tests, shear tests can be divided into bulk and joint tests. The adhesive displacement in joint tests is very small, and it is therefore more difficult to measure accurately. Bulk specimens give more accurate results because the gauge length is higher. However, it can be argued that the size and thickness of the specimens used are not representative of the adhesive properties in a joint. The National Physical Laboratory and other British laboratories (Dean et al. 1996) have carried out an

extensive theoretical and experimental study on various shear test methods. Many of their findings are well accepted by the adhesive community and are also presented here.

**19.4.1 Bulk Specimens**

**Bulk Torsion**

The shear properties of the adhesive can be obtained with solid or tubular bars in torsion. The dimensions of the specimen vary from author to author. An example is given in Fig. 12a (Chen et al. 2011) for solid bars. The specimen manufacture depends on the type of adhesive and is described above in Sect. 2.1. The round shape needs to be obtained by machining, which might not be possible with very flexible adhesives. Alternatively, round specimens can be cast in a centrifuge. The square sections at the two ends are used to locate into the grips of the test machine and to transmit the torque. The round shape is free of stress concentrations, and therefore the true adhesive properties can be measured with this test. Due to this advantage, torsion testing machines are used to characterize adhesives and are also continuously being improved. As an example, a new type of torsion testing machine concept was recently proposed to a provisional Portuguese patent to test specimens under torsion loads (Guimarães et al. 2016). The torque and the relative twist ( $T - \varphi$ ) along the gauge length of the specimen are recorded. The shear stress  $\tau$  and shear strain  $\gamma$  are obtained from the  $T - \varphi$  curve using the following equations:

**Fig. 12** Bulk torsion specimens (dimensions in mm): (a) solid bar torsion specimen (Chen et al. 2011) and (b) tubular specimen (Gali et al. 1981)

$$\tau = \frac{Tr}{J} \quad (3)$$

$$\gamma = r \frac{\phi}{l} \quad (4)$$

where  $r$  is the radius,  $l$  is the gauge length, and  $J$  is the polar moment of inertia. Contacting extensometers are used to measure the angular rotation of a known gauge length of the specimen. The use of large gauge length enables high accuracy with this test. In case the specimen is sensitive to the extensometer, the rotation of the specimen clamps can be used. For this type of solid bar, the shear strain varies linearly along the radial direction with zero strain at the center. The shear strain at the outside surface can be derived from the measured twist. However, the stress distribution is linear only if the material is absolutely linear elastic. Nonlinear behavior is bound to occur, especially in the pure shear state. Departure from linearity will redistribute the stress in such a way that some load carried by the most-stressed material at the outside surface (in the elastic case) shifts to the material inside. The graphical correction method due to Nadai (1931) can be applied to the recorded torque–twist curve to derive the shear stress–strain response at the surface of the specimen. The correction is illustrated in Fig. 13 (Adams et al. 1997). A tangent to the curve is made for any point of the nonlinear part. For example, the correction to the height AB is made by subtracting one quarter of the intercept height DC, giving the corrected height AE. The relevant properties are determined from the shear stress–strain curve.

Tubular specimens (thin walls) can also be used and do not require a Nadai correction (Nadai 1931). The specimen geometry used by Gali et al. (1981) is presented in Fig. 12b. Again, relevant properties are determined from the shear stress–strain curve.

**Fig. 13** Nadai correction

### V-Notched Beam Shear Method (Iosipescu)

The V-notched beam shear method (or Iosipescu) and the notched plate shear method (or Arcan) are two methods of measuring the shear properties in bulk. The two methods are similar, differing only in the type of loading and geometry. Both test methods were made so that a conventional tensile testing machine can be used to apply shear. This test was originally developed for metals (Iosipescu 1967), but it has been adapted for laminated composites in the standard ASTM D 5379 following developments by Adams and Walrath (1987). The specimen is rectangular with two V notches at its center, as shown in Fig. 14. The geometry is usually 75 mm wide, 20 mm high, and at least 4 mm thick. The specimen is loaded in four points, creating an area with uniform shear between the notches since the bending moments from both sides cancel each other. Since the specimen is loaded at the edges, this can cause bending of the specimen along its longitudinal axis. To reduce this problem, thick specimens are recommended (3–4 mm). For very flexible adhesives such as polyurethanes, the testing method may not be adequate even with thick specimens. There is a stress concentration at the notch root, but the shear stress calculated with the force and the cross-sectional area is a good approximation. Alternatively, a correction can be applied with a finite element (FE) analysis. For brittle adhesives, the stress concentration at the root of the notch might be sufficient to induce premature failures and give only part of the stress–strain curve. That is one of the main disadvantages of this type of test. The same thing happens with the Arcan test. The shear displacement can be measured by strain gauges mounted at  $+45^\circ$  and  $-45^\circ$  with the specimen axis. If  $P$  is the load applied,  $t$  the specimen thickness, and  $h$  the distance between the notches, the shear stress  $\tau$  is given by

$$\tau = \frac{P}{th} \quad (5)$$

and the shear modulus  $G$  by

$$G = \frac{P}{th(\epsilon_{45} - \epsilon_{-45})} \quad (6)$$

**Fig. 14** V-notched beam shear method (or Iosipescu) specimen dimensions (in mm) and loading

where  $\varepsilon_{45}$  and  $\varepsilon_{-45}$  are the strains measured by the strain gauges bonded at  $+45^\circ$  and  $-45^\circ$  with the specimen axis. However, as in the tensile bulk test, strain gauges tend to stiffen the adhesive and have a limited strain limit (typically 10%). Alternatively, noncontacting devices, such as digital image correlation, can be used. The stress–strain curve can be used to determine the shear modulus, strength, and ductility.

**Notched Plate Shear Method (Arcan)**

The notched plate shear method, also called Arcan, is used to obtain the shear properties on bulk specimens. The specimen geometry looks like a butterfly (Fig. 15), and the test is also known as the butterfly test (Voloshin and Arcan 1980). The specimen contains two symmetric notches at  $90^\circ$  with a radius of curvature of 1.5 mm to minimize the stress concentration. The holes on the sides of the specimen allow the application of a shear loading (Fig. 16) that is uniform between the two notches. This loading arrangement avoids the problem of instability at the edges that occurs in the Iosipescu test and enables to work with thinner specimens. This is useful for flexible adhesives or for adhesives that have a big exothermic reaction during cure. There are, however, stress concentrations near the notches that can induce premature failures, especially for brittle adhesives (Dean et al. 1996). The stress is obtained dividing the load by the resistant area between the two notches. The displacement in the uniform shear deformation zone between the two notches can be measured with extensometers mounted on the specimen, with strain gauges bonded at  $+45^\circ$  and  $-45^\circ$  with the loading axis, or with noncontacting methods (Pinto et al. 2010). Dean et al. (1996) have developed an extensometer that

**Fig. 15** Notched plate shear method (or Arcan or butterfly) (dimensions in mm)

**Fig. 16** Loading jig of the Arcan specimen

is mounted on the specimen and which consists of a pair of levers and displacement transducers. The extensometer is fixed to the grips and contacts the specimen at two points near the specimen center. For large strains (typically 20%), instabilities due to the loading arrangement make the results unreliable.

Arcan et al. (1978) proposed a biaxial fixture, commonly known as the Arcan fixture, to produce biaxial states of stress. The compact nature of the Arcan fixture enables obtaining the shear properties in all in-plane directions in a relatively simple manner. The Arcan fixture can be used to apply both shear and axial forces to the test specimen. The adhesive characterization in mixed mode loading allows for the generation of the yield surface of the adhesive in the hydrostatic versus the von Mises plane, which enables one to develop more accurate adhesive models for better simulations. Several modifications to the original test fixture have been proposed to include compression, such as that by El-Hajjar and Haj-Ali (2004). A scheme of the test fixture is shown in Fig. 17.

#### 19.4.2 Joint Specimens

One can argue that the adhesive properties measured in a joint are more representative. Furthermore, the fabrication and testing procedure is relatively simple, especially for the case of the thick adherend shear test (TAST). However, the main disadvantage is the need for high-precision measurement devices due to the low adhesive displacements. In many cases, extensometers that measure both adherend and adhesive displacements are used, which means that a correction is necessary to

**Fig. 17** Modified Arcan fixture for mixed loading

remove the adherend displacement. Another feature common to all joint tests is the fact that for a constant test speed, the strain rate in the adhesive will increase when the adhesive deforms plastically, which will increase the yield stress of the adhesive compared to a test carried out under constant strain rate.

### Arcan and Iosipescu Joint Methods

The Arcan and Iosipescu specimens can also be used as a joint where the adhesive is in a thin layer between two substrates. The test methodology is very similar to the bulk version. The adhesive displacement can be measured by noncontacting devices or extensometers of the type proposed by Dean et al. (1996). For devices that measure the adhesive and adherend displacement, a correction must be applied to have only the adhesive displacement. The stress distribution is not perfectly uniform, and an FE analysis can be used to have the value at the center of the specimen where the strain is obtained. Grabovac and Morris (1991) and Wycherley et al. (1990) used the Iosipescu method where two shaped adherends are bonded together. Weissberg and Arcan (1988) proposed a joint test based on the Arcan configuration. Cognard et al. (2005) proposed an Arcan joint method to produce not only shear but also biaxial stress states. The number of available loading directions is given by the number of holes on the modified Arcan device (Fig. 18b). There are two important parameters in this test: the geometry of the substrate (beaks machined on the substrates to reduce edge effects as illustrated in Fig 18a) and the geometry of the joint near the edge. A special system to guarantee an accurate control of the thickness and avoid misalignments is used (Fig 18c). However, the modified Arcan test is very sensitive to misalignments of the specimen regarding the direction of the applied load, and the procedure to control this aspect is very time-consuming which limits the application of this test in industry.

**Fig. 18** Modified Arcan test: (a) sample geometry with beaks, (b) recorded force divided into normal and tangential parts, (c) testing device, and (d) post-processing step to retrieve the normal and tangential displacements (Cognard et al. 2011)

More recently, improvements of the modified Arcan test were proposed by Créac'hadeac et al. (2015). The test substrate is a one-piece substrate that includes the bonding system and a new geometric beak.

Arnaud et al. (2014) used tubular bonded joints which enable a wide range of loadings, between tension, torsion, compression, and mixed loadings. Compared to the modified Arcan test, it has the advantage to allow nonproportional loadings and offers a continuous and infinite domain of mixed loadings.

### Butt Joint in Torsion

The butt joint with solid substrates or tubes can be used. The geometry of the specimen is represented in Fig. 19 for the butt joint with solid substrates (Adams and Coppendale 1977). As in the bulk torsion method, this test is free of stress

**Fig. 19** Butt joint in torsion with solid adherends (dimensions in mm) (Adams and Coppendale 1977)

**Fig. 20** Napkin-ring test specimen

concentrations, which enables having larger strain to failures than other types of tests where stress concentrations exist. Also, the adhesive displacement generated is higher, which gives a higher accuracy for the strain than other joint methods. If the same dimensions are used as the bulk torsion test, the same test apparatus can be used. Contacting extensometers used for the bulk torsion test are also applicable to the butt joint, but a correction is needed to remove the displacement of the substrates, especially if the adhesive is strong and stiff (Adams et al. 1997). As in the bulk torsion test, the shear stress–strain curve obtained must also be corrected as in the bulk torsion method (Nadai 1931). The manufacture can be difficult when an adhesive of low viscosity is used because it is difficult to fill the bonded area properly. Adams and Coppendale (1977) designed a jig to produce fully filled joints with low-viscosity adhesives.

Another type of butt-joint test in torsion is the napkin ring where the adhesive is in a thin layer between two tubular substrates. ASTM E 229, ISO 11003-1, and DIN 54451 describe this method (Fig. 20). Because tubes are used, the adhesive is essentially at the same shear stress, since the shear stress is proportional to the radius  $r$  (see Eq. 3). Althof and Neumann (1974) have shown that the napkin-ring test and the thick adherend shear test (see Sect. 4.2.3) give a very similar shear stress–strain curve. The main disadvantage of this type of test is the difficulty of manufacture. In case the adhesive has low viscosity, the manufacture is particularly difficult because the adhesive will not stay in position. In the napkin-ring test, the adhesive fillets inside and outside should be removed because they make the calculation of the shear strength and modulus less exact. The outer fillet is easy to remove. However, the inner fillet is impossible to clean away. If the thickness of the tubes is thin enough, the effect of the fillet can be neglected.

### Thick Adherend Shear Test

The thick adherend shear test (TAST) is one of the most popular types of failure strength test because it is easy to make and test the specimens. Shear properties obtained with this test are presented in Table 1. The conventional single-lap shear joint, which is mostly used for comparison and quality control of adhesives, puts the adhesive in a complicated state of stress (see Sect. 4.2.4). Therefore, it is not suitable for the determination of the true adhesive properties. When stiff and thick metallic adherends are used, the adhesive is in a state of essentially uniform shear over most of the overlap, and peel stresses are reduced. Two forms of the TAST are used, as developed by Krieger (1988) (ASTM D 3983), in the USA, and Althof and Neumann (1974) (ISO 11003-2), in Europe. The main difference between the two tests is the size of the specimen: the Althof specimen is half the size of Krieger's. They both developed extensometers for measuring the very small displacements across the bond line (Fig. 21). The extensometer measures not only the displacement of the adhesive but also the displacement of the adherend (Fig. 22). Therefore, it is necessary to apply a correction to the measured displacements. According to ISO 11003-2, the correction should be deduced from the measurement of the shear strain on a “dummy” specimen consisting of the adherend material alone. Vaughn (1998)

**Fig. 21** Thick adherend shear test (TAST) extensometer

**Fig. 22** Thick adherend shear test (TAST) transducer measured displacement

modeled the TAST specimen and the “dummy” specimen. The predicted profile of shear stress along the centerline of the adhesive is almost constant. Conversely, the shear stress distribution in the “dummy” is not uniform, so the correction cannot be deduced from that specimen. As part of a project to evaluate the relative performance of shear tests, Vaughn (1998) suggests that the adherend correction can be derived from simple elasticity assuming that the adherends experience pure shear only:

$$\begin{aligned} d_{\text{adhesive}} &= d_{\text{transducer}} - 2 \times d_{\text{adherend}} \\ 2 \times d_{\text{adherend}} &= \frac{2 \times t_{\text{adherend}} \times P}{G_{\text{adherend}} \times l \times w} \\ 2 \times t_{\text{adherend}} &= 3.8 \text{ mm} - t_{\text{adhesive}} \end{aligned} \quad (7)$$

where  $d$  is the thickness (mm),  $P$  the load (N),  $G$  the shear modulus (MPa),  $l$  the length of the overlap (5 mm), and  $w$  the width (25 mm). However, an FE analysis shows that direct axial stress is also carried by the adherend. Thus, an accurate correction cannot be properly calculated assuming that the adherends experience only pure shear. Taking this into account, it is better to use an FE analysis correction. Nevertheless, a simple elasticity correction is shown to be acceptable as long as the adhesive thickness is not too small. The adhesive displacement can also be measured with a conventional clip gauge used for tensile testing (da Silva et al. 2008). However, a correction is also needed. Optical methods such as image correlation analysis are probably the best because they give the adhesive displacement directly and do not interfere with the adhesive behavior (Pinto et al. 2010).

Despite the almost uniform stress distribution in the adhesive, stress concentrations still exist, especially at the edges of the overlap close to the interface. Several researchers have proposed modifications of the TAST geometry to reduce these

**Fig. 23** Thick adherend shear test (TAST) (dimensions in mm)

effects, including Lilleheden (1994) and Cognard et al. (2008), who propose the use of specially shaped adherends to reduce these stress concentrations. However, the machining cost is quite substantial. Another alternative is to use a spew fillet to reduce stress concentration, which avoids premature failures and enables the determination of the maximum of the stress–strain curve.

As regards the specimen manufacture, ISO 11003-2 recommends machining the specimens from two plates bonded together. However, this technique has disadvantages such as the effect of cutting in the highly stressed region at the end of the adhesive layer where initial failure is likely to occur. Vaughn (1998) proposed that a better solution was to machine the adherends to the correct dimensions before bonding (Fig. 23). The bending stiffness is higher than when the joint is composed of two bonded bars and, therefore, reduces the peel stresses. A specially built jig was designed for aligning and holding the specimens. To control the overlap and fillet, steel shims were inserted into the gaps once the adherends were brought together.

The test speed recommended by the standard ISO 11003-2 is 0.5 mm/min. However, a constant crosshead displacement rate will induce an accelerating strain rate in the adhesive once it starts yielding, influencing the yielding properties. This is a common feature of all the joint tests, contrarily to the bulk tests where the strain rate is much more constant for a given crosshead rate. To have a constant adhesive strain rate, the crosshead speed can be controlled using the adhesive displacement measurements.

### Tests with Thin Sheet Adherends

Tests with thin sheet adherends, and in particular the single-lap joint (SLJ) test, are very common in the industry. This has to do with the fact that it reproduces joints encountered in aeronautical structures that were the pioneers of adhesive bonding technology. The SLJ is described in ASTM D 1002 and ISO 4587. The usual dimensions are indicated in Fig. 24a. These standards recommend cutting specimens

**Fig. 24** Single-lap joint: (a) dimensions in mm (ASTM D 1002), (b) adhesive shear stress distribution along the overlap, and (c) adhesive peel stress distribution along the overlap

from two bonded plates 178 mm (7 in.) wide. However, the joints can be made individually in a mold, reducing the defects introduced by cutting. As seen in Part E, the SLJ is in a complex state of stress. Due to the load misalignment, even if tab ends are used, and due to the differential adhesive straining effect (Volkersen 1938), the adhesive is subjected to a state of nonuniform shear and peel stresses (see Fig. 24b, c). Nevertheless, the ASTM D 1002 standard recommends reporting the results as the average shear stress at failure (maximum load divided by bond area). It is important to choose adherends that do not yield prior to joint failure. Otherwise, what causes the failure of the joint is the yielding of the adherend. In other words, the yielding of the adherend is being measured and not the actual strength of the adhesive.

The SLJ has the advantage of being simple and cheap. It is widely used and gives an idea of the adhesive shear strength. Valuable information is contained in the lap shear strength. The lap shear strength depends, among other things, on the yield strength of the adherends and the overlap length as shown schematically in Fig. 25. For the mild steel adherends, as the overlap increases, there is some increase in strength, but a plateau is reached quickly. In this case, the plastic deformation of the mild steel controls failure. As for the hard steel, the adherends remain elastic, and the strength increases almost linearly as the overlap increases, especially if the adhesive is ductile. An interesting result is that the slope of the tangent to the curves (as indicated in Fig. 25) gives a shear strength ( $\tau = \text{load}/(\text{overlap length} \times \text{joint width})$ ) equal to the maximum shear stress given by a shear stress–shear strain curve. Therefore, the lap shear strength gives an approximate value of the shear strength of

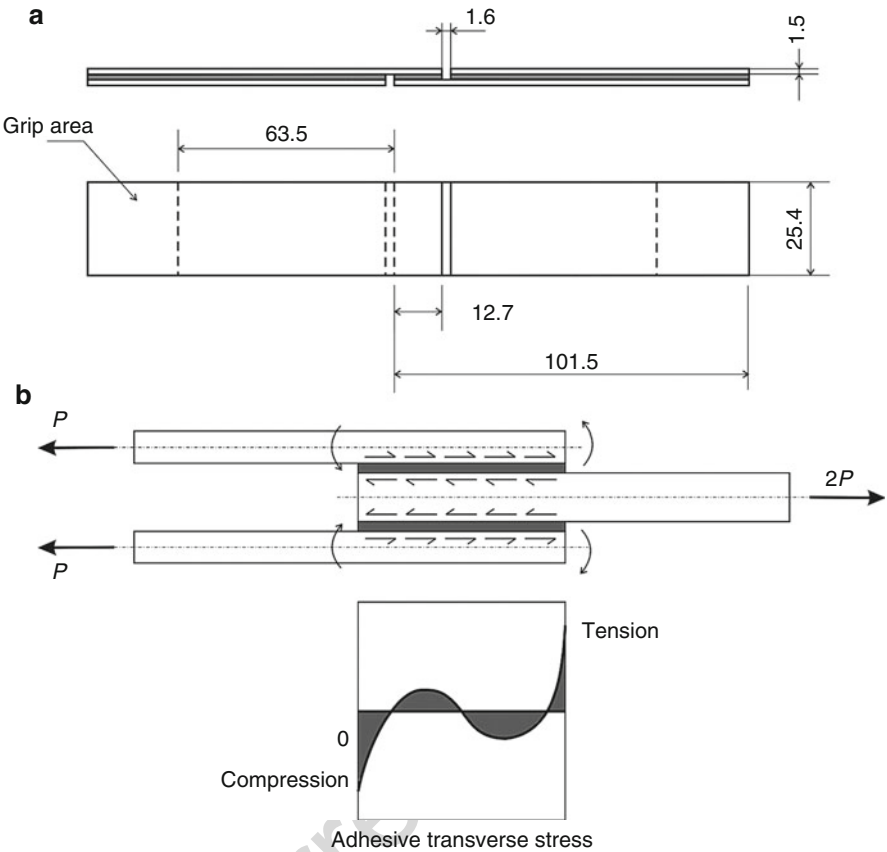

**Fig. 25** Lap shear strength versus overlap strength

the adhesive, provided high-strength adherends are used (with no yield) (Banea and da Silva 2009). Another factor that should be taken into account is the adhesive thickness. It has been shown experimentally by many authors that the joint strength decreases as the adhesive thickness increases. Also, the effective strain rate at constant displacement rate is affected by adhesive thickness. Therefore, it is important to indicate the adhesive thickness used. This is valid for all the joint tests. For relatively thin values (0.1–0.4 mm), the SLJ strength variation is not substantial (Adams and Peppiatt 1974, da Silva et al. 2006). The SLJ test does not give the shear strain at failure. The adhesive must be tested in uniform shear to obtain the shear stress–shear strain curve.

Other tests with thin sheet adherends have been used to have a more uniform adhesive stress distribution along the overlap, such as the laminated joint shown in Fig. 26a according to ASTM D 3165. The bending moment is largely reduced, but the differential straining is still present. The double-lap joint (Fig. 26b) also reduces the peel stresses due to the alignment of the load. Internal bending effects in the joint cause peel stresses at the ends of the internal adherend. Another type of double-lap joint, also called double-strap joint, can be used. Here again, despite the reduction of the peel stresses, the adhesive shear stress is still not uniform due to the differential straining effect.

### Pin-and-Collar Test

Standards ASTM D 4562 and ISO 10123 describe a shear test in which the specimen is a pin bonded inside a collar. The test uses a press to force the pin through the collar, which rests on a support cylinder. The test results are the load required to initiate failure divided by the bonded area between the pin and the collar. This type of

**Fig. 26** (a) Laminated joint (ASTM D 3165) and (b) double-lap joint with stress distribution (ASTM D 3528) (dimensions in mm)

test is particularly suited to test anaerobic adhesives. The shear strength determined with this test is only an average value because the stress distribution is not uniform along the overlap (Nemeş et al. 2006; Martínez et al. 2008). ASTM E 229 also uses a pin-and-collar type of specimen except that here torsional loadings cause failure. The adhesive stress distribution in this case is more uniform and may be used to determine the adhesive shear modulus and strength. However, the standard was withdrawn in 2003.

### 19.4.3 Recommendations

The most recent literature shows that all the test methods described above do not show a systematic variability in the shear stress–strain curves (Althof and Neumann 1974; Jeandreau 1993; Dean et al. 1996; da Silva and Adams 2005). The differences

can be attributed to material variability and different precision associated with each test method and manufacture.

The test that offers the most accuracy is the bulk torsion test in case of bulk specimens and the butt joint in torsion for the joint tests. However, torsion devices are not common in most laboratories. The bulk torsion specimen is also limited to adhesives that are sufficiently rigid to be machined. For example, it is not applicable to a silicone or a polyurethane.

In case a torsion machine is not available, the TAST is probably the simplest and most reliable technique to use. The Arcan joint is also a good alternative and is easily adaptable to mixed loading, which is very important for the proper adhesive yielding failure envelope.

---

## 19.5 Relation Between Tensile, Compressive, and Shear Properties

---

As described above, there is a wide range of test methods available, and it is difficult to make the right choice. However, the properties obtained in compression, tension, and shear can be related. One of the objectives of the adhesive characterization is to generate test data for constitutive modeling. If a von Mises-type criterion is used, then only one type of test is sufficient. Generally, in such a case, the bulk tensile test or the TAST is used. But other tests such as the bulk torsion test can also be used. However, if a more refined yielding model is used such as that of Dolev and Ishai (1981), then the properties of the adhesive in at least two loading modes are necessary. In this case, the tests generally chosen are the bulk tensile test and the TAST. Various authors have shown that the elastic properties obtained by each method correlate reasonably well. For a homogeneous material, the relation between Young's modulus  $E$  and the shear modulus  $G$  is

$$E = \frac{G}{2(1 + \nu)} \quad (8)$$

where  $\nu$  is Poisson's ratio. If  $E$  is taken from the bulk tensile test and  $G$  from a shear test such as the TAST, values of  $\nu$  between 0.3 and 0.5 are obtained for most adhesives (Lilleheden 1994; Dolev and Ishai 1981; Jeandrau 1991; da Silva and Adams 2005). Figure 27 shows on the same graph three stress–strain curves obtained by compression on bulk specimens (ASTM D 695), tension on bulk specimens (EN ISO 527-2), and shear using the TAST (ISO 11003-2). The predicted shear stress–strain using a modified von Mises model (Dolev and Ishai 1981) curve from the compressive and tensile results is also shown. The agreement with the experimental shear curve is very good. However, if the shear stress–strain curve of the same epoxy adhesive were to be predicted using the conventional von Mises model, then the predicted curve would be below the experimental one (also shown in Fig. 27). Adhesive properties in tension, compression, and shear are therefore well correlated provided a model that takes into account the hydrostatic stress component

**Fig. 27** Basic stress–strain data curves under uniaxial loading in tension and compression and under shear for an epoxy adhesive

is used. However, the prediction of the shear strain to failure does not compare well with the experimental value. The shear strain to failure is the most difficult parameter to obtain in terms of both accuracy and precision. It is highly dependent on the type of loading and the quality of the specimen. The adhesive has a different behavior when loaded in shear and in tension in the presence of defects such as voids. In tension, once a crack is triggered next to a void, the specimen fails due to the high stress concentration. In shear, even if a crack is triggered, the remaining area is capable of further deformation, especially if the adhesive is ductile. For example, in bulk tension, a small void will cause a premature failure, whereas in the TAST, the presence of a void is not as critical. There have been recent advances in this area where the same type of specimen is used for all loadings giving very good results up to the failure strain (Cognard et al. 2010).

### 19.6 Conclusions

This chapter describes the major failure strength tests used to determine intrinsic adhesive properties. Tensile, compressive, and shear tests are described with reference to major international standards. Bulk and in situ (adhesive in a joint) tests are discussed and related. The major conclusions that can be drawn are the following:

1. The elastic properties can be determined by any test except tests with thin adherends or the pin-and-collar test.
2. In tension, the recommended test is the bulk tensile test. The axially loaded butt joint has poor repeatability and suffers from constraining effects.

3. Compressive tests are, in general, difficult to perform, and little data exists in the literature. Bulk specimens are commonly used, but the failure stress and strain are difficult to measure.
4. There is a wide variety of shear tests. All the test methods described in this chapter do not show a systematic difference in the shear stress–strain curves. Torsion tests are the most accurate. However, torsion devices are not common in most laboratories. In case a torsion machine is not available, the TAST is probably the simplest and most reliable technique to use.
5. Adhesive properties (except the strain to failure) in tension, compression, and shear can be correlated, provided a model that takes into account the hydrostatic stress component is used.
6. The shear strain to failure is the most difficult parameter to obtain in terms of both accuracy and precision. It is highly dependent on the type of loading and the quality of the specimen.
7. Devices based on Arcan and TAST geometries are being developed that can apply mixed loadings to the same type of specimen. The results obtained show that even the strain to failure can be related.

**Abstract**

This chapter considers first the fracture in a bulk adhesive specimen under mode I, that is, tensile opening loading conditions. Then, the testing of adhesive joints using a linear-elastic fracture mechanics approach is considered. In these tests, the substrates are assumed to only deform in a linear-elastic manner, and any permanent deformation of the substrates is avoided. In adhesive joints, due to the directional constraint of the failure path that is often observed, it is common to encounter failures in other loading modes, in addition to mode I. Thus, mode II (in-plane shear) and mixed-mode I/II testing of adhesive joints are also

considered. There is often the need to measure the resistance to fracture in a joint with flexible substrates. In this case, the assumptions of linear elastic fracture mechanics may no longer be valid, and permanent deformation of the substrates may occur. One such test is the peel test and some variants of the peel test are considered in the present chapter, with a focus on the recent development of a geometry-independent peel test.

---

## 20.1 Introduction

Fracture tests are performed on bulk adhesive specimens and on adhesive joints for a number of reasons. Bulk adhesive specimens are frequently studied as part of the materials development process. For paste adhesives, the bulk specimens are usually formed by casting the paste into a mold and then curing the specimens according to the manufacturers' instructions. For film adhesives, bulk specimens can be prepared by carefully stacking multiple layers of film and applying pressure in a mold during cure. (It should be noted, however, that the use of multiple layers of film adhesive is not common in industry. If thicker layers are needed, a thicker film is usually used.) The cured plates may be machined into standard compact tension (CT) or single-edge notched bend (SENB) test specimens for subsequent fracture mechanics testing to determine the fracture toughness,  $K_{Ic}$ , or fracture energy,  $G_{Ic}$ , using standard techniques developed for polymers (ISO 2000). The manufacture of bulk adhesive specimens is not a trivial exercise; there is the need to minimize the presence of air voids, the need to obtain complete mold fill, and also the need to avoid uncontrolled exothermic degradation of the adhesive during cure. However, the testing of bulk adhesive samples isolates the adhesive from the interface or interphase regions and from the presence of substrates and so focuses entirely on the cohesive fracture properties of the adhesive. Such bulk tests have been used extensively in the literature to study; for example, the effects of combining different resins and hardeners, the effects of adding toughening particles to the adhesive formulation, and bulk specimens have been used to determine fracture resistance under different loading conditions, for example, quasi-static and fatigue and also to investigate the effects of test rate, temperature, and environment.

In practice, however, adhesives are usually applied as thin layers with the purpose of joining different substrates together to resist separation. Thus, in their common application, the adhesive exists as a thin layer, typically in the range of 0.1–2.0 mm thick and forming part of a system incorporating the adhesive, the substrates, and a region in between these, described as the interphase. Whereas the interface has only two dimensions, the interphase has three dimensions, potentially extending through an oxide layer on a metallic substrate or into the adhesive. The adhesive, as present in the cured joint, may possess different properties to the adhesive in a cured bulk specimen. This is because the adhesive may have cured under different conditions in the joint compared to the bulk. An equivalent temperature cycle applied to joints and to bulk specimens will be likely to induce different rates of heating and cooling of the

adhesive. This can lead to subtle changes in the microstructure. The measurement of thermal properties such as the glass transition temperature may detect when this has occurred. In addition to changes in the properties between bulk and joint, the behavior of the adhesive in the joint is influenced by the presence of the nearby substrates. This can limit the size of the plastic zone forming at the crack tip and can thus limit the toughness of the joint. Studies investigating the effect of bondline thickness on the toughness of adhesive joints frequently show a critical thickness at which the toughness of the joint reaches a maximum limiting value (Kinloch 1987). This limiting value is frequently equivalent to the value measured in the bulk adhesive.

Another important aspect of testing the adhesive as part of an adhesive-joint system is that the joint presents a number of “options” for the location of the failure path. Failure may be cohesive in approximately the center of the adhesive layer. It may be cohesive but near the interface as is often seen in peel testing. It may be interfacial along the adhesive–substrate interface or it may run entirely within an interphase, for example, within a metal oxide/adhesive interphase region. The failure path could run cohesively through the substrate, for example, the crack could run in the interlaminar region of a fiber-reinforced polymer composite substrate (Kinloch et al. 1992). Finally, some combination of the above could occur. Each of these options for the failure path may lead to a different fracture resistance being measured and thus adhesive-joint tests and their interpretation are necessarily more complex than bulk adhesive studies.

A final point is that a crack in a bulk material will always tend to run under local mode I tensile opening conditions. Thus, a crack loaded in, for example, the in-plane shear mode (mode II) will deviate to run locally in mode I. However, in the adhesive layer of a joint, the direction of the crack and the resulting failure path are usually constrained and thus cracks may truly propagate under mixed-mode and mode II loading conditions. Indeed, modes I and II and combinations of I and II have received the most attention in the literature and are considered in the present chapter. The out-of-plane shear mode (mode III) is less important and is not discussed in this chapter.

Adhesive-joint tests that have been developed to measure fracture resistance under these various loading modes have typically relied on the concepts of Linear Elastic Fracture Mechanics (LEFM), which imposes the restriction that the deformation of the substrates remains linearly elastic and that any plasticity is limited to a small region ahead of the crack tip. This requirement may not be met in the case of high elongation adhesives such as polyurethanes and also when substrates consisting of relatively thin materials, for example, sheet materials, are used. This is a common problem with peel testing: very frequently there is permanent plastic deformation of the peel arm during the test. As such, the concepts of elastic–plastic fracture mechanics need to be invoked and, for example, the energy dissipated in the plastic bending of the peel arm should be deduced and should be subtracted from the total work done on the joint during peeling. Without such correction, the peel strength of an adhesive joint may be manipulated simply by, for example, changing

the thickness of the substrate material to invoke more plastic energy dissipation in the joint.

## 20.2 Fracture Tests on Bulk Adhesive Specimens

Mode I fracture tests on bulk adhesive samples may be carried out according to the international test standards for the determination of the fracture toughness ( $K_{Ic}$  and  $G_{Ic}$ ) for plastics – an LEFM approach. The ISO method is ISO 13586 (ISO 2000) and the equivalent ASTM method ASTM D5045 (ASTM 1999) are commonly employed. The standards specify that either compact tension (CT) or single-edge notched bend (SENB) specimens be prepared. These Linear Elastic Fracture Mechanics (LEFM) standards require a natural crack to be positioned in the specimen and then the tests specify the conditions for the reinitiation of this crack.

The choice of whether to use the CT or SENB test is influenced by several factors. First, the amount of material available: CT specimens are larger than SENB specimens so if the quantity of adhesive is limited, this would favor the SENB test. Second, the type of crack propagation observed: the tests are quasistatic and unstable crack initiation from the initial defect is intended in the test. If stable growth is obtained, the CT specimen will usually permit a greater length of crack propagation to occur than the SENB test. Figure 1a shows the CT and Fig. 1b shows the SENB test specimens. For either, it is necessary to mold bulk adhesive samples with sufficient dimensions to satisfy the validity criteria (see below) and to be sufficiently void free (see ► Chap. 19, “Failure Strength Tests” for more details on how this can be achieved for common adhesive types).

**Fig. 1** (a) Compact tension (CT) specimen used for bulk adhesive fracture testing. (b) Single-edge notched bend (SENB) specimen used for bulk adhesive fracture testing

Typically, the plates of bulk adhesive are prepared and then they are machined to size using a saw and a mill. A chevron notch is also machined into the specimen, and from this, a natural precrack is grown ahead of the initially machined notch by a razor tapping or sliding approach. The results obtained in the tests are critically dependent upon the quality of the precracks obtained. The initial dimensioning of the specimens is described in the standards. The size criteria for test validity are designed to ensure that LEFM conditions pertain and that the specimen is in a state of plane strain. A further restriction on the test is that the maximum force value obtained should not exceed 110% of the force at the 5% compliance offset point. This ensures the loading conditions are linear in the test. Obtaining sufficient thickness of the specimen,  $B$ , is usually the most difficult dimension to achieve, so the specimen thickness is usually given by the thickness of the prepared plate. For both specimens, the ratio of crack length to specimen width is given by:

$$0.45 < a/W < 0.55 \quad (1)$$

and  $W = 2B$  initially. The dimensions are defined in Fig. 1.

The success of the test depends very largely on the quality of the natural precrack obtained ahead of the machined notch. The precrack can be obtained using fatigue loading but it is usually more convenient to obtain a natural crack by lightly tapping a razor blade into the tip of the machined crack such that crack extension ahead of the razor blade is obtained. This requires some skill and practice is needed before satisfactory precracks are obtained. The cracks grown should be several times longer than the original notch tip radius. For brittle adhesives, razor tapping too firmly may cause the crack to run through the entire specimen, or the precrack may be otherwise too long or not straight. For tough adhesives, it may not be possible to obtain any crack growth ahead of the machined notch by razor tapping. In that case, razor tapping should be abandoned, as residual compressive stresses may be introduced by the tapping which will lead to artificially high values of  $K_{Ic}$  and  $G_{Ic}$  being deduced. In such cases with tough adhesives, it is recommended that a razor blade is drawn across the notch tip to create a precrack. The sliding action of the blade minimizes the introduction of compressive stresses ahead of the precrack.

The standards specify that the specimens should be tested at a temperature of 23 °C and with a loading rate of 10 mm/min. The loading time should be recorded. The loading supports for the SENB test should not be constrained but should be free to roll and should be of sufficient diameter to avoid plastic indentation into the specimen. The displacement of the specimen during the test can be obtained either by measuring the crosshead displacement of the test machine (which then requires a machine compliance correction to be performed as described in ISO 13586 (ISO 2000) and ASTM D5045 (ASTM 1999)), or by directly using a displacement transducer mounted at the load point. For the CT test, the displacement should be obtained using a clip gauge mounted close to the pins. For the determination of  $K_{Ic}$ , only the force and the specimen dimensions are required, but for  $G_{Ic}$ , the displacement is needed, and if only the

crosshead displacement is recorded, then machine compliance and pin indentation corrections are required to obtain accurate results.

A provisional value of the fracture toughness,  $K_Q$ , is determined at the intersection of the 5% compliance offset line with the force–displacement curve,  $P_Q$ . The provisional value is calculated from:

$$K_Q = f \frac{P_Q}{B\sqrt{W}} \quad (2)$$

where  $f$  is the geometry factor (a function of  $a/W$ ) given in the standards. The linearity of the loading (i.e., the cross-check on LEFM conditions) is assessed by determining the value of  $P_{\max}/P_Q$  and the criterion is passed if:

$$\frac{P_{\max}}{P_Q} < 1.1 \quad (3)$$

that is, up to a 10% nonlinearity is permitted. The attainment of plane strain conditions is assessed via the three size criteria. These are given by:

$$B, a, (W - a) > 2.5 \left( \frac{K_Q}{\sigma_y} \right)^2. \quad (4)$$

If the linearity criteria is violated, a possible option is to increase  $W$  for the same value of  $B$ . Values of  $W/B$  up to 4 are permitted. The uniaxial tensile yield stress  $\sigma_y$  is required for the assessment, and for polymers this is conventionally taken at the maximum load in the tension test, as described in ► [Chap. 19, “Failure Strength Tests”](#). If the linearity and size criteria are met, then  $K_Q$  is recorded as  $K_{Ic}$ , that is, the plane strain value. The corresponding fracture energy,  $G_{Ic}$ , can be obtained using:

$$G_{Ic} = \frac{K_{Ic}^2 (1 - \nu^2)}{E} \quad (5)$$

provided that Young’s modulus,  $E$ , and Poisson’s ratio,  $\nu$ , are obtained at the equivalent rate and temperature. However, there are many uncertainties when using this technique to obtain  $G_{Ic}$  (Williams 2001) and it is considered far preferable to measure the energy,  $U$ , directly from integrating the corrected load versus load-point displacement diagram (ISO 13586) and thus:

$$G_{Ic} = \frac{U}{BW\phi}, \quad (6)$$

where  $\phi$  is a calibration factor, a function of compliance,  $a$  and  $W$ . Round-robin testing by the ESIS TC4 group on various polymers found that the methods have a reproducibility of 5% in  $K_{Ic}$  values and 12% in  $G_{Ic}$  values (Williams 2001).

201 **20.3 Fracture Tests on Adhesive-Joint Specimens**

202 **20.3.1 The Mode I Double Cantilever Beam (DCB) Test**

203 The mode I fracture resistance of adhesive joints is most commonly determined  
204 using the double cantilever beam (DCB) test. This test was initially described in the  
205 ASTM standard (ASTM 1990) and has been developed more recently in the British  
206 standard (BSI 2001) and the international standard (ISO 2009). The original ASTM  
207 test standard specified metallic substrates and the critical strain energy release rate in  
208 mode I,  $G_{Ic}$ , was determined for repeated crack initiations using a version of simple,  
209 shear-corrected beam theory. The later standards additionally accommodate nonme-  
210 tallic substrates and employ corrected beam theory to determine values of  $G_{Ic}$  at both  
211 crack initiation and during steady-state crack propagation.

212 The DCB adhesive-joint test specimen, as shown in Fig. 2, comprises two sub-  
213 strates (the double cantilevers) bonded together with a thin layer of adhesive to form  
214 the joint. During joint fabrication, an initial crack is formed at one end of the joint. In  
215 the ASTM method, this can be achieved by positioning a shim at one end of the joint  
216 and having an area over which no adhesive is applied. In the BS and ISO standards,  
217 the initial crack is formed by placing a releasing film centrally in the adhesive layer  
218 during joint fabrication. This film, typically a fluoropolymer and 12–14  $\mu\text{m}$  in  
219 thickness, is then molded into the joint during adhesive cure. The ASTM test  
220 specimen comprises of substrates 300 mm long, 25 mm wide, and 12.7 mm high  
221 ( $24 \times 1 \times 0.5$  in). These are cut out from a larger bonded panel. The BS and ISO  
222 standards are more flexible on the substrate dimensions allowed, but have a require-  
223 ment that plastic deformation of the substrates must always be avoided. Typically,  
224 those following the BS and ISO test standards manufacture smaller test specimens  
225 than specified in the ASTM standard. They may either be fabricated individually, or  
226 by cutting from a larger bonded panel.

227 The surface pretreatment applied to the substrates prior to bonding is an important  
228 aspect of joint preparation. Usually the intention is to avoid interfacial crack growth  
229 between the adhesive and the substrate and as such, a surface pretreatment is carried  
230 out on the substrates prior to bonding. This may involve simply cleaning the surfaces  
231 to remove contaminants such a mill oils, greases, or release agents, but may  
232 additionally involve abrasion and/or a more detailed surface pretreatment incorpo-  
233 rating acid etching or anodizing in the case of metallic substrates and plasma or  
234 corona treatments in the case of polymeric substrates. Readers are referred to specific  
235 procedures for surface pretreatments prior to adhesive bonding (see ► Chap. 8,  
236 “Surface Treatments of Selected Materials” and BSI 2009) and a number of excellent

**Fig. 2** Mode I double cantilever beam (DCB) adhesive-joint specimen

review publications on this subject, for example, Molitor et al. (2001), Baldan (2004), and Bishopp (2005).

Once the substrates have been prepared, the adhesive layer is applied to the joint. If film adhesive is being used, the films are cut to size and applied to the substrates. The substrate can often be used as a cutting template in this procedure. The thickness of the adhesive layer applied to the joint is another important parameter. The thickness may be obtained using a single layer of film (applied to one substrate only), or may be obtained by using two or more film layers stacked inside the joint. For example, two layers of film are achieved by placing a single film layer on each substrate, four layers of film are achieved by placing two layers per substrate, etc. It should be noted that in most industrial applications using film adhesives, only a single layer of film is applied to the joint, and that stacking of multiple film layers may result in effects not seen when only single layers are used. If paste adhesives are being used, it is necessary to apply an adhesive bead to each substrate (or panel) and typically this is spread over the surface area of the substrates prior to closing the joint. Shims may be placed at either end of the joint to control bondline thickness, or ballotini (glass spheres) may be added or mixed into the adhesive paste formulation.

Once the joint is formed, the adhesive is cured according to the manufacturer's instructions. Adhesive data sheets usually specify a recommended cure schedule (temperature and time) and often a recommended pressure to be applied to the joint. Sometimes a range of cure schedules are quoted. It is important to ensure that the adhesive layer (as opposed to just the oven or even the jigging) reaches the cure temperature for sufficient time for full cure to be achieved. Massive jigs and large metallic substrates can very much increase the thermal inertia of the joint and the time taken for full cure to be achieved. A thermocouple wire placed in one end of the bondline can be used to confirm the thermal history of the adhesive layer during manufacture. When the cure is complete, the joints are removed from the jig and the adhesive fillets are removed to make a joint with smooth sides.

The DCB test requires that the initial crack in the joint introduced by the presence of the disbond or releasing film be extended by applying a load to the substrates. The load can be introduced via circular holes drilled through the end of the substrates, or via circular holes through the center of metallic load blocks bonded to the ends of each arm. In the ASTM method, load is applied until crack growth occurs, at which point the loading is stopped until the crack length stabilizes. The load is then increased until the crack grows again and this process is repeated a number of times. Repeated values of the load to initiate crack growth and for crack arrest are thus recorded, together with the corresponding crack lengths. In the BS and ISO methods, the loading is applied at a constant applied displacement rate until the crack initiates, at which point the loading is stopped and the specimen is fully unloaded. This is the precracking stage. The specimen is then reloaded at constant applied displacement rate. In this cycle, the crack initiates from the mode I precrack formed previously. This is the testing stage. After a specified length of crack propagation, the joint is fully unloaded. Both the loading and unloading force-displacement traces are recorded via analog or digital means. The resistance to both crack initiation from the precrack and for steady-state crack propagation is determined.

Upon unloading the joint, the force–displacement trace not returning to the origin may indicate that plastic deformation of the substrates has occurred; see ISO (2009) for full procedures. Such an occurrence would invalidate the values of  $G_{Ic}$  determined. The presence of stick-slip crack propagation in the continuously loaded BS or ISO methods requires some special considerations to be taken into account. Again, full details are provided in ISO (2009). Under these conditions, steady-state propagation values of  $G_{Ic}$  are not determined, instead values at crack initiation and crack arrest are obtained.

The fracture tests developed for modes I, II, and mixed-mode I/II loading require the measurement of the load, load-point deflection, and usually crack length together with some beam dimensions (e.g., thickness and width) and sometimes Young's modulus of the substrate. The use of the  $G$  rather than the  $K$  parameter has become common place for adhesive joints. The analysis methods referred to here assume that the adhesive layer makes negligible contribution to the overall compliance of the joint. The analysis schemes proceed by either using experimental compliance methods or by using simple or corrected beam theory. The fracture resistance in any mode may be determined using the Irwin–Kies equation:

$$G_c = \frac{P^2}{2B} \cdot \frac{dC}{da}, \quad (7)$$

and then the analysis proceeds by experimentally determining  $dC/da$  (experimental compliance methods) or by modeling the  $C(a)$  function using beam theory. The beam theory approach requires corrections to be implemented to take account of the ways in which the test specimens differ from the “simple beams” assumed in the analysis. Thus, “corrected beam theory” analyses are commonly employed.

The analysis methods developed assume that the adhesive layer is thin and that the adhesive has a low value of Young's modulus compared to the substrate material. Thus, the contribution of the adhesive layer to the overall beam compliance is assumed to be negligible. In the ASTM method for mode I (ASTM 1990),  $G_{Ic}$  is determined using simple, shear-corrected beam theory:

$$G_{Ic} = \frac{4P^2m}{E_sB^2}, \quad (8)$$

where  $P$  is the load,  $E_s$  is the axial modulus of the substrate,  $B$  is the substrate width, and  $m$  the geometry factor given by:

$$m = \frac{3a^2}{h^3} + \frac{1}{h}, \quad (9)$$

where  $a$  is the crack length and  $h$  is the height of one substrate. The first term in the above expression represents the contribution to the displacement from bending, and the second term the contribution from shear. The rationale for presenting the analysis in this form was that an alternative test specimen was identified with a constant value

of the geometry factor, making the values of  $G_{Ic}$  independent of crack length (see Sect. 3.2). However, a limitation of this approach is that the bending analysis assumes the DCB arms to behave as perfectly built-in cantilevers. Such an assumption can lead to significant errors, although the  $G_{Ic}$  values deduced in this way are usually conservative. The corrected beam theory analysis for the DCB test was initially outlined by Williams (1988) and was applied to fiber-reinforced polymer composites (Hashemi et al. 1990) and was shown to be valid for adhesively bonded joints (Blackman et al. 1991). During the development of a standardized DCB test for adhesively bonded joints via the British Standards Institution and ISO, a series of interlaboratory round-robin tests were performed on adhesively bonded joints using various substrate materials. The results of this program demonstrated the utility and reproducibility of the test method (Blackman et al. 2003b).

In the BS and ISO methods, additionally an experimental compliance and a corrected beam theory analysis are specified for the determination of  $G_{Ic}$ . The experimental compliance method is based on Berry's method (Berry 1960) and is given by:

$$G_{Ic} = \frac{nP\delta}{2Ba}, \quad (10)$$

where  $P$  is the load,  $\delta$  the displacement,  $B$  the specimen width, and  $a$  the crack length. The parameter,  $n$ , is determined from a linear regression to the log compliance versus log crack length data, recorded during the test. The corrected beam theory method is given by:

$$G_{Ic} = \frac{3P\delta}{2B(a + \Delta)} \frac{F}{N}, \quad (11)$$

where  $\Delta$  is the crack length correction term, accounting for the beam root rotation and deflection effects (incorporating those due to shear);  $F$  is a large-displacement correction factor (accounting for the shortening of the moment arm as the substrates deform elastically in bending); and  $N$  is a correction factor applied if end blocks are used (to account for the potential stiffening effect of the blocks and their rotation). The round-robin interlaboratory test program (Blackman et al. 2003b) indicated that the experimental compliance and corrected beam theory analyses yield  $G_{Ic}$  values in close agreement.

The definition of crack initiation has been a contentious issue in the formation of the DCB test standards. In line with the mode I test published for fiber-reinforced polymer composites (ISO 2001), three different definitions of crack initiation have been established and are now embodied in the BS and ISO standards. The first relates to the instant when the load–displacement trace deviates from linearity. This definition is termed the nonlinear (NL) initiation point. The second relates to the point when the crack is seen to grow ahead of the initial precrack. This definition is termed the visual (VIS) initiation point. Third, in line with earlier fracture mechanics test standards, initiation has also been defined as corresponding to when the initial

compliance of the test specimen has increased by 5%. This is termed the 5% offset value. To limit the potential magnitude of this value, it is a requirement that it precedes the point of maximum load. This initiation point is therefore called the Max/5% initiation point; the value taken is the one occurring first (the max point or the 5% offset point).

Various studies, for example, Blackman et al. (2003b), have shown that the nonlinear definition of crack initiation usually results in the lowest initiation values of  $G_{Ic}$  and is subject to the largest degree of scatter. Indeed, there is evidence to suggest that this point corresponds to the initial growth of the crack across a limited section of the joint width and as such NL values of initiation may not be true  $G_{Ic}$  values. The visual initiation point is more popular but remains operator sensitive, depending upon such factors as the magnification of the traveling microscope or video camera used to measure the crack length and eye sight! The Max/5% initiation point is usually the least conservative and the most reproducible.

In the continuously loaded DCB test (ISO 2009), the steady-state propagation value of  $G_{Ic}$  is the value most commonly reported in the research literature. When, following crack initiation, the values of  $G_{Ic}$  do not tend to change significantly with increasing crack length, a flat resistance curve (R-curve) results. In this case, the mean propagation value of  $G_{Ic}$  can be deduced from an average of the propagation points and is termed  $G_{Ic}$ -mean propagation. However, when following crack initiation, the values of  $G_{Ic}$  increase with increasing crack length, this is referred to as rising R-curve behavior and the determination of a characteristic “propagation” value becomes more difficult to define. If a constant, steady-state propagation value is eventually reached, then this may be defined as a plateau value of  $G_{Ic}$  and may be termed  $G_{Ic}$  plateau. If the R-curve continues to rise and fails to reach a steady state, it may be beneficial to manufacture a longer test specimen such that a steady state might be reached. If continuously rising R-curve behavior cannot be avoided, and thus a steady state is not achieved, the significance of the  $G_{Ic}$  values measured become questionable and great care is required in the interpretation of such data. Figure 3 shows the R-curve behavior for a typical brittle epoxy adhesive.  $G_{Ic}$  has been determined using simple, shear-corrected beam theory (SBT), which shows an apparent rising R-curve, but when calculated using either corrected beam theory (CBT) or the experimental compliance method (ECM), the variation in  $G_{Ic}$  with crack length largely disappears resulting in a flat R-curve being measured. In this case, the mean propagation value of  $G_{Ic}$  was approximately 380 J/m<sup>2</sup>. This type of flat R-curve behavior is typical for many structural epoxy adhesives tested in mode I.

Another commonly encountered feature of mode I DCB testing is the occurrence of nonsteady, discontinuous crack growth behavior. This is usually referred to as stick-slip crack propagation as the crack grows in a series of rapid bursts, interspaced by periods of crack arrest. The reasons for such crack growth behavior are complex but are thought to originate from an imbalance between the resistance of a crack to initiation versus its resistance to continued propagation. This imbalance results in there being an excess in available strain energy in the specimen arms once the crack has initiated, resulting in an unstable burst of growth. (This concept is analogous to that of static vs. kinetic coefficients of friction.) A consequence of stick-slip behavior

**Fig. 3** Typical resistance curve (*R*-curve) for a DCB specimen bonded with a brittle epoxy adhesive ( $G_{Ic}$  values have been deduced using simple beam theory (*SBT*), corrected beam theory (*CBT*), and the experimental compliance method (*ECM*))

**Fig. 4** Mode I tapered double cantilever beam (*TDCB*) test specimen

is that it is not possible to record crack growth increments every 5 mm as required in the standard. However, a series of initiation and arrest points can be identified in the force–displacement traces and the crack lengths associated with the “stick” and “slip” points can frequently be identified on the fracture surfaces. The mode I DCB standards require that only the stick points (i.e., the initiation points) be used for the analysis to determine  $G_{Ic}$  values and that all the slip points (i.e., the arrest points) be disregarded. The rationale for disregarding the arrest points is that these points are influenced by such factors as the kinetic energy in the moving substrate arms and as such the arrest points are substrate dependent. When stick-slip crack growth occurs, the use of simple beam theory is recommended.

### 20.3.2 The Mode I Tapered Double Cantilever Beam (TDCB) Test

The tapered double cantilever beam (TDCB) adhesive-joint specimen was initially developed as a means to perform long-term, environmental crack growth studies, without the need to measure crack length (Ripling et al. 1964). The height of the beam is tapered to provide a constant rate of change in compliance with crack length, that is, the value of  $dC/da$  is a constant. The TDCB joint is shown in Fig. 4. An advantage of the TDCB test specimen is that the increasing height provides a greater resistance to plastic deformation in the specimen arms as the increased height

reduces the applied bending stresses in the arms. As such, it may be easier to maintain LEFM conditions in joints using the TDCB rather than the DCB specimen. However, the TDCB specimens are more expensive to manufacture; the nonlinear height profile is best achieved using a computed numerically controlled (CNC) milling machine. The mode I standards describe corrected versions of the analysis to deduce  $G_{Ic}$  values from the TDCB test, which take into account (1) the effects of the discontinuous profile used in the joints and (2) the beam root rotation effects in the joint. The original TDCB analysis assumed that the taper continued all the way back to the loading point, where a zero beam height would be implied. The analysis proceeds as follows. Values of  $G_{Ic}$  are determined using simple beam theory via:

$$G_{Ic} = \frac{4P^2m}{E_sB^2}, \quad (12)$$

where  $P$  is the load,  $E_s$  the substrate modulus,  $B$  the substrate width, and  $m$  the geometry factor defined previously. A more accurate, corrected beam theory analysis has been developed, which may be applied to the data (Blackman et al. 2003a). Using corrected beam theory, values of  $G_{Ic}$  are determined via:

$$G_{Ic} = \frac{4P^2}{E_sB^2} \cdot m \cdot \left[ 1 + 0.43 \left( \frac{3}{ma} \right)^{\frac{1}{3}} \right], \quad (13)$$

where the second term in square brackets represents the correction for the beam root rotation effects. It should be noted that this more accurate expression requires the crack length,  $a$ , to be determined during the test. Finally, the values of  $G_{Ic}$  can be deduced directly from Eq. (7) as the value of  $dC/da$  is a constant for this test geometry and the value can be deduced from a linear regression of the measured compliance versus crack length data. When using beam theory to determine  $G_{Ic}$  for an adhesive joint, it is important to check that the geometry factor  $m$  is indeed a constant along the length of the substrate over which it is tapered. It is also important to ensure after the test that the substrates have not deformed plastically, as such deformation would violate the assumptions of linear-elastic fracture mechanics. Any plastic deformation may be observed in the substrates after the test via careful visual inspection, or may be evident from the load–displacement traces not returning to the origin upon unloading the joint.

### 20.3.3 Mode II Adhesive-Joint Tests

The mode II fracture testing of adhesive joints is significantly more complex than mode I testing and is yet to be standardized. The later development of mode II fracture tests reflects a greater skepticism held within the scientific community regarding the significance and uniqueness of mode II fracture. Such skepticism was well voiced by O'Brien in his "Shear measurement or Sheer Myth?" paper on

**Fig. 5** (a) Mode II, end-notched flexure (ENF) test specimen. (b) Mode II, end-loaded split (ELS) test specimen. (c) Mode II, four-point loaded end notched flexure (4-ENF) test specimen

mode II (O'Brien 1998). Despite the arguments that still exist surrounding the origins, true meaning, and uniqueness of mode II fracture, there is clearly a need to characterize how joints fail when mode II loading is applied to a joint, and there is a corresponding need to determine the fracture resistance in mode II.

In pursuit of this measurement, a number of different tests have been proposed and used by various researchers to obtain mode II fracture in adhesive joints. However, to date, no single method has proved entirely satisfactory. The most popular tests used have been the end-notch flexure (ENF) test (Fig. 5a), and the end-loaded split (ELS) test (Fig. 5b). Both of these are currently under consideration for standardization of mode II delamination toughness testing in fiber-reinforced polymer composites, and they have also been applied to study the fracture of structural adhesive joints. In both cases, a nonadhesive insert film is placed in the center of the adhesive layer during the manufacture of the joint and this then acts as the crack starter in the subsequent mode II test. The ENF test was used by Chai in his detailed study of mode II fracture in adhesive joints (Chai 1986, 1988). The ELS test requires the test specimen to be clamped on a linear bearing trolley which is free to slide in a horizontal direction. The specimen can be designed such that stable crack growth is achieved following initiation. The sliding trolley removes the horizontal forces which would otherwise develop during the test. In the ELS test, the specimen is loaded vertically via a load-block, and the load, beam displacement, and crack length are measured during the test. In the ENF test, the specimen is loaded in simple

**Fig. 6** Mode II, tapered end-notched flexure (TENF) test specimen

three-point bending and the position of the initial crack is usually such that  $a/L = 0.5$ , the specimen is centrally loaded, and the support span is  $2L$ . A disadvantage of the ENF test is that the fracture tends to be unstable, with the crack growing instantly to the central loading point after initiation, that is, to  $a = L$ . Thus, only an initiation value of  $G_{IIc}$  is determined, whereas a complete R-curve may be obtained from the ELS test.

A version of the ENF test using four-point loading was described by Martin and Davidson (1999) for composite delamination (Fig. 5c) and this has also been applied to adhesive joints. This test is commonly referred to as the 4-ENF test, and it has the advantage that stable fracture is achieved, circumventing the limitation in the conventional 3-ENF test. However, a limitation is that the test requires larger forces to be applied, and as a consequence, the frictional forces acting on the faces of the initial and subsequently grown fracture surfaces are greater than in the 3-ENF. As work is done against friction as the substrates shear relative to one another, then this leads to an increase in the “apparent” value of  $G_{IIc}$  that is determined.

Measuring crack length in a mode II test has posed significant difficulties. No beam opening occurs and shear fractures usually propagate in a complex manner, often via a microcracking mechanism. The experimental uncertainty associated with the measurement of the crack length in mode II can be significant. Some researchers have tackled this problem by using height contoured beams for substrates. The development of tapered ENF (TENF) specimens (Fig. 6) has been reported by some researchers, for example, Edde and Verreman (1995) and Qiao et al. (2003a, b), but their use has not become widespread.

A modified version of the ELS test has been under development in Europe, led by the European Structural Integrity Society’s Technical Committee 4 (ESIS/TC4) on Polymers, Composites, and Adhesives. An interlaboratory round-robin test program investigated the use of the ELS test using an effective crack length approach. In the effective crack length approach, there is no need to measure mode II crack lengths: rather the crack length is determined by changes in compliance in the specimen. The use of such procedures (Blackman et al. 2005) requires that the clamp used in the test be calibrated, such that the measured compliance can be accurately converted to crack length. There has been significant recent interest in effective crack length approaches with the concepts being extended to model damage zones in mode I, to analyze mixed-mode loading (see below), and also in fatigue crack growth studies (Brunner et al. 2009).

Summarizing the analysis methods for mode II, for the ELS test,  $G_{IIc}$  can first be determined from experimental compliance. If the relationship between compliance and crack length is assumed to be of the form:

$$C = C_o + ma^3, \quad (14)$$

where  $C$  is the compliance,  $a$  the crack length, and  $C_o$  and  $m$  are constants, then on substitution into Eq. 7:

$$G_{IIc} = \frac{3P^2 a^2 m}{2B}. \quad (15)$$

Second, simple beam theory can be applied, which leads to:

$$G_{IIc} = \frac{9P^2 a^2}{4B^2 h^3 E_s}, \quad (16)$$

where  $E_s$  is the substrate modulus. Third, corrections to this equation lead to:

$$G_{IIc} = \frac{9P^2 (a + \Delta_{II})^2}{4B^2 h^3 E_s} \cdot F, \quad (17)$$

where  $\Delta_{II}$  corrects for crack tip rotation, deflection, and shear effects, and  $F$  corrects for large beam displacements (Davies et al. 2001). It is noteworthy that all three analysis schemes require a measured crack length and indeed the experimental compliance method is most sensitive to measured crack length errors due to the dependence of  $m$  upon crack length.

Considering the 3-ENF test, first  $G_{IIc}$  may be deduced using the experimental compliance method. If a relationship between the compliance and crack length is assumed of the form:

$$C = C_o + C_1 a^3, \quad (18)$$

then

$$G_{IIc} = \frac{3P^2 a^2 C_1}{2b}. \quad (19)$$

Second, via simple beam theory:

$$G_{IIc} = \frac{9P^2 a^2}{16B^2 E_s h^3}. \quad (20)$$

And third, via corrected beam theory (Hashemi et al. 1990)

$$G_{IIc} = \frac{9P^2(a + \Delta_{II})^2}{16B^2h^3E_s} \cdot F. \quad (21)$$

The data reduction reported for the 4-ENF test uses an experimental compliance approach (Martin and Davidson 1999). For this test, the compliance is assumed to be a linear function of crack length, that is:

$$C = C_o + ma, \quad (22)$$

and thus  $dC/da$  is given directly by  $m$ , hence:

$$G_{IIc} = \frac{P^2}{2B} \cdot m. \quad (23)$$

The data reduction for the tapered ENF (TENF) specimen can take the form of an experimental compliance or a simple beam theory approach, as reported by Edde and Verreman (1995) or a corrected beam theory approach following the work of Qiao et al. (2003b), using a beam on an elastic foundation model. These authors showed that substrates with a linear taper gave an almost linear relationship between compliance and crack length, within a certain range of crack lengths.

The ELS method may be employed together with an effective crack length approach to circumvent the need to measure crack length in the test (Blackman et al. 2005). This requires a calibration of the clamping fixture by use of the so-called inverse ELS test. In this procedure, the test specimen is fixed in the clamp with the cracked portion of the specimen held fully within the clamp. The free length is varied through a range and the values of  $C^{1/3}$  are plotted against the free length,  $L$ . Such plots are usually linear, with a negative intercept on the  $L$  axis which is termed  $\Delta_{\text{clamp}}$ , as shown in Fig. 7. In the ensuing mode II fracture test, the effective crack length is determined for each experimentally determined value of compliance using beam theory and an independently measured value of substrate modulus. Using this scheme, the effective crack length is given by:

$$a_e = \left[ \frac{1}{3} \left\{ 2Bh^3E_sC - (L + \Delta_{\text{clamp}})^3 \right\} \right]^{\frac{1}{3}}, \quad (24)$$

and the mode II fracture resistance is then given by:

$$G_{IIc} = \frac{9P^2a_e^2}{4B^2h^3E_s}. \quad (25)$$

545

As discussed above, this scheme has the advantage of being independent of measured crack length. When the above analysis scheme is used, many adhesives

**Fig. 7** Graph of  $C^{1/3}$  versus clamp length in the inverse ELS clamp calibration procedure (The negative  $L$  intercept gives the value of the clamp correction,  $\Delta_{\text{clamp}}$ )

exhibit strong rising R-curve behavior in mode II. This is thought to be due to the development of the damage zone and microcracking of the adhesive layer. Usually,  $G_{\text{IIc}}$  values lie in the range of  $\times 1-2G_{\text{Ic}}$  for crack initiation, and then rise to as much as  $\times 7G_{\text{Ic}}$  during crack propagation (Blackman 2008). Table 1 shows some typical values of  $G_{\text{Ic}}$  and  $G_{\text{IIc}}$  reported in the literature for various adhesive joints.

**20.3.4 Mixed-Mode I/II Adhesive-Joint Tests**

In addition to pure modes I and II testing, there is considerable interest in determining the fracture resistance of joints subject to mixed-mode (I/II) loading as adhesive joints in engineering structures will frequently experience such mixed-mode conditions in service. There has also been a significant effort in the literature directed toward developing mixed-mode failure criteria for adhesively bonded joints, such that fracture resistance envelopes might be predicted if the resistance to the pure modes is known.

The experimental tests developed to measure mixed-mode fracture resistance use similar test specimens to the pure mode I and II tests, often developed originally from composite delamination tests. Some are shown schematically in Fig. 8. Test methods include the fixed-ratio mixed-mode (FRMM) test, also known as the asymmetric double cantilever beam (ADCB) test; the mixed-mode flexure (MMF) test (also known as the single leg bend test); and the mixed-mode bending (MMB)

567 test. As the name implies, the FRMM test provides a single mixed-mode ratio of  $G_I/$   
568  $G_{II} = 4/3$  for a joint with equal thickness substrates. The same ratio is achieved with  
569 the MMF test. However, the MMB test provides the option to change the mixed-  
570 mode ratio almost without limit between the pure mode I and pure mode II loading  
571 conditions, as the upper two loads are applied via a lever arrangement. This test is  
572 now standardized by ASTM for mixed-mode delamination testing (ASTM 2004b).  
573 In addition to the tests listed above, various other fixtures have been employed to  
574 obtain mixed-mode loading conditions including use of the ARCAN loading fixture,  
575 and other variable mode-mix loading frames, for example, as reported in Fernlund  
576 and Spelt (1994).

577 As with mode II, a common feature of mixed-mode testing is that the failure path  
578 is usually not in the center of the adhesive layer, but deviates to run close to the  
579 interface with the upper substrate. It has been shown that this makes only a very  
580 small difference to the applied mixed-mode ratio, but the locus of failure being close  
581 to an interface may have other effects on the test (Dillard et al. 2009). It is interesting  
582 to note that such studies highlight that profound effects can be observed if the mode  
583 mix alters the path taken by the crack. A fracture path between the adhesive and the  
584 carrier in a film adhesive, or within a polymeric fiber-composite substrate, can have a  
585 significant and deleterious effect on the fracture resistance of a joint.

586 Assuming that the failure path remains essentially the same (e.g., cohesive in the  
587 adhesive layer), it is usually observed that the fracture resistance increases as the

**Fig. 8** (a) The fixed-ratio mixed-mode (*FRMM*) test specimen. (b) The mixed-mode flexure (*MMF*) test specimen. (c) The mixed-mode bend (*MMB*) test specimen

percentage of mode II increases. This is consistent with the notion that  $G_{Ic}$  represents the lower bound value of fracture resistance and that additional mechanisms come into play as the mode II loading contribution is increased. Such mechanisms include the increased friction contribution, the increased elongation and distortion of the damage zone ahead of the crack tip, the increase in microcracking, and the ensuing shear failure of the ligands between such features should these be present. Many different failure criteria have been proposed to model mixed-mode fracture envelopes for adhesive joints and many of these criteria were initially developed for the delamination of composites. Reeder (1993) and Dillard (2010) have reviewed a number of these criteria. The criteria tend to be phenomenological in nature and reasonable modeling of the envelopes can often be achieved provided the failure path remains unchanged. Simple criteria developed include the linear, the bilinear, and the linear interaction criteria. More complex interaction criteria have also been developed. This is still an evolving research area.

### 20.3.5 Effects of Adhesive Layer Thickness

In all the fracture tests described above, the values of  $G_c$  determined can depend upon the thickness of the adhesive layer. The dependence of adhesive layer (or bondline) thickness,  $h_a$ , was discussed by Kinloch (1987) where the dependence of  $G_{Ic}$  values on  $h_a$  in TDCB joints bonded with epoxy adhesives was described. Such tests revealed that for a brittle adhesive, the values of  $G_{Ic}$  were insensitive to bondline thickness, but a strong dependence was observed for tougher adhesives, with values increasing to a maximum before reaching a plateau. The trends may be rationalized by a consideration of the plastic zone size,  $r_p$ , at the crack tip. Under plane stress conditions (as exist at the edges of the joint), the value of  $r_p$  is given by:

$$r_p = \frac{1}{2\pi} \cdot \frac{EG_c}{\sigma_y^2}, \quad (26)$$

where  $E$  is Young's modulus of the adhesive and  $\sigma_y$  its yield strength. Under plane strain conditions (as exist at the center of the joint), the value of  $r_p$  is given by:

$$r_p = \frac{1}{6\pi} \cdot \frac{EG_c}{\sigma_y^2}. \quad (27)$$

When the value of  $h_a$  is too small to allow for the full development of the plastic zone, then  $G_c$  is dependent upon  $h_a$ . Clearly, brittle adhesives (low  $G_c$ , high  $\sigma_y$  values) will have smaller values of  $r_p$  and will be less likely to show the dependence of  $G_c$  upon  $h_a$ . The ISO standard for mode I testing (ISO 2009) gives some recommendations for selection of values of  $h_a$ . First, the analysis has only been verified experimentally for values of  $h_a$  between 0.1 and 1.0 mm, so ideally bondlines should be selected within this range. Second, as the usual goal is for  $G_{Ic}$  to be independent of specimen geometry, then values of  $h_a > 2r_p$  should ideally be selected.

The dependence of  $G_{Ic}$  (and also  $G_{IIIc}$ ) upon bondline thickness was observed by Chai (1986, 1988) who noted that values of  $G_{Ic}$  and  $G_{IIIc}$  were also dependent upon bondline thickness for brittle adhesives. Adhesive layer thickness should therefore be considered carefully when designing adhesive-jointed structures and test coupons.

## 20.4 Peel Testing

### 20.4.1 Introduction to Peel Testing

The adhesive-joint fracture tests discussed above have been concerned with joints formed between substrates that deform in a linear-elastic manner during the loading of the joint such that the concepts of linear-elastic fracture mechanics apply. Such tests are used routinely to measure fracture energy,  $G_c$ . However, there is also a

requirement to be able to measure the performance of adhesive joints formed between substrates that may deform extensively during an adhesion test. Examples include the adhesion of flexible layers such as food packaging laminates, electronic components, and the structural bonding of relatively thin sheet metal in the automotive industry. In his forward to the special issue on peel in the *International Journal of Adhesion and Adhesives* (Moore 2008), Moore distinguished between two general types of peel test, namely, those that are dependent upon geometry and those that are geometry independent. Geometry-dependent peel tests are numerous and these typically measure the peel force per unit width of joint, commonly called the peel strength. Geometry-independent peel tests, on the other hand, measure a geometry-independent parameter such as fracture energy,  $G_c$  with units  $\text{J/m}^2$ . Using fracture mechanics and the concept of energy balance, significant progress has been made in recent years toward the goal of developing and refining geometry-independent peel tests (Kinloch et al. 1994; Kinloch and Williams 2002). At least in principle, a peel test can now be used to determine the adhesive fracture energy of a joint even when extensive plastic deformation of the peel arm(s) has occurred during the test.

#### 20.4.2 Geometry-Dependent Peel Tests

As discussed by Moore (Moore 2008), several peel test configurations have been developed over the years and many developments and modifications to these have been variously proposed in the literature. It is not the aim of the present chapter to review these techniques, but rather the aim here is to identify some of the main types of peel test that fall into this category and discuss their advantages and their limitations.

In the so-called fixed-arm peel tests, one substrate is fixed to a rigid base (the rigid substrate) and the other (the flexible substrate) is peeled by a test machine at a defined applied peel angle, which can be varied between tests. Figure 9a shows a schematic fixed-arm peel test. Standardized peel tests describe both  $90^\circ$  and  $180^\circ$

**Fig. 9** (a) The fixed-arm peel test arrangement and (b) the T-peel test arrangement

fixed-arm peel tests (BSI 1993a, b), but the peel angle can be varied typically from 45° to 180°. Peel tests are typically performed at a constant rate of peeling and the standards specify such details as the width, thickness, and width–thickness ratio of the substrates. The apparatus used to control the peel angle is also described in the various standards, for example, by attaching the peel arm to a cylinder mounted on bearings that is then rotated to create the peel. A floating roller and a climbing drum apparatus are specified in two tests that have been standardized by ASTM (2004a, 2006). The average peel force per unit width (the peel strength) is reported. For the peeling of two flexible substrates, the T-peel test is often adopted. In the T-peel test, the two flexible substrates are bonded over part of their length and the unbonded ends are peeled at 180° and the peel strength is determined as above. A T-peel test has been standardized (BSI 2005). It is common for the substrates in a T-peel test to take up an asymmetric profile when the failure path runs along one adhesive–substrate interface. The T-peel can then become a “Y-peel” as the local peel angle differs from the 180° peel angle applied. In such cases, the effective peel angle between the bonded portion of the joint and the load-line should be measured. For the peeling of two rigid substrates a fixture such as the floating roller peel test can be used. Such a fixture incorporates two rollers, and the peel arm is forced through the rollers at constant speed such that it slides on the roller and curves through a defined angle during peel. Again, the average peel force per unit width is measured and reported as the peel strength.

Clearly, while comparative measurements can be made using the above types of peel test, the results obtained will depend upon such factors as the mechanical properties of the peel arms, their thickness, and also upon such factors as the applied peel angle, and the effective “local” peel angle at the peel front. Also, in a study to evaluate these different types of peel test, Kawashita et al. (2005) demonstrated that in tests such as the floating roller peel test, frequently the peel arm does not conform to the roller geometry. This was identified using a modified and partially cutaway apparatus, which allowed the conformation to be evaluated. Such peel tests can be valuable to industry for the purposes of selecting a suitable adhesive for a given substrate material, for developing a surface pretreatment, or for investigating the effects of altering one test parameter (e.g., temperature, humidity or rate of peel). However, the results obtained in one peel test are rarely transferable to other geometries and have limited predictive capability. For this reason, much recent attention has been directed toward the development of geometry-independent peel tests, as is discussed in the next section.

### 20.4.3 Geometry-Independent Peel Tests

The peel strength determined in the above “geometry-dependent” peel tests is a measure of the total work done on the joint during the peeling process. Due to the plastic deformation of the peel arm(s), this total energy measure can be significantly greater than the energy required to drive a crack through the joint under linear-elastic conditions. Bearing this in mind, it is easy to see how peel test results can be

manipulated to achieve impressive numerical results by simply changing the substrate, for example, by changing from a high yield strength aluminum alloy to pure aluminum for the peel arm, significant increases in measured peel strength can be obtained for an otherwise identical joint. Recent research activity into peel testing (Kinloch and Williams 2002) has thus focused on the development of procedures (both test techniques and analysis schemes) to isolate the energy required to fracture the peel sample, termed the adhesive fracture energy,  $G_A$ , from the total input energy to the system, termed  $G$ . The underlying energy balance is:

$$G_A = G - G_p, \quad (28)$$

where  $G_p$  represents the plastic energy dissipated in the peel arm. In, for example, the 90° fixed-arm peel test for flexible to rigid peel arms, energy is dissipated by local plastic bending of the peel arm at the peel front. Then, as the section of the peel arm forced through a tight curvature at peel front subsequently straightens out, there is further, reversed plastic bending in the arm. In addition, there may be sufficient tension in the peel arm to exceed the yield strength of the substrate and hence there is additional tensile plastic energy dissipation in the joint. Thus, in the above energy balance,  $G$  is a measure of how difficult it is to peel one substrate from another in the joint whereas  $G_A$  is a measure of how well the substrates are stuck.

As described in Kawashita et al. (2006), the ESIS TC4 committee has developed a test protocol covering both the fixed-arm and the T-peel tests, together with an analysis to obtain the geometry-independent adhesive fracture energy,  $G_A$ , termed the adhesive fracture toughness in the ESIS TC4 protocol, but equivalent to the adhesive fracture energy,  $G_c$ . Because the tests require that the plastic energy dissipated in the peel arms be determined, it is also necessary to perform an additional tensile test on the peel arms. The tests developed accommodate situations where the adhesive layer thickness is negligible (e.g., when two polymer films are molded together as is common in packaging laminates) and also when the adhesive layer thickness is not negligible, that is,  $h_a > 0$ ; thus the deformation of the layers needs to be taken into consideration in the analysis. For this latter case, the tensile modulus of the adhesive material is required. This may be available from adhesive manufacturers' data sheets, otherwise a tensile test on the bulk adhesive will be needed.

In the fixed-arm peel test as shown schematically in Fig. 9, the substrates (which can be the same or different materials) are bonded along their length but excluding one section, typically 30 mm in length, which is left unbonded to allow for gripping in a test machine. The size of the test specimen and indeed the test jig to be used are not defined precisely in the ESIS protocol. The protocol permits applied peel angles in the range of 0–180° to be selected although in practice the fixed-arm peel tests are most commonly performed with an applied peel angle of 90°. The protocol additionally requires peel test to be performed at applied angles of 45° and 135°. During the development of the procedures and analysis, there was great interest in applying different peel angles to the joints, as although the total energy applied to the specimen,  $G$ , will be a strong function of applied peel angle, the adhesive fracture

toughness,  $G_A$ , should be independent of peel angle, as has indeed been shown to be the case in the round-robin tests coordinated by ESIS-TC4. Perhaps the most difficult experimental aspect of the fixed-arm peel test is ensuring that the fixed arm is (and remains) rigidly attached to the base. Also, the peel force is usually applied via the crosshead of a testing machine and the base should be fixed to a linear bearing trolley such that the specimen can slide with minimum friction during the peeling of the arm. If the fixed arm is attached to the base using an adhesive, it is important to ensure that this does not fail during the test. The fixed arms are commonly bolted to the free-sliding base. When bolts are used, it is necessary to accommodate the bolt holes in the fixed arm only at the peeling end of the joint, and through both the peel arm and fixed arm at the other end. When this is done, the second bolt is outside of the length of joint to be peeled in the test. It is also possible to use a wider fixed arm than peel arm, such that the extra width of the fixed-peel arm can be used to bolt down this arm to the sliding base.

The fixed-arm peel test is conducted at a rate of 10 mm/min when the applied angle is  $90^\circ$  and when other angles are used, then at speeds to give the same equivalent crack speed. The peel force is measured as a function of peel-arm displacement and an average force is determined over a minimum of 30 mm of peel fracture. If peel proceeds via a stick-slip mechanism, then average peel forces at initiation (cohesive fracture) and arrest (interfacial fracture) are determined separately. Figure 10 shows the steady-state peel force obtained in a fixed-arm peel test.

**Fig. 10** Peel force versus crosshead displacement obtained during fixed-arm peeling at 10 mm/min at an angle of  $90^\circ$ . The adhesive used was Bondmaster ESP110 and the peel arm was 0.1 mm thick aluminum

**Fig. 11** Stress–strain data obtained for an aluminum peel arm, showing the initial modulus  $E_1$ , the initial plastic modulus  $E_2$  used in the bilinear model, and the yield coordinates

In this test, an aluminum peel arm of thickness 0.5 mm has been bonded to a rigid aluminum alloy base using Bondmaster ESP110 epoxy adhesive. This was then peeled at an angle of  $90^\circ$  and at a rate of 10 mm/min.

As mentioned above, in addition to the fixed-arm peel test, it is necessary to perform a tensile test on the peel arm. This is performed at the same test speed as used in the peel test. The stress–strain curve is determined. Five parameters are obtained from the tensile test, namely,  $E_1$ ,  $E_2$ ,  $\alpha(E_2/E_1)$ ,  $\epsilon_y$ , and  $\sigma_y$ . These are shown in Fig. 11. The elastic modulus ( $E_1$ ) is defined as the slope of the stress–strain curve at small deformations and before yielding has occurred. In order to define the plastic modulus ( $E_2$ ), it is suggested that the tensile specimen be allowed to continue extending for as long as possible.  $E_2$  is drawn to the slope of the initial plastic region. This straight line should be drawn approximately between the limits of  $\epsilon_y - 10\epsilon_y$ . The parameter  $\alpha$  is then given by the ratio of the two slopes,  $E_2/E_1$ . If the peel arm work hardens, a work hardening coefficient is determined from the power law:

$$\sigma = A\epsilon^N. \quad (29)$$

If the “work hardening” portion of the stress–strain curve exhibits a negative slope, then values of  $\alpha$  and  $E_2$  are set to zero (and not negative) (Moore and Williams 2007).

The plastic bending in the fixed-arm peel test can be modeled using large-displacement beam theory with modifications for plastic bending (Kinloch and Williams 2002). Much of the development of the correction procedures has focused on how the

**Fig. 12** T-peel schematic specimen showing asymmetric loading due to differing peel-arm stiffness

stress–strain behavior of the peel arm is treated. Indeed, solutions have been formulated for three cases: the various approaches investigated and adopted have been (1) the use of a bilinear model to fit the data, (2) the application of a power law, and (3) the digitization of the complete stress–strain curve. The digitization procedure provides the most accurate results but frequently the simple bilinear model of the stress–strain behavior is sufficient. The analysis of the test results is most conveniently performed using software developed at Imperial College called ICPeel. This software is freely available from the Imperial College Web site <http://www.imperial.ac.uk/meadhesion>.

Preparing T-peel test specimens is simpler than preparing fixed-arm peel specimens as there is no need to attach one substrate to a fixed base and no need for a linear bearing trolley to accommodate the specimen sliding. A typical T-peel test specimen is shown schematically in Fig. 12b. Two flexible substrates are bonded with a 30 mm disbond, as above. The substrates may or may not be of the same material. According to the protocol (Moore and Williams 2007), loading is performed at 10 mm/min. Figure 12 shows the peel angles that may be obtained in the T-peel test. If the loading remains symmetric in the test, then both the peel angles will be  $90^\circ$ . However, if the substrates are of different stiffness, or the crack runs to an interface such that the adhesive is all on one side, then the peel angles will be  $\varphi$  and  $\theta$  (rather than  $90^\circ$ ) as shown in Fig. 12. To account for the plastic work done on the substrates, a tensile test on the arms is again necessary. If the substrates are dissimilar, then tensile tests on each peel-arm material is required. The analysis of the resulting tensile test is as described above for the fixed-arm peel test.

The analysis of the T-peel test data is similar to that for the fixed-arm peel test, except that the peel arms are treated individually. Only one of the peel angles needs to be considered since  $\varphi = \pi - \theta$ . For the two peel arms individually:

$$G_1 = \frac{P}{b}(1 + \cos \phi) \text{ and } G_2 = \frac{P}{b}(1 - \cos \phi), \quad (30)$$

where subscripts 1 and 2 refer to the individual peel arms. Determining the adhesive fracture toughness,  $G_A$ , for the two peel arms individually then:

$$(G_A)_1 = G_1 - (G_P)_1 \quad \text{and} \quad (G_A)_2 = G_2 - (G_P)_2. \quad (31)$$

For the complete T-peel joint combining the individual contributions above leads to:

$$G_A = (G_A)_1 + (G_A)_2. \quad (32)$$

The main limitation of the peel tests described above is that the adhesive fracture toughness,  $G_A$ , is determined from the difference between two numbers, that is,  $G - G_P$ . When modern, structural adhesives are employed to bond the substrates, these two numbers may be large, and as a consequence, the repeatability of the  $G_A$  values determined may be poor. Recent research has investigated the application of various validity criteria for peel tests. One such criterion has been to limit the size of the plastic correction term,  $G_P$ , to a fixed percentage of  $G$ , for example, a limit of  $(G_P/G) < 80\%$  has been utilized. Another criterion proposed has been to limit the maximum strain in the peel arm.

## 20.5 Relationship Between $G_c$ (Bulk, Fracture, and Peel)

As discussed in Sect. 1, fracture tests on bulk adhesive specimens are frequently undertaken as part of the materials development process. Loading is necessarily in mode I in bulk tests as even if other loading modes are applied, the crack path will tend to deviate to run locally in mode I. Values of  $K_{Ic}$  or  $G_{Ic}$  are determined, and these relate to the toughness of the bulk adhesive. The tests are very sensitive to the initial notching conditions and the values are those associated with crack initiation (unless steady-state propagation is clearly observed in the CT specimens).

Fracture tests on adhesive joints are more complex, as the loading mode, the adhesive, the substrate, and the interface or interphase region all have an effect on the values of  $G_c$  determined. In addition, both initiation and steady-state propagation values of  $G_c$  are usually determined, allowing the resistance curve, that is, the plot of  $G_c$ , versus crack length to be drawn. Comparisons of  $G_c$  values between bulk and mode I adhesive-joint fracture tests can be drawn, but considerable care is required when making this comparison. For example, it is often observed that for the DCB or TDCB tests, provided the adhesive layer is sufficiently thick to avoid the effects discussed in Sect. 3.4 and provided the crack grows cohesively through the adhesive layer with no rising R-curve observed, the value of  $G_{Ic}$  from the joint is equivalent to the value of  $G_c$  obtained in the bulk test. Clearly, if the bondline thickness is insufficient to allow for the full development of the plastic zone or if a weak interface causes the crack failure path to deviate from running cohesively in the adhesive, then lower values of  $G_c$  may be measured in the joint than in the bulk. If the adhesive joint exhibits rising R-curve behavior, which may occur if additional energy absorbing

mechanisms develop as the cracks propagate, then in such cases only the initiation values of  $G_{Ic}$  from the joint may be comparable to the bulk values. Also, when comparing bulk and joint adhesive properties, the state of cure of the adhesive should be shown to be equivalent as the exact processing conditions are affected by factors such as the thermal inertia of the joint and potential exothermic reactions of the bulk. Measurement of the glass transition temperature of the cured adhesive in the bulk and joint can be compared using techniques such as differential scanning calorimetry.

Finally, peel tests are used routinely by industries to assess adhesion. In geometry-dependent peel tests,  $G$  is the total energy dissipation on peeling and is significantly affected by factors such as the material properties of the peel arm, its thickness, and the angle of peel. In broad terms, these tests measure how difficult it is to peel the arms. This value of  $G$  may be many times greater than the value of  $G_{Ic}$  determined using the DCB or TDCB test. The degree of adhesion is just one of several factors that influence this measure. In geometry-independent peel tests, the energy dissipated plastically in the peel arms is determined and taken away from the total energy dissipation  $G$  to yield the adhesive fracture toughness,  $G_A$ . It is the value of  $G_A$  that may be considered equivalent to  $G_{Ic}$ , provided that the failure paths in the peel test and in the adhesive joint are both cohesive, in the adhesive layer. It should be noted that in the fixed-arm peel test, failure paths often occur close to the adhesive-substrate interface and thus may, in principle, yield values of  $G_A$  that are lower than the values of  $G_{Ic}$  determined using DCB or TDCB specimens in which cohesive cracks run through the center of the adhesive layer. This difference may be insignificant for brittle adhesives where the plastic zone size is small, but may be larger for tough adhesives. T-peel tests are sometimes preferred for this reason, as similar failure paths can be observed to the LEFM tests.

---

## 20.6 Conclusions

This chapter has described and discussed the fracture tests commonly performed on both bulk adhesive specimens and on adhesive joints. Whenever possible, fracture mechanics approaches have been followed with the goal of determining geometry-independent toughness values. Fracture tests on bulk adhesives are commonly conducted as part of the materials development process. Key to obtaining valid fracture results in bulk tests is to ensure (1) the generation of sufficiently sharp initial notches and (2) the manufacture of sufficiently good quality test specimens that pass the linearity and size criteria, as imposed by the standard, and thus allow the plane strain fracture toughness of the adhesive to be measured. The fracture toughness values obtained in bulk tests (i.e.,  $K_{Ic}$  and  $G_{Ic}$ ) will not be influenced by “adhesive-joint” factors such as constraint or substrate effects, or the quality of interfacial adhesion achieved.

Fracture tests on adhesive joints are always more complex than tests on bulk adhesive specimens and a  $G$  rather than a  $K$  approach is invariably followed for their analysis. The adhesive is present as a thin layer, it may be constrained by the

presence of nearby substrates and the failure paths may be influenced by the poor adhesion with the substrate. Fracture tests on adhesive joints are commonly conducted in mode I (tensile opening mode), mode II (in-plane shear mode), and mixed-mode I/II (combinations of mode I and II). The key to success in all LEFM fracture mechanic tests is to ensure that the substrates do not deform plastically during loading. Plastic deformation of the substrates would violate the assumptions of LEFM and invalidate the results. In mode I, the DCB and TDCB test specimens are almost universally employed and these tests have been standardized. Either test may be used for the determination of  $G_{Ic}$ . The choice of which to use is likely to depend upon factors such as the toughness of the adhesive, the properties of the substrate material employed, and whether or not crack length measurement is possible. In mode II, the ELS, ENF, the 4-point loaded ENF, and the tapered ENF (TENF) test specimens have all been employed to measure  $G_{IIc}$  values in adhesive joints with various levels of success. There is currently no agreed test standard for the determination of  $G_{IIc}$  in adhesive joints, but efforts are underway in the ESIS-TC4 (a European Fracture Committee) to develop a mode II standard, based on the ELS test method. The situation for mixed-mode fracture is similar, with several test specimens having been proposed but none yet standardized for adhesive joints. Values of  $G_c$  obtained from fracture tests on adhesive joints can be sensitive to variations in bondline thickness, and to assess this possibility reference should be made to the size of the plastic zone in relation to the bondline thickness.

Peel testing of flexible substrates can be considered as a class of fracture test, albeit one accompanied by extensive plastic deformation of the peel arm(s). A multitude of peel tests have been proposed and typically these determine a value of the peel strength, that is, a measure of how difficult it is to peel the arms during the test. Peel tests are thus highly geometry dependent. Recent research has focused on test and analysis methods to obtain geometry-independent values, for example, adhesive fracture toughness – one measure of how well the substrates are bonded. The method requires additional information about the stress–strain characteristics of the peel arms and also of the adhesive layer, so that the energy dissipated in these can be determined and accounted for in the fracture toughness values determined.

Finally, a major goal of fracture mechanics has been to derive geometry-independent values of the fracture parameter  $G_c$ . Great progress has been made in this endeavor with the determination of  $G_{Ic}$  from standardized bulk and adhesive-joint tests and  $G_A$  from geometry-independent peel tests. However, great care is required with the interpretation of these fracture parameters.

**Abstract**

Assessing the mechanical properties of adhesives and the joints strength requires specific tests. Indeed, since polymers are, in general, sensitive to the strain rate they undergo, different phenomena can be induced when a load is applied abruptly. Under such a condition, usually the adhesive tends to react to the deformation with higher stress and lesser ductility, which causes higher resisting loads but lower absorbed energy. This is why the common standard impact tests for adhesives, involving bonded blocks or strips, aim at measuring the energy required to break the bond.

However, since this result is not sufficient to characterize an adhesive, other types of tests have been introduced to obtain a deeper insight. Different types of specimens (samples of bulk adhesive, lap joint, butt joint, double cantilever beam) and test rigs (pendulum, falling weight, hydraulic actuator) have been

adopted in many works to measure the properties of interest. The fracture energy, typical of fracture mechanics, requires ad hoc tests and processing to be measured in dynamic conditions. The Split-Hopkinson pressure bar, a special apparatus conceived to test materials at high strain rate, has been also applied with success to adhesives and joints. Also test rigs based on the falling weight schemes have been widely used. A special case is that of conductive adhesives, which are getting into use to replace soldering in electronic packaging: their capability to withstand the impact that a device can undergo in use must be assessed.

This chapter, mainly relying on the results available from the technical literature, presents a survey of various test methods, focusing on the related problems and achievements.

---

## 21.1 Introduction

In many of the applications in which adhesives are used, it is likely that they are exposed to loads applied abruptly. A first case is that of a bonded assembly included in a mechanism which, in its service, undergoes discontinuous loading. Examples are mechanisms which undergo intermitting contact, or machineries which exert a crushing action on a material (like mills), or devices conceived to absorb impacts regularly. A second case is that of structures which under normal service are not loaded impulsively but in special conditions (accidents of various types) can be subjected to impacts. This is especially true for automotive applications, in which the crashworthiness is of crucial importance, but it also applies to devices which accidentally can undergo impacts (for instance, due to misuse, fall, etc.). According to the case, the expectations are different: if the impacts are a normal service condition, they must be sustained repeatedly without damage; otherwise, if the impact is an exceptional case, the goal is to minimize its consequences, accepting that a certain level of damage (sometimes high) is unavoidable. It can be remarked that in the former case, the determination of the adhesive performance can be expressed in terms of force or stress, while in the latter case, the typical quantity involved is the absorbed energy.

Two typical issues arise about the behavior of an adhesive subjected to impact. The first one is whether an abrupt loading can cause brittle behavior in a material that under static or quasi-static conditions would not be brittle; this aspect is critical regarding the capability of absorbing energy. The second issue is assessing the influence of the loading rate on the adhesive response, i.e., the sensitivity of the adhesive properties to the strain rate.

It is clear that such issues, all concerning material response, need experimental results to be addressed. For this reason, ad hoc tests have been proposed and developed, also as international standards. The commonest is the block impact test, defined as an American Society for Testing and Materials (ASTM) standard – and subsequently also as European Standard (EN) and International Organization for Standardization (ISO) standard – in which an impact is applied, with a loading scheme similar to that of the Izod pendulum, to a block bonded to a base. Another

popular test, especially in the automotive industry, is the impact wedge peel test, originally developed by Ford and presently also defined as an ISO standard; in this case the bond between two sheet metal strips is broken by a wedge that goes through the joint. These two tests are described in the next two sections of this chapter.

In addition to these standard tests, a considerable amount of research on the impact of adhesives has been carried out and presented by many scientists over the last four decades. A special apparatus, developed for testing materials under high strain rate and applied also to adhesives, is the Hopkinson bar, described in a subsequent section. A selection of other special testing methods and the related modeling are described in a further section.

In many cases, apart from the rupture energy (which can be obtained directly with pendulum-like devices), the measurement carried out in impact testing is the force time history. The typical feature of the latter is its oscillating behavior – posing serious problems when analyzing the curve – which is justified by two arguments. The first explanation is based on the discontinuous nature of crack propagation: when the critical condition is attained, the crack grows, and this relieves the local stresses and makes the system more compliant; thus the load decreases; then, as the impactor advances further, the cycle restarts. The second explanation considers that the specimen receiving the impact starts to vibrate, independently of the damage that can occur. Moreover, the vibrational properties are not necessarily a feature of the specimen alone, since they often depend on the system formed by the specimen and the test rig (which comes into play with its deformability). Unfortunately, in many cases it is very difficult to distinguish one contribution from the other, especially when the recorded time history is the only information available. The operation of smoothing the recorded curve (e.g., by filtering the high-frequency content) implies the risk of losing some useful information; on the other hand, the raw data can be misleading, in the sense that purely dynamic effect can be taken as material properties (e.g., force peaks at breakage). Thus, the evaluation of impact measurements often requires careful judgment, to avoid erroneous interpretation and false results.

It is clearly impossible to recall in a short space all the experiences about impacts tests on adhesives reported in the literature and describe in detail the findings. The objective of the present review is to give general information about what is (and can be) done in this field regarding the experimental arrangements adopted, the types of results obtained, and the behaviors observed. Another broad and detailed state-of-the-art review on adhesives and joints under impact has been very recently presented by Machado et al. (2017). From these reviews, an interested reader could get an address to select the types of experiments and results that fit his/her need. Of course, examining the original literature is always recommended. Among the several contributions appeared in recent times, the special issue of the *Int. J. of Adhesion and Adhesives* on “Impact phenomena of adhesively bonded joints,” Sato and Goglio (2015), can be mentioned.

It can be also remarked that often the cited articles are not exclusively dedicated to experimental works, since they report also the numerical and/or analytical modeling of the specimen behavior. This is due both to the use of the experimental results

115 to validate the models and to the additional insight given by modeling to understand  
116 the stress and strain state during the tests.

## 117 21.2 Block Impact Tests

118 The basic principle on which this test, given by the ASTM D950 standard and by  
119 ISO 9653:1998 and EN ISO 9653:2000 as well, relies is to apply an impact loading  
120 condition, mainly in shear, by means of a test rig similar to that used for Izod  
121 resilience measurement. Figure 1 shows the experimental arrangement. An upper  
122 block (usually of steel) is bonded onto another larger block which, in turn, is fixed  
123 to the base of the test rig. The first block is struck by a hammer, in a direction parallel  
124 (at least at the beginning of the impact) to the bond surface. The energy required to  
125 fracture the sample is obtained from that lost by the pendulum, considering a  
126 correction for the kinetic energy of the projected parts. The reason for using this  
127 type of specimen, quite different from a real joint, is double. First, the block offers a  
128 large lateral face, which is easy to hit by means of the hammer. Secondly, the scheme  
129 aims at creating a condition of pure and constant shear in the adhesive layer.

130 A thorough analysis of this case has been carried out by Adams and Harris (1996)  
131 who, examining the features of this test, have analyzed in detail the contact condi-  
132 tions between hammer and side of the block. In an ideal situation, the impacting  
133 surfaces of the hammer and of the block should be perfectly parallel, giving a  
134 uniform load on the block. In practice, a certain degree of misalignment is unavoid-  
135 able. The authors, by means of finite element analyses, have compared (Fig. 2) the  
136 ideal case (I) with the limit cases in which – due to misalignment – the contact occurs  
137 at the upper edge of the block (case II) or near to the bond (case III). Their main  
138 findings are that, even in case of perfect alignment (Fig. 3, case I), the stresses in the

**Fig. 1** ASTM block impact test (From Bezemer et al. 1998, copyright Elsevier)

**Fig. 2** Possible modes of impact of the pendulum against the block: (I) perfectly parallel; (II) far from the bond; (III) close to the bond (From Adams and Harris 1996, copyright Elsevier)

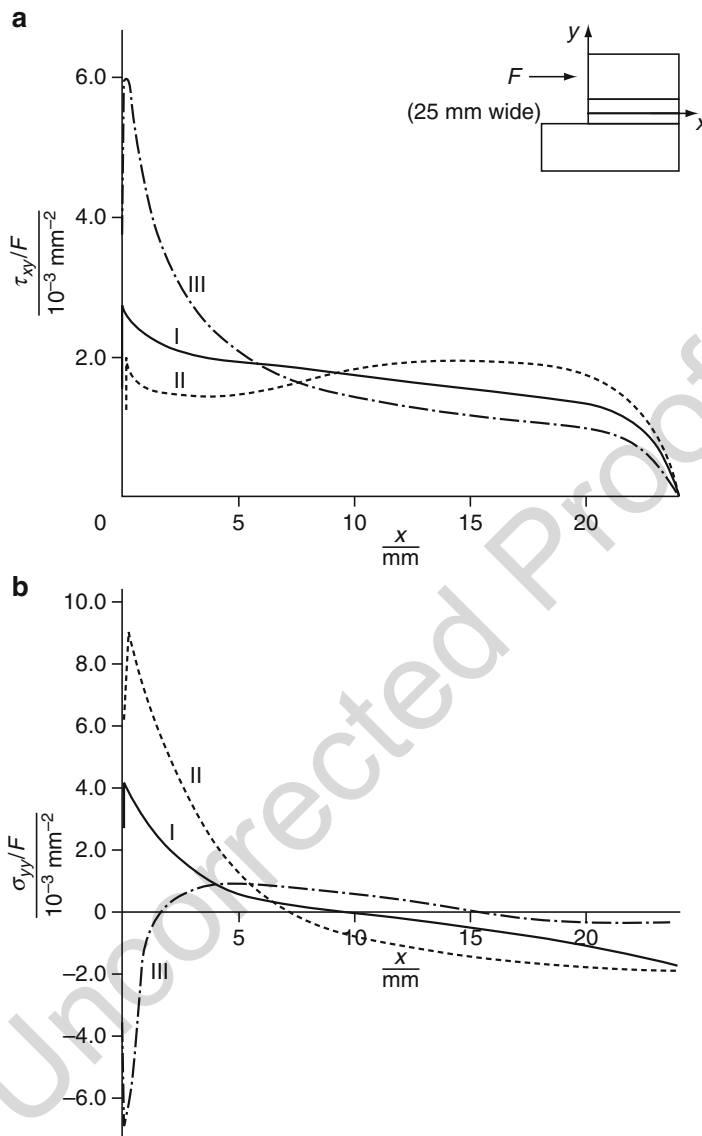

adhesive are far from being constant: the shear stress peaks near to the bond end at the impacted side; also the peel stress is significant and peaks near to the bond end at the impacted side; then it decreases monotonically assuming negative sign at the opposite bond end. The non-constancy of the shear stress is generated by the “differential straining” mechanism due to the deformability of the block (see ► Chap. 24, “Analytical Approach”) that emphasizes the stress value at the end of the bond. The peel stress can be primarily regarded as a bending stress caused by the rotation of the impacted block, which – also in this case due to the deformability – is not linearly distributed.

In case of misalignment, the distribution of the shear and peel stress is strongly influenced, as shown in Fig. 3 (cases II and III), due to the changes of moment value and the compressive local deformation of the block (this effect can be regarded as a compression that “irradiates” from the contact point).

If the contact occurs far from the bond (case II), the bending moment is higher, and the peak of peel stress increases, while the local deformation of the block has little influence and the shear stress is not much affected. Conversely, if the contact occurs close to the bond (case III), the combination of low bending moment and compressive local deformation of the block causes a compressive peel stress in the adhesive close to the impacted bond end. At the same time, the local deformation of the block increases the differential straining at the same bond end, which causes a higher peak of shear stress.

Obviously, these features refer to the stress distribution at the beginning of the impact; then the situation evolves depending on the deformations (and damage) that take place. Thus, in global terms, the loading conditions and the strain energy are influenced, depending on the specific case; this aspect is important, since the elastic energy in the steel blocks can be even higher than the rupture energy of the adhesive.

From all these reasons, it comes out clearly that the block impact test is not suitable to give absolute figures about the energy absorption of an adhesive, due to the dependence of the results on the test rig and testing conditions. The only usefulness of the test is that of comparing the behavior of different types of adhesives, but also in this perspective the results must be considered carefully, keeping in mind the importance of the possible misalignments.

**Fig. 3** Stress distribution on the adhesive midplane of the impact block ASTM 250 for different loading cases: (a) shear stress; (b) peel stress (From Adams and Harris 1996, copyright Elsevier)

171 An alternative specimen for impact testing of adhesives, aiming at a stress  
 172 distribution mainly in shear and suitable for a speed higher than that reachable  
 173 with a pendulum, has been proposed by Bezemer et al. (1998). The specimen  
 174 in this case is formed by a ring bonded to a coaxial rod; the radial gap defines the  
 175 desired thickness of adhesive. In the test, the rod is hit axially – and pushed away

from the ring – by a projectile released from a drop tower or launched by an air gun, depending on the speed which is wanted; obviously, also static loading on a standard test machine is possible, especially for the sake of comparison. The contact force between projectile and rod is measured and recorded during the test; hence the displacement can be calculated by integration of the time history, and, in turn, also the energy can be obtained. The authors recognize that, though the motion of the rod with respect to the ring generates a tangential relative displacement, the strains and the stresses are not of pure shear; thus also a considerable normal stress is applied to the adhesive, in spite of the expectation. On the other hand, compared to the block impact, this solution still offers the advantages of a lesser sensitivity to misalignment and broader range of possible loading speed. However, this type of test is not widespread and has not reached the level of a standard.

### 21.3 Impact Wedge Peel Tests

Another objection against the block impact test is that the adherends involved (blocks) are thick and this does not reflect real applications, in which bonding is usually adopted to join thin parts. From this viewpoint, it appears more realistic to test a bond which joins two metal strips, highly deformable both elastically and plastically. This is just what is done with the “Impact wedge peel test,” foreseen by the standards ISO 11343:2003 and EN ISO 11343:2005. The specimen (Fig. 4) is made by two metal strips, formed and bonded together to obtain the shape of a Y. The strips are 90 mm long and 20 mm wide; their thickness can range between 0.6 and 1.7 mm. The bonding length is 30 mm, without any pre-cracking or crack initiator; the not bonded zones form the arms of the Y, which are clamped when the specimen is mounted on the test rig. Even if, to obtain the Y shape, the strips can be formed after bonding, it is recommendable to preform them, to avoid the risk of damaging the adhesive in the forming operation. The specimen is loaded by a wedge which is one side of a rectangular shackle and goes through the bond, thus separating the strips in peeling mode. The pull is applied to the shackle by means of a pendulum

**Fig. 4** ISO 11343 wedge impact peel test specimen (From Blackman et al. 2000, copyright Kluwer)

or an actuator, with typical test speeds of 2 or 3 m/s depending on the material of the strips (lower value for steel, higher value for aluminum). During the test, the impact force is measured and recorded for subsequent processing.

A broad study of this test has been carried out by Blackman et al. (2000), who – on the basis of a series of tests carried out on several types of adhesives, at different speeds and temperatures, and using a high-speed hydraulic machine – have analyzed the effect of the specimen geometry and type of crack growth. The onset and the propagation of the rupture have been observed by means of high-speed photography. Furthermore, the authors have reviewed the methods proposed by the standard to extract the results and have applied a finite element model to reproduce the fracture of the specimen.

Two types of crack growth can be observed in this test, stable and unstable. In case of stable growth it has been observed that the crack tip runs ahead the wedge at approximately constant offset; thus the propagation speed is given by the wedge speed. The force time history exhibits initial peaks, due to dynamic effects originated by the sudden contact of the impactor with the specimen, and then a plateau appears and lasts for most of the test. Furthermore, the elevated plastic deformation of the metal strips that takes place involves a considerable amount of strain energy.

In case of unstable growth, typical at low temperature ( $-40\text{ }^{\circ}\text{C}$  in these experiments), or with a brittle adhesive, the crack runs rapidly through the whole bond, at a speed much higher than that of the wedge. The force time history after the initial peaks does not exhibit any plateau and oscillates close to zero. After the test, the strips appear almost undeformed, i.e., little plastic deformation takes place, and the measured energy is much lower than in the previous case.

According to the ISO standard, the average cleavage force can be calculated from the time history by considering the data between 25% and 90% of the time interval from the beginning to the end of the curve. The energy is given by the area under the curve between the same end points multiplied by the test speed. The reason for this assumption is to discard the data corresponding to the initial peaks and the “tail” of the curve. Blackman et al. (2000) remark that such procedure works well in case of stable crack growth, but it fails and can lead to false results in case of unstable growth, which does not exhibit any plateau.

An important aspect of the impact wedge peel test is that in case of stable crack growth; part of the energy is spent for deforming the metal strips (this aspect does not affect the unstable crack growth, which, however, is not suitable for the abovementioned reasons). Thus, also with this test, the measurement does not yield a property of the adhesive *in se* but of the assembly formed by adhesive and strips. Another factor that potentially affects the results is the friction between the wedge and the surfaces of the specimen during the fracturing process. However, the finite element simulations performed by Blackman et al. (2000) show that this aspect has minor importance, the leading factor being the adhesive fracture energy  $G_c$ . From the knowledge of the latter parameter, which can be measured with a fracture mechanics test such as the double cantilever beam, the time history of the impact wedge test can be reconstructed with finite element modeling.

## 21.4 Hopkinson Bar Apparatus

In addition to the limitations already mentioned, the two tests described in the previous sections present the further restriction that the strain rate attained in the adhesive cannot be much high, since it usually does not exceed  $10^2 \text{ s}^{-1}$ . When testing at higher strain rates is needed, the suitable equipment is the so-called Hopkinson bar, which in the last years has become probably the most used by the researchers of the field.

This name is due, historically, to the apparatus used at the beginning of the twentieth century by B. Hopkinson to study the pressure waves generated by explosions or projectiles. In the experiment, the explosion (or the projectile) attained one end of a long and thin bar suspended horizontally, creating a pressure pulse which propagated through the bar until the other end, where a short cylinder of the same diameter of the bar was provisionally attached by means of a grease film or magnetically. This cylinder, called time-piece, was projected by the pulse against a ballistic pendulum which gave the measure of the momentum contained in it; the momentum remained in the bar was measured by observing its oscillation. By varying the length of the time-piece, it was possible to assess the length of the pressure pulse.

The version of the apparatus used nowadays was introduced by Kolsky (1963), who added a second bar, from which the name “Split-Hopkinson pressure bar” comes from; the specimen of material to be tested is inserted between the two bars, as shown schematically in Fig. 5a. The projectile, usually fired by means of a pneumatic gun, impacts the first bar (incident bar), generating the incident pulse which, at the bar/specimen interface, is partially reflected and partially propagates in the specimen. From the specimen, the pulse is transmitted to the second bar

**Fig. 5** Schematics of the Split-Hopkinson pressure bar (a) and related Lagrangian diagram (b)

**Fig. 6** Split-Hopkinson pressure bar: (a) overall view of the rig including three bars for different test conditions; (b) detail of the bending fixture (Politecnico di Torino, DYNLAB)

(transmitter bar). The situation is described graphically by the so-called Lagrangian diagram presented in Fig. 5b. A concrete example of Split-Hopkinson pressure bar is shown in Fig. 6. The pulses are measured by means of strain gages placed on both incident and transmitter bar, thus their time history can be stored by means of a transient recorder, usually a digital oscilloscope or an acquisition board. From such measurements the stress ( $\sigma$ ), strain ( $\epsilon$ ), and strain rate ( $\dot{\epsilon}$ ) in the specimen can be obtained as

$$\sigma(t) = E_0 \frac{A_0}{A} \epsilon_{\text{tra}}(t) \quad (1)$$

$$\epsilon(t) = -2 \frac{c_0}{L} \int \epsilon_{\text{ref}}(t) dt \quad (2)$$

$$\dot{\epsilon}(t) = -2 \frac{c_0}{L} \epsilon_{\text{ref}}(t) \quad (3)$$

where, respectively,  $E_0$ ,  $A_0$ , and  $c_0$  are Young's modulus, cross section, and wave velocity of the bar,  $A$  and  $L$  are the cross section and the length of the specimen,  $\varepsilon_{tra}$  is the strain pulse transmitted in the second bar, and  $\varepsilon_{ref}$  is the strain pulse reflected in the first bar. Equations 1, 2, and 3 are based on the assumption that the specimen has reached equilibrium conditions; this requires that its length be smaller than the length of the pulse. Clearly, the measurement cannot be taken directly at the interface; thus the strain gages are placed at a distance from the end of each bar; this is potentially a source of error since the pulses during their travel (from the bar end to the gage) change in shape and assume a delay that must be evaluated.

As far as the adhesives are concerned, the Hopkinson bar has been applied to the characterization of materials and also butt or lap joints. The arrangement described above is suitable for testing in compression (that can be applied by simple contact); in case of tension, the system must be modified, usually by means of a threaded connection. Moreover, it is required to generate a tensile pulse in the bars, and this can be obtained in two ways. The first is to use a reverse loading system, so that the impact of the projectile applies tension to the first bar, as done by Yokoyama (2003) and also (actually to test polymers, but the case would apply also to adhesives) by Chen et al. (2002). The second and more popular solution is to generate, as usually, an initial compressive pulse that travels through both bars; the transmission of this pulse from the first to the second bar is given by a split ring, inserted between them, which prevents the specimen from being loaded in compression (Fig. 7). It is also possible to avoid the use of the split ring if the dimensions of the threaded parts of specimen and bars are accurately manufactured to obtain a precise fit of the ends of the bar (Fig. 8). When the compressive pulse reaches the end of the second bar, it is

**Fig. 7** Use of threaded specimen and split ring to carry out tensile tests with the Hopkinson bar (From Goglio et al. 2008, copyright Elsevier)

**Fig. 8** Use of threaded specimen without split ring to carry out tensile tests with the Hopkinson bar: (a) tubular specimen; (b) solid specimen (From Bragov and Lomunov 1995, copyright Elsevier)

reflected back as a tensile pulse which stresses the specimen, while the ring gives no contribution under tension.

Several studies based on the Hopkinson bar have been presented by Yokoyama and co-workers. In Yokoyama and Shimizu (1998), the shear strength of pin-and-collar specimens (ASTM D4562) bonded with cyanoacrylate has been studied with the Hopkinson bar and compared to the static case. Both steel and aluminum have been considered as adherend materials. Later, Yokoyama (2003) has tested under tension butt joints made with cyanoacrylate adhesive and two different types of adherends, namely, a bearing steel and a high-strength aluminum alloy. The impact tests have been carried out on a Hopkinson bar; other comparative tests at intermediate and low loading rates have been performed on a standard test machine. The experimental work is supported by a finite element analysis of the stress state in the joint. In both studies, the main findings are that the joint strength, expressed as peak force or stress, increases with the loading rate, while the deformation decreases. There is an optimum value of adhesive thickness (about 35  $\mu\text{m}$ ), for which the tensile strength is maximized; furthermore, the strength is influenced by the material of the adherends, steel, or aluminum. In the case of butt joints also the absorbed energy has been evaluated, by integrating the load-deformation curve. It has been noticed that the amount of energy is influenced by the material of the adherends; as in case of steel adherends, it decreases significantly with the loading rate.

Again, Yokoyama et al. (2012a, b) have studied with the Hopkinson bar the response of bulk specimens made of two different structural adhesives (epoxy and methacrylate) tested in compression. A tapered striker has been used to apply a nearly constant strain rate. Both adhesives have shown marked strain rate dependence, and it has been found that a modified Ramberg-Osgood model predicts well the stress-strain curve in loading, but not the strain softening after yielding and the unloading phase.

Recently, Yokoyama and Nakai (2015) have tested brim-and-crown butt joints, fabricated with aluminum alloy or pure titanium and joined by an epoxy. A Hopkinson apparatus modified by adopting a tubular output bar has been used. The experiments have shown that the tensile strength increases significantly with the loading rate and decreases under increasing adhesive thickness, for both adherend types.

Goglio et al. (2008) have tested a bicomponent epoxy under tension and compression, to assess the effect of the strain rate on the strength of this adhesive. Also, in this work both the Hopkinson bar and a hydraulic test machine have been employed, depending on the desired strain rate (from  $10^{-3}$  to  $3 \times 10^3 \text{ s}^{-1}$ ).

Under compression, the stress-strain curve of the adhesive exhibits an initial linear (elastic) rise, then a wide plateau, and again a rise with increasing slope. These features remain the same under any strain rate values, as it can be observed in Fig. 9: increasing the strain rate, the yield stress increases; thus the plateau is shifted upward and starts at larger strain. This observation has led to define a dynamic factor as  $k = \sigma_{\text{dynamic}}/\sigma_{\text{static}}$ , obtained by the ratio (averaged over the plateau) of the points on the curve at a chosen rate to the points on the static curve. The available data have been used to define prediction formulae for  $k$  as a function of the strain rate, based on

**Fig. 9** Dynamic stress-strain curves under compression at different strain rates, case of cold cured adhesive (From Goglio et al. 2008, copyright Elsevier)

a log-log fit as shown in Fig. 10. The two popular models, to account for the strain rate influence, of Cowper-Symonds and Johnson-Cook have been applied to this case. None of them can reproduce the experimental data over the whole range tested ( $10^{-3}$ - $10^3$   $s^{-1}$ ); thus they can be conveniently replaced by a poly-linear (in log-log scale) fit in the form  $k = A\dot{\epsilon}^n$ , where  $A$  and  $n$  are coefficients determined over each chosen range. From Fig. 10, it can be also appreciated that the  $k$  factor assumes, at the highest strain rate tested, values close to 3; this gives a measure of the elevated sensitivity of the adhesive to the strain rate.

Testing under tension at high strain rate presents particular problems. Apart from the abovementioned modifications to the apparatus required to apply positive stress, the measurement is hindered by the different response of the material. Indeed, the material usually behaves as brittle, and the specimen cracks soon after the stress-strain curve has reached its maximum. The only value that can be obtained is in practice the 0.2% (or other chosen percentage) proof stress. However, this value is also strongly dependent on the strain rate.

There are other specific problems, which affect testing with the Hopkinson bar, that deserve to be mentioned.

One concerns the first part of the stress-strain diagram, corresponding to the elastic behavior and, therefore, useful to evaluate the elastic modulus of the material. This part of the diagram corresponds to a time range of the test in which the equilibrium conditions still have not been achieved in the specimen, since as a

**Fig. 10** Dynamic factor  $k$  (case of cold cured adhesive): fitting of the experimental values with Cowper-Symonds, Johnson-Cook, and poly-linear models (From Goglio et al. 2008, copyright Elsevier)

practical rule it can be assumed that equilibrium is achieved after the waves have traveled back and forth more than three times along the specimen (Chen et al. 2002). Thus, the values of the elastic modulus can be affected by uncertainty and must be regarded with care.

A general survey – not specifically related to adhesives – of the problems concerning the measurements by means of the Hopkinson bar has been presented by Bragov and Lomunov (1995). Apart from presenting nonconventional applications of the Hopkinson bar (such as dynamic hardness and toughness testing), these authors discuss the problems of signal synchronization and strain rate constancy. The former problem is originated by the difficulty in recognizing the exact beginning of the three measured pulses (incident, reflected, transmitted), which in this paper is corrected by checking that the sum of the incident and reflected pulses equals the transmitted strain pulse. The latter problem is due to the fact that the strain rate, according to Eq. 3, is proportional to the reflected pulse, which decreases as the specimen hardens and its cross section increases during the test. The remedy is to modify the shape of the incident pulse, by means of a tapered projectile or an auxiliary specimen (pulse shaper) placed at the impacted end of the first bar: in this way the incident pulse assumes an increasing amplitude, while the reflected pulse tends to be constant.

Zhao and Gary (1996), presenting a study related to the measurement of small strains with the Hopkinson bar, have considered two important sources of error. The first is the dispersion (related to the difference between phase and group velocities of the waves), which the authors correct with a numerical procedure. The second is the determination of the time delay between the signals, for which an iterative procedure

is proposed. These authors also propose an identification technique to treat the data corresponding to the initial transient of the measurement, when the equilibrium in the specimen is not yet attained.

In a general perspective, not solely related to testing of adhesives, the problem of the dispersion has been considered by Tyas and Watson (2001). They have proposed to correct the measurement by means of two factors, termed  $M_1$  and  $M_2$ , one relating measured surface strain to average strain over the cross section and the other relating average axial strain to average axial stress (dynamic elastic modulus).

Another source of error is the effect of the nonuniform distribution of stress and strain over the cross section, related to radial inertia. This problem, considered again in general case by Forrestal et al. (2007), becomes important when the diameter of the bar is large and, therefore, the wave is no longer mono-dimensional. The corrections which are proposed are based on the theoretical solution for the wave propagation.

Sen et al. (2011) have carried out tests on single-lap joints of different overlap lengths; they have found that the (apparent) strength expressed as average stress decreases by increasing the overlap – in accordance to what is found also under static loading – and that the edges of the adhesive are subjected to the maximum strain. An important remark about this type of measurements is that, as stated previously, in Hopkinson bar testing, the stresses should be uniform throughout the length of the sample, which is more difficult to achieve in case of lap joints.

Similarly, Challita et al. (2011) have carried out quasi-static, intermediate, and high strain rate tests (the latter on a Hopkinson bar) on double-lap joints, using compression-shear and tensile-shear specimens. It has been found that the shear strength increases for increasing strain rate until  $10^3 \text{ s}^{-1}$  then decreases. Correction coefficients based on the previous work Challita and Othman (2010) have been used to estimate the maximum stress, accounting for the nonuniform distribution.

Testing with the Hopkinson bar has been applied also to nonconventional cases, to assess the material response in special conditions. For instance, Martinez et al. (1998) have studied the behavior of a confined adhesive, i.e., when it cannot freely expand laterally under compression. The interest for such case is related to the use of an adhesive to join, in an armored panel, the front ceramic layer to the metal backing plate. To this aim, the adhesive specimen in the Hopkinson bar tests has been surrounded by a confinement tube. The study, carried out on several types of adhesives, has evidenced an optimum value of the adhesive thickness in the armor, in order to ensure enough strength to contain the ceramic fragments and the minimum reflection of the pressure wave. A work by Adamvalli and Parameswaran (2008) has studied the influence of the temperature on the strength of single-lap joints, bonded with an epoxy adhesive, tested at different loading rates (Fig. 11). It has been found that, on the one hand, at the highest loading rate tested ( $4.7 \text{ MPa}/\mu\text{s}$ ), the strength is more than three times the corresponding static value; on the other hand, an increase of temperature from  $25^\circ\text{C}$  to  $100^\circ\text{C}$  reduces by 35% the strength.

Ravi Sankar et al. (2015) have used a Hopkinson bar to test lap joints with split-cylinder geometry, made with similar or dissimilar metals (steel, aluminum) joined by an epoxy. The results, supported by finite element modeling to assess the stress

**Fig. 11** Setup of the Hopkinson bar for testing lap joints at high temperature (From Adamvalli and Parameswaran 2008, copyright Elsevier)

distribution, indicate that the strength is dictated by the less stiff adherend. A further interpretation by these authors is that the strength measured using the Hopkinson bar represents the volume averaged shear stress in the adhesive layer, as stated by Challita and Othman (2010).

The method of the Hopkinson bar testing has also been applied to specimen types other than cylinders or lap joints.

Sato and Ikegami (1999) have measured the dynamic strength of an epoxy adhesive by testing butt joints of tubes subjected to shear and normal stress. Their equipment (Fig. 12) include a Hopkinson bar suspended vertically and loaded at the upper end by hydraulic actuators which apply, before the beginning of the test, a torsional and a tensile preload. Nearby the lower end, the bar is clamped by a mechanism that can be released rapidly. The specimen is formed by an upper short tube (load input tube), screwed at its upper end to the Hopkinson bar, and a long lower tube (load output tube), instrumented with strain gages. When the clamp is released, the elastic energy accumulated in the bar creates the waves that travel from one tube to the other, thus loading the adhesive layer. The reason for an elevated length of the output tube is to avoid that the back reflection of the waves at its lower end could interfere with the useful signals. The result is a chart, of the type shown in Fig. 13, reporting the failure conditions under different combinations of peel and shear stress. Also, cases of failure under static loading are reported in the diagram, for comparison with the dynamic case; it is evident that the stress values under impact are approximately double than the static ones. The authors have also tried to interpolate the experimental points with the popular Tresca and von Mises failure criteria, but the best fit (solid lines in the figure) is given by a polynomial in the form

$$\tau_d'^2 (\sigma_d - \sigma_d') + \sigma_d' \tau_d'^2 = 0 \quad (4)$$

where  $\sigma_d$  and  $\tau_d$  are the applied normal and shear stresses and  $\sigma_d'$  and  $\tau_d'$  are the strength values measured experimentally. This formula, although not supported by a theoretical background, has also the merit of predicting an increase of the bearable

**Fig. 12** Schematic of the modified Hopkinson bar used by Sato and Ikegami (1999) to test butt joints of tubes under tension and torsion

shear stress in case of negative (i.e., compressive) normal stress; this can be noticed by extrapolating to the left the curves in Fig. 13.

An evolution of the Hopkinson bar is the test rig presented by Kihara et al. (2003) to measure the shear strength of adhesive layers (Fig. 14). A prism of hexagonal cross section, screwed between bars 1 and 2, is bonded to a pair of plates which, in turn, are screwed to the additional bars 3. When the pulse, generated from top by the impact of the projectile 0 against bar 1, travels through the prism, it propagates also laterally to the bonds and the plates. The skew slit contained in each plate acts as a reflector which deviates most of the pulse toward bar 3. In addition to the strain gages placed on bar 1 and 2, as usually in the Hopkinson bar scheme, a rosette is applied on each lateral plate to measure the strains in a point close to the adhesive layers. A peculiar phenomenon noticed by the authors is that in case of low incident pulse (in bar 1), the adhesive withstands the shear stress and is fractured by the tensile normal stress generated by the reflection in the plate. Conversely, in case of high incident pulse, it is the shear stress (in combination with compressive stress) that causes the fracture of the adhesive. By means of this apparatus, the authors have

**Fig. 13** Limit curves for dynamic and static stress of tubular butt joints subjected to normal and shear stresses based on the results of Sato and Ikegami (1999)

obtained a value of shear strength comparable to that obtainable by cylindrical butt joints subjected to torsion.

Wang and Xu (2006) have performed tensile dynamic tests with the Hopkinson bar on convex-edge joints, shaped in such a way to eliminate the edge singularity in the interface of dissimilar materials, so obtaining a nearly uniform stress distribution and a more correct measurement of the strength. This specimen type is not exactly a bonded joint; however the findings can be useful to design a butt-bonded specimen.

Gilat et al. (2007) have studied the response of two epoxy resins, one untoughened and one toughened, in the strain rate range  $10^{-5}$ –700 1/s, under tensile and torsion loading. Tests at low and medium strain rates have been carried out on a hydraulic (biaxial) machine, those at high strain rates with a tensile or a torsional Hopkinson bar. The latter have been adapted by clamping, respectively, a force or a torque which is then released. A transition from ductile to brittle behavior has been noticed under tension under increasing strain rate; conversely, ductile behavior has been observed under torsional shear at any strain rate.

In a comprehensive work concerning the mechanical properties of the crash-optimized adhesive Betamate 1496 V, May et al. (2015) have used a modified Hopkinson apparatus in which no input bar is foreseen: the striker hits directly the specimen, and the force is measured by a film transducer attached to the end of the output bar. The deformation of the specimen is captured by means an electro-optical system based on a high-speed camera which keeps track of a pair of markers painted on the edges of the specimen.

Very recently, Neumayer et al. (2016) have used a Hopkinson bar to study the impact response of butt- and lap-shear joint specimens, measuring the strain in the adhesive by means of Digital Image Correlation (DIC), achieving a better accuracy than in traditional way. It has been noticed that DIC has given a 12.28 times higher

**Fig. 14** Test rig to measure the impact strength of adhesive layers (From Kihara et al. 2003, copyright Elsevier)

509 adhesive stiffness and a 1.83 times lower energy in case of butt joints (respectively,  
 510 6.13 and 1.29 times in case of lap-shear joints).

## 511 21.5 Other Test Methods

512 In addition to the test schemes described in the previous sections, some other methods  
 513 have been applied to test adhesives and joints under impact loading. Most of them are  
 514 based on schemes that reprise static cases, for the geometry of the specimens or the  
 515 loading system. The reason for this is not only to recover known cases but – most of  
 516 all – to evaluate easily the changes in the joint response induced by the loading rate.

### 517 21.5.1 Fracture Energy

518 Regarding the measurement of the adhesive fracture energy  $G_c$ , under impact (or, in  
 519 general, dynamic) conditions, the double cantilever beam test and the tapered double  
 520 cantilever beam test (Fig. 15) must be adapted to account for the effect induced by  
 521 the loading rate. Indeed, in statics the base for the measurement is the formula  
 522 (Williams 1984):

$$G_c = \frac{P_c^2}{2b} \frac{dC}{da} \quad (5)$$

**Fig. 15** Double cantilever beam specimen (a) and tapered double cantilever beam specimen (b)

where  $P_c$  is the critical load for crack propagation,  $b$  is the joint width,  $a$  is the crack length, and  $C$  is the specimen compliance, i.e., the displacement to force ratio ( $\delta/P$ ). In case of an impact test, the main problem which arises in evaluating the fracture energy is that (as already remarked previously) the force-displacement curve exhibits strong oscillations and, therefore, it is tricky to read from it the relevant information. To avoid this problem, expressions that do not directly make use of load values must be adopted, such as for the double cantilever beam specimen (Kinloch 1997):

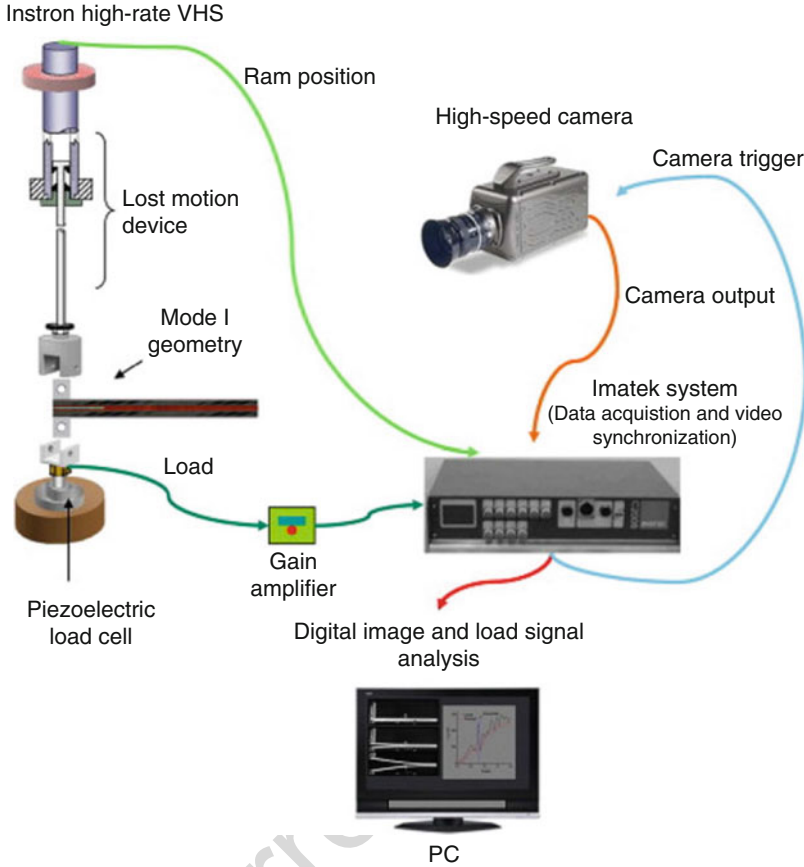

$$G_c = \frac{3}{16} \frac{F}{N^2} \frac{\delta_c^2 h_s^3 E_s}{(a + \chi_1 h_s)^4} \quad (6)$$

where  $F$  and  $N$  are correction factors which, respectively, account for the large deflection of the beam and the stiffening effect of the loading block at the ends of the arms,  $\chi_1$  is another correction factor accounting for beam root rotation, and  $h_s$  and  $E_s$  are, respectively, the height of the beams and Young's modulus of the substrate material. The critical displacement for crack propagation  $\delta_c$  and the crack length  $a$  can be monitored by means of an optical system, as long as the test goes on. In the case of the tapered double cantilever beam specimen, the formula accounts also for the variable beam height.

A sophisticated analysis about the measurement of the fracture energy at high rate of loading has been presented by Blackman et al. (2009). These authors have used the double cantilever test and the tapered double cantilever test to evaluate the behavior of an epoxy adhesive, under loading conditions varying from quasi-static to 15 m/s. The experimental setup includes a hydraulic actuator to apply the load, a high-speed camera, and the suitable electronic devices for measuring, amplifying, processing, and storing the data (Fig. 16). Four different types of crack growth have been identified in this work, namely, (1) slow-rate stable, (2) slow-rate unstable, (3) fast-rate unstable, and (4) fast-rate stable. Here, "stable" is termed the case of steady propagation, while "unstable" is a discontinuous growth, showing sequences of arrest and propagation. It is interesting to notice that the unstable crack growth can occur at intermediate load rate in the tested range; the difference between slow rate and fast rate depends on whether the kinetic energy of the specimen arms is negligible or not with respect to the fracture energy of the adhesive. It is also remarkable that, at the highest load rate adopted in the tests, the crack growth is again stable; obviously in this case the dynamic effects (importance of the kinetic energy, uncertainty on the measured load) are important. For instance, in case of fast-rate loading and double cantilever beam specimen, the formula for the corrected fracture energy (i.e., accounting for the dynamic effects) is

$$G_{lc} = \frac{3}{4} \frac{Eh^3(V/2)^2 t^2}{(a + \Delta_I)^4} \frac{F}{N^2} - \frac{33}{140} \frac{Eh(V/2)^2}{c_L^2} \quad (7)$$

for type 3 crack growth and

**Fig. 16** Experimental setup for high rate testing of adhesives under high rate of loading (From Blackman et al. 2009, copyright Elsevier)

$$G_{Ic} = \frac{3}{4} \frac{Eh^3(V/2)^2 t^2}{(a + \Delta_I)^4} \frac{F}{N^2} - \frac{111}{280} \frac{Eh(V/2)^2}{c_L^2} \quad (8)$$

for type 4 crack growth. In both Eqs. 7 and 8,  $E$  is Young's modulus of the substrate material,  $h$  is the height of the beam,  $V$  is the velocity applied by the actuator,  $t$  is the time,  $a$  is the crack length,  $\Delta_I$  is the correction factor for beam root rotation,  $F$  and  $N$  are – again as in Eq. 6 – the correction factors for large deflection of the beam and stiffening effect of the loading blocks, and  $c_L$  is the longitudinal wave speed in the substrate material. The first term in Eqs. 7 and 8, which can be obtained from Eq. 6, has the meaning of energy calculated as in static conditions, from which the second term, corresponding to the kinetic energy of the beams, is subtracted. Analogous formulae, of higher complexity due to the non-constancy of the beam section, are available for the tapered double cantilever beam specimen (see again Blackman et al. 2009).

### 21.5.2 Drop-Weight-Based Tests and Alternative Tests

Also in the field of adhesive joining, drop-weight machines are probably the test rigs that have been used first to generate impact conditions.

Beevers and Ellis (1984) have carried out tests on joint specimens fabricated both from mild steel and aluminum coupons, bonded with a toughened epoxy. A drop-weight machine equipped with a strain-gage transducer has been used for impact testing. Compared to the static case, at 4 m/s impact, the steel joints have exhibited a significant increase in ultimate load, while only a small change has been observed for the aluminum joints. This is ascribed to the different strain rate response of the two materials.

Jordan (1988) has described the use of a special drop-weight testing machine, defined “instrumented guillotine.” Its peculiar features are the use of a counterweight to adjust the impact energy, from a maximum of 800 J to values lower than 100 J, and a striker of linear shape. The apparatus has been used to test sandwich-type specimens, comparing the impact behavior of epoxy- and acrylic-bonded joints with riveted or spot-welded ones.

Regarding the measurement of the impact strength in terms of force or stress, a first case is represented by the simple butt joint of hollow cylinders, loaded axially in tension. A thorough evaluation of it has been presented by Sawa et al. (2002, 2003). In these works, impact tests have been carried out on specimens made of two hollow steel cylinders bonded together (Sawa et al. 2002) and a hollow steel cylinder bonded to a hollow aluminum cylinder (Sawa et al. 2003); in both works the adhesive is an epoxy, and the outside and inside diameters of the cylinders are 15 and 5 mm, respectively. Figure 17 shows the experimental setup; it can be noticed

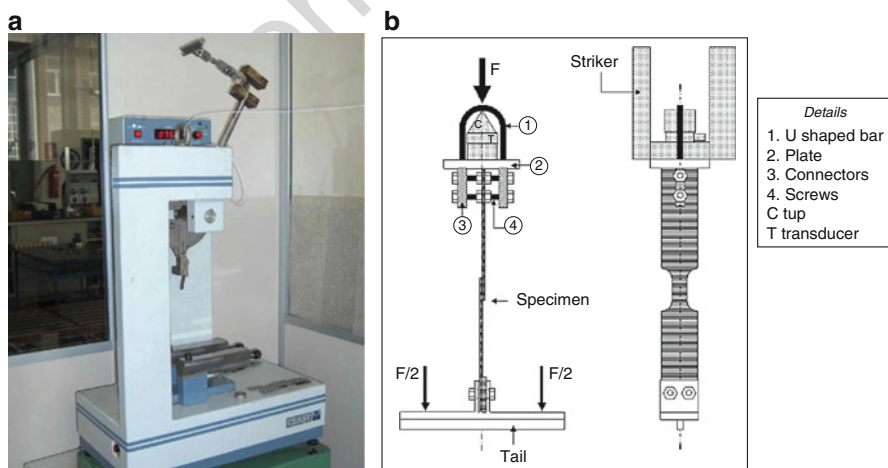

**Fig. 17** Schematics of the impact test on cylindrical butt joints used by Sawa et al. (2002) and Sawa et al. (2003)

that the load is applied by releasing, from a chosen height, a weight that hits the flange of the coaxial guide bar which, in turn, applies the tension to the lower cylinder. The measurements are taken by means of strain gages placed on the surface of the cylinders, close to the bond. The papers describe in detail the finite element elastoplastic modeling of the experiments, which aims at assessing the state of stress and strain in the adhesive; in particular, the peak stress occurs at the outside edge of the interface, its value decreases as the adhesive thickness increases (while the opposite trend occurs under static loading). When the specimens are formed by two steel cylinders, fracture always occurs at the lower adhesive/metal interface, which is reached first by the pulse arriving from bottom; in case of dissimilar adherends, fracture occurs at the adhesive/aluminum interface. The impact energy is higher in case of steel-aluminum specimens than in case of steel-steel, about 1.7 times if the lower cylinder is of aluminum, and about 1.5 times if the upper cylinder is of aluminum. Conversely, the opposite behavior is observed for the peak load, which is higher in case of steel-steel specimen.

Another notable case is the study of lap joints under different impact conditions. A reason in favor for this choice is that the single-lap joint is the commonest type of specimen used for static testing; thus it appears straightforward to test the same geometry under dynamic conditions, to evaluate the influence of the loading rate without introducing additional (and possibly misleading) effects due to a change of geometry.

Goglio and Rossetto (2008) have tested single-lap specimens using a modified instrumented Charpy pendulum (Fig. 18). The specimen is mounted on the hammer by means of a fixture that pulls its front half; the back half of the specimen is connected to a transverse tail. When, at the end of the fall, the hammer reaches its lowest position, the tail impacts a pair of stoppers fixed to the pendulum base, and

**Fig. 18** Charpy pendulum adapted to test lap joints: (a) overall view; (b) fixation of the specimen on the hammer (From Goglio and Rossetto 2008, copyright Elsevier)

this causes tension in the specimen. This scheme is opposite to that used in other works, such as by Harris and Adams (1985), in which the specimen is fixed at its back half to the pendulum base; the hammer during its fall hooks the front half specimen, thus applying the traction. The hammer is instrumented with a piezoelectric load cell, so that the force can be measured and recorded. The scheme reproduces, in dynamic conditions, the usual stress state of the single-lap joints, with shear and peel stresses concentrated at the overlap ends. It is worth noting that in this kind of test, although the hammer speed is moderate (some m/s), for adhesive layers of some tenths of mm the magnitude of the resulting shearing strain rate is  $10^3 \text{ s}^{-1}$ .

In the work by Goglio and Rossetto (2008), several combinations of bonded length (3, 8, 12.5 mm), adherend thickness (1.5, 3 mm), and adhesive thickness (0.5, 1 mm) have been tested, with the aim of producing failure under different blends of stress. In all cases the adherends were of mild steel, and the adhesive was a bicomponent epoxy; failure occurs in the adhesive, while the adherends remain undamaged. The main result is represented by the graph of Fig. 19 in which (with the same style as of Fig. 13) the maximum values of stress (calculated with a mono-dimensional model) corresponding to failure conditions are reported. Also the points corresponding to failure under static loading are plotted for comparison. The increase of stress values changing from static to impact conditions is evident; regarding the effect of the adhesive thickness, it must be remarked that the thinner layer, under the same speed applied by the pendulum, undergoes a higher strain rate.

A drawback of the use of a pendulum is that, due to the transfer of energy from the hammer to the specimen, the speed during the impact is not exactly constant (although the speed drop is usually limited). A solution to avoid this, used by Cayssials and Lataillade (1996), is to replace the pendulum with a heavy rotating

**Fig. 19** Failure locus described by normal and tangential maximum stresses; bars show  $\pm 1$  standard deviation (From Goglio and Rossetto 2008, copyright Elsevier)

**Fig. 20** Schematic of the inertia wheel used by Cayssials and Lataillade (1996)

wheel, termed “inertia wheel,” schematized in Fig. 20. Once the wheel (driven by a motor) has reached the desired speed, the specimen is set in position and struck by a hammer fixed at the wheel periphery. Due to the high moment of inertia of the wheel, the reduction of speed is negligible. Also Marzi et al. (2015) have used a rotary device, to assess the dynamic strength of bonded T-peel specimens. Their work has especially aimed at evaluating the performance of a 3D optical systems designed to measure the deformations.

A further alternative to the drop-weight scheme is the use of the “quick crusher,” mounted on a standard tensile testing machine. With this device, the jaws are initially kept open, while the crosshead accelerates; then, they suddenly clamp the specimen, applying an impact load. Schiel et al. (2015) adopted it to assess the impact behavior of bonded joints between zinc-coated or painted sheet metal, typical of the automotive industry. They have found that, in joints fabricated with epoxy adhesives, the weak point is the metal-coating interface or the coating itself.

Another mode in which a lap joint can be impact loaded is out of plane bending. The reason of interest for this case is that, although bonded panels are designed and tested considering their service condition (which, usually, causes in plane loading), the capability of sustaining unexpected transverse impact loads must be assessed as well. For instance, in aerospace construction cases of interest are impacts with debris (in service) and fall of tools (during manufacturing or maintenance).

To validate a spring-mass model of a lap joint under three-point bending, Pang et al. (1995) have carried out low-velocity impact tests on joints of composite laminates, hit by the hemispherical impactor of a drop tower instrumented with semiconductor strain gages to measure the force. Two different overlap lengths and two different adherend thicknesses have been used in the experiments; also the drop height has been varied to obtain different velocities in the range 3.6–4.6 m/s approximately. In this way, the authors have measured the force time history in the

**Fig. 21** Schematic of the transverse impact tests carried out by Higuchi et al. (2002)

impacts and, in particular, the peak force, to correlate it with joint geometry and impact velocity.

Similar experiments have been carried out by Higuchi et al. (2002) to validate the finite element analysis of a single-lap joint. The specimens used in this work were mild steel plates bonded with an epoxy adhesive; strain gages have been applied (in longitudinal direction) on the mid thickness of the adherends to measure the local strain during the impact (see Fig. 21); the impact velocity was about 1 m/s. The goal of this work is to assess the stress distribution on the adherend-adhesive interface which is obtained from finite element results, since it is not possible to measure it directly (the model is validated by comparing its results in points at mid thickness of the adherends, where experimental measurements have been obtained with strain gages). The main findings concern the maximum principal stress  $\sigma_1$ , which attains its maximum near the edge of the interface of the adhesive with the upper (impacted) adherend. It has been noticed that, unlike the case of static loading, such principal stress increases for increasing adherend Young's modulus, overlap length, and adherend thickness; this is due to the fact that, increasing these parameters, the joint reacts with higher stiffness to the displacement imposed by the impactor. Conversely, increasing the adhesive thickness, the principal stress decreases, as it happens in the case of static loading.

Vaydia et al. (2006) have considered the case of bonded composite panels, again impact loaded in three-point bending. In this work, the specimens were epoxy-carbon strips manufactured from carbon fabric; three distinct types of adhesives were used, namely, two different bicomponent epoxies and a nanoclay-reinforced (7%) epoxy. The latter case is considered to test the strength of an adhesive composition suitable to improve its performance under harsh condition (moisture uptake), although such high nanoclay content is expected to reduce the mechanical properties. Impact is applied by the tip of a drop-weight machine, with the setup shown in Fig. 22; the velocity is in the range 1–2 m/s. An extensive finite element analysis was carried out to understand the response of the joint to this loading condition. Model results confirm that there is a strong stress concentration at the ends of the overlap; in particular the peel component has a negative peak at the end of the upper (i.e., impacted) adherend and a positive peak at the end of the unloaded adherend. This fact can be understood by means of a simple argument about the rigid body relative rotation of the two adherends induced by the impact. Also, the shear stress peaks at the ends of the overlap, but the intensity is lower. The examination of

**Fig. 22** Schematic of the transverse impact testing of bonded composites (From Vaidya et al. 2006, copyright Elsevier)

the broken specimen suggests that the crack is initiated by the shear stress and then propagated by the dominant peel stress.

In addition to the strength of adhesives under impact, also the properties related to dynamic deformability are of interest. Sato and Ikegami (2000) have studied the cases of lap joints and scarf joints subjected to axial impact loads. Preliminarily, they have measured the attenuation of the axial strain waves in a special specimen of epoxy adhesive, manufactured (by molding the adhesive resin) as a cylinder of length 900 mm and diameter 20 mm. From these results, the complex compliance of the material was obtained and, in turn, used to identify the parameters of a five-element Voigt model of viscoelasticity. These material data have been introduced in the finite element simulation of the impact tests on the joints. The joints used in these tests were made by aluminum strips 4 mm thick – bonded with the abovementioned epoxy – and adopting three different kinds of geometry, namely, single lap (square ended), tapered, and scarf. The equipment used for carrying out the tests is shown in Fig. 23; the impact bar driven by the cam hits the upper end of the specimen applying the impact load. The main difference between the types of specimen is that in the lap joint, the offset of the adherend midplanes creates a bending moment, from which high stresses originate; in the tapered lap joint this effect is mitigated; for the scarf joint the adherends are aligned and the stresses propagate easily through the joint. The measurements confirm these remarks; in the tapered lap joints (overlap length 100 mm, taper length 50 mm), the peak stresses are reduced about 50% with respect to the single lap (overlap length 100 mm); in the case of scarf joint, the stresses are even much smaller and smoothly distributed, since the stress concentration is relieved.

A comparison of the effect of the strain rate on the mechanical response of a brittle and a ductile adhesive has been carried out by Sugaya et al. (2011), using a drop-weight machine in the tests at higher rates. These authors have found that for the brittle adhesive, the elastic modulus is insensitive to the strain rate, while under increasing strain rate, the tensile strength and the strain at failure increase (the latter remained anyhow small, as only the elastic range was extended). The effect of the strain rate on the ductile adhesive is to increase the tensile strength and to reduce the strain at failure.

**Fig. 23** Experimental equipment for impact testing of lap and scarf joints (From Sato and Ikegami 2000, copyright Elsevier)

Liao and Sawa (2011) have studied the strength of steel shafts bonded in epoxy hollow cylinders and subjected to axial push-off loads. To support their finite element modeling, they have carried out experiments on a drop-weight machine, and the strains in the cylinder have been measured with strain gages. Good agreement has been found between calculated and measured results.

Al-Zubaidy et al. (2012) have tested experimentally the impact behavior of adhesive bonds between steel plates and CFRP sheets, mainly used for retrofitting existing steel structures. Double strap specimens with different numbers of CFRP layers, fabricated with an epoxy adhesive, have been subjected to impact loads up to

5 m/s applied by means of a drop-weight machine. The results have shown the existence of an effective bond length, above which a further increase in overlap does not increase the ultimate load. Compared to the static strength, the impact strength has increased at loading rate 3.5 m/s and decreased at higher rates.

Liao et al. (2013) have modeled single-lap adhesive joints with dissimilar adherends (aluminum-steel) subject to tensile impact and carried out experiments on a drop-weight machine. In the finite element calculations, the Cowper-Symonds model has been used to account for the strain rate dependence. Finite element and experimental results have agreed in showing that (unlike the case of static loading) under impact the failure starts at the interface of the stiffer adherend.

By investigating the behavior of a phenolic resin adhesive blended with rubber, using a pendulum-like testing machine, Adachi et al. (2015) have found an experimental validation of the principle of equivalence between strain rate and temperature. They advance that impact strength could be predicted by applying the principle.

Kadioglu and Adams (2015) have studied the behavior of a flexible viscoelastic tape for automotive application. Single-lap joints of high-strength steel have been tested on a pendulum equipped with a load cell and a laser for measuring the displacement. Compared to static response, an increase of more than twice in adhesive shear strength has been noticed at 1.4 m/s impact speed.

The impact behavior of a pressure-sensitive adhesive has been studied by Hayashida et al. (2015) using butt joint and double cantilever beam specimens and measuring the deformations by means of a high-speed camera. Transparent adherends have been used to observe cavitation and fibrillation, which are the phenomena controlling ductility for this adhesive. It has been noticed that under increasing strain rate, the strength of the butt joints increases, while the fracture energy of the double cantilever beam specimens decreases. This is ascribed to the fact that at high strain rate, the pressure-sensitive adhesive becomes brittle due to viscoelastic effects.

Silva et al. (2016) have studied joints for automotive use, fabricated by combining adhesives of different types, ductile or brittle, as sketched in Fig. 24. The ductile and soft adhesive is placed in the ends of the joint overlap, to smoothen the stress concentrations, while the brittle and hard adhesive is set in the middle of the joint. Impact tests carried out with a drop-weight machine have shown that such a design exploits the best of the two kinds of adhesives, in terms of ultimate load (as shown in Fig. 25) and energy.

## 21.6 Conductive Adhesives

A field of application that has received attention in the last two decades is the use of conductive adhesives to replace soldering in electronic applications. Such change can bring advantages mainly of ecological type, eliminating the dangerous substances that can be produced by the soldering process and the need for energy to melt the solder. An important advantage given by adhesive joining is that the pitch between neighboring contacts can be shorter compared to the case of soldering, and this is beneficial as far as miniaturization is concerned. Apart from the technological differences introduced by adopting a new technology, the main concerns related to the use of adhesives in this field are unstable contact resistance and impact strength.

Zwolinsky et al. (1996) have reported results obtained by a project of the National Center for Manufacturing Sciences (NCMS), carried out in the early 1990s to assess the suitability of 25 conductive adhesives available on the market at that time. In particular, regarding the assessment of the impact strength, experiments of two types were performed. In the first phase of the project, specimens made with a plastic leaded chip carrier (PLCC) bonded on a coupon were dropped repeatedly from two

different heights, respectively, 0.457 m (18 in.) and 0.914 m (36 in.), recording the number of drops needed to detach the PLCC for each height. In the second phase, drop tests were carried out in specimens formed by a board containing a collection of components, joined by bonding. Each specimen was subjected to three drops from the height of 0.914 m (36 in.). The presence of damage due to the impacts is noticed both by visual inspection and by measurement of the electrical resistance. The result of this series of tests was that the commercial adhesives used at that time were not capable to withstand the impact condition. The authors recommend evaluating the impact performance of an adhesive with a series of 6 drops from 1.52 m (60 in.), with a specimen formed by a bonded PLCC. This recommendation is one of the bases of the NCMS specification for solder replacement adhesives.

Another study of the impact performance of the conductive adhesives was carried out by Daoquiang and Wong (1999). To overcome the poor impact performance of the commercial conductive adhesives, these authors have proposed an adhesive of new formulation containing epoxy-modified polyurethane resin and bisphenol-F. The adopted impact test method is again the one proposed by NCMS and mentioned above (Fig. 26); the channel in which the specimen under test is dropped has the aim of avoiding rotation, thus forcing the part to impact the ground with a defined edge. In their work, these authors have also measured the internal damping of the adhesive, and they have noticed that the materials having high loss factor ( $\tan \delta$ ) are also the most capable to withstand the impacts.

It is evident that the abovementioned experiments obtain, as outcome, the simple result of failure or survival of the specimens. No insight is found about the stress state in the bonds; furthermore, the drop test assesses the strength of the bonded

**Fig. 26** Schematics of the NCMS drop test for bonded electronic components

**Fig. 27** Falling wedge test arrangement for conductive adhesives (From Xu and Dillard 2003, copyright IEEE)

specimen, not of the adhesive itself. More recent works aim at studying the impact behavior of the bonded electronic parts with the methods of fracture mechanics or structural dynamics.

Wu et al. (2003) have tested surface mount joints in printed circuit boards, comparing the behavior of an isotropic conductive adhesive with a traditional lead-tin soldering alloy. Joint specimens have first undergone impact on a modified Hopkinson bar, specialized to create three-point bending conditions. Then, after the impact, the specimens (if not already failed) have been destructively tested under shear to assess their residual strength. It has been noticed that the residual shear strength of the joints decreases under increasing strain rate. Compared to the soldering alloy, the adhesive has exhibited lower strength, which nonetheless can be considered satisfactory for practical applications.

Xu and Dillard (2003) have studied the impact strength of conductive adhesives by means of a new impact test, termed falling wedge test (Fig. 27). Its principle is similar to that of the double cantilever beam: a pair (because of the symmetry of the specimen) of wedges fall along a drop tower and with its motion splits apart the two substrates of the bonded joint, mounted vertically on the base of the test rig. To avoid the typical problems related to impact load measurement (already recalled in this section), no load measurement is carried out directly. In the test rig the deformation of the sample is captured by means of a high-speed camera, so that the displacement of the end points and the deformed shape of each beam are obtained from the images. The fracture energy is calculated as

$$G_c = \frac{9\delta_0^2 EI}{4Ba^4} \quad (9)$$

where  $\delta_0$  is the opening displacement,  $E$  is Young's modulus of the substrate,  $I$  is the moment of inertia of the beam section,  $B$  is the beam width, and  $a$  is the crack length. It is easy to notice that Eq. 9 is a simplified version of Eq. 6, in which the correction factors are neglected. The specimens are coupons of printed circuit boards bonded in their central part (by means of a spacer); the adhesives are three different silver-filled epoxy adhesives, especially produced for this research. The tests have been carried out at several temperatures, between  $-70^\circ\text{C}$  and  $90^\circ\text{C}$ , at a fixed impact speed of about 1.6 m/s. It has been observed that the results are influenced by the temperature when the glass transition temperature ( $T_g$ ) of the adhesive is in the considered range; in particular a maximum of  $G_c$  has been noticed for a test temperature close to the  $T_g$  of the adhesive under consideration. These series of tests have confirmed the correlation between the loss factor of the material and the fracture energy.

Rao et al. (2004), reprising the case considered in a work mentioned above (Daoquiang and Wong 1999), have added the study of the first natural frequencies and mode shapes of an electronic packaging formed by a PLCC bonded to a coupon of printed board. From the theoretical viewpoint, an ideal impulse would excite all natural frequencies of the system. This study has considered the first ten natural frequencies, whose range of values, obtained with a finite element model, is extended up to 2 kHz approximately. The impact behavior of the adhesive is adequate if its damping is high enough to dissipate energy over the whole range. The authors have measured the loss factor of four different adhesives, in a frequency range from 0.1 to 3,000 Hz. Comparing these measurements with the results obtained from the drop tests, it has been once again observed that the capability of withstanding the impact is related to the internal damping.

A comprehensive state-of-the-art review on conductive adhesives has been presented by Irfan Mir and Kumar (2008), which considers the main related problems and, among these, the aspects regarding impact strength.

## 21.7 Response to Environmental Conditions

A quite peculiar case is that considered by Park and Kim (2010), who have tested single-lap joints between composite panels subjected to transverse impact of ice spheres, to reproduce the effect of hailstones against an aircraft or other structures exposed to the phenomenon. The experiments and the related finite element simulations have shown that damage occurs if the kinetic energy of the impactor exceeds a threshold. The most important failure mode is delamination, both for panels and joints; however, also adhesive failure can occur. Examination of the specimens has shown that the damage is mainly due to the stress concentration related to the joint. Thus, a joined assembly is more susceptible to this type of damage than a monolithic panel.

Zhang et al. (2015) have studied the response to the strain rate after hydrothermal exposure in an experimental study on joints made of metal adherends (steel, aluminum) bonded with a toughened epoxy. By comparing the response at several crosshead speeds with the quasi-static conditions, they have noticed that: loading rate and aging can be regarded as independent influencing factors (with negligible interaction); the ultimate load is increased by loading rate and decreased by the hydrothermal exposure. The effects of these two factors can be accounted for by means of a linear empirical formula, to predict the resulting strength.

---

## 21.8 Conclusions

This chapter has described the main tests used to assess the impact strength of adhesives and joints, considering both those foreseen by international standards and those appeared in research papers. The main types of test rigs used in the experiments are pendulum, falling weight and Hopkinson bar, or evolutions of these.

The major conclusions of this survey are the following:

1. Of the two standard test methods, the block impact (ASTM D950) is the easiest to carry out and does not require sophisticated equipment, but the only result it gives is the absorbed energy. Moreover, the specimen made of bonded blocks is far from the case of a typical joint, made of thin substrates; thus, this test can give (at best) only a comparison between different adhesive systems. The study by Adams and Harris (1996) has shown that even small errors of alignment can deeply modify the stress profile in the specimen; thus also the use of this test for comparison between adhesives is questionable.
2. The other test foreseen by a standard is the wedge peel impact (ISO EN 11343). Although in this case the arrangement is more representative of a real joint, the immediate answer given by the test rig is a property (energy) of the system formed by specimen and adhesive. Sophisticated data processing is required to extract further information and correlate the result of this test with the adhesive fracture energy  $G_c$ , as done by Blackman et al. (2000). These authors have also shown that in case of unstable crack growth, the ISO standard procedure to process the force time history can produce wrong results. They have also found that the effect of the friction between wedge and strips plays a minor role, compared to  $G_c$ .
3. When the mechanical properties of the adhesive at high loading rate (strain rate  $10^3 \text{ s}^{-1}$ ) are sought, the appropriate test rig is the Hopkinson bar. This apparatus is suitable to test specimens of adhesive under compression in straightforward manner; tests under tension can be carried out with modifications of the basic scheme. Also simple joints can be tested, by properly adapting the ends of the bars. In the last decade, this equipment has become more and more popular and adapted to tests specimens of various shapes (e.g., lap, pin-collar) under different loading conditions (e.g., tension, bending, shear).

4. In the research works presented in the literature, many test rigs are based on the falling weight scheme; alternatively, the impact is applied by a hydraulic ram. In most cases, the specimens are single-lap joints, impacted axially (i.e., in tension) or transversally (i.e., in bending). Usually, in this kind of tests, the impact force is measured by a load cell embedded in the impactor, and the time history is recorded electronically. The typical problem of this measurement is that what is actually measured depends also on the dynamic response of the system formed by specimen and test rig; thus the observed oscillation is not only due to the start and growth of the crack in the joint. For this reason, when the determination of fracture mechanics properties (usually  $G_c$ ) is sought, the use of force measurements is avoided, and the displacement is preferred instead.

As a final remark, it can be added that frequently the experimental studies on the behavior of adhesive or joints under impact are presented together with finite element simulations. This interaction between testing and modeling is, in this field, especially needed, since the possibility of direct measurement of the desired quantities is limited and hindered by the complications introduced by the dynamic response of the tested system.

**Abstract**

This chapter gives a brief description of special mechanical tests for various types of materials and sample geometries, such as blister tests for membranes/adhesives/coatings, tensile tests and shear tests for sealants and foam adhesives, indentation and scratch tests for coatings, tack tests for pressure sensitive adhesives, and bimaterial curvature tests for characterizing residual stress, stress-free temperature, and coefficient of thermal expansion of adhesives bonded to substrates of interest. In addition, some applications of these tests are also described in this chapter.

## 22.1 Introduction

In addition to standard adhesion tests or failure tests, many of which are described in other chapters of this handbook, a wide range of special tests are also performed for specific purposes in industry or in scientific research. In this chapter, several of these special mechanical tests are reviewed, including blister tests for membrane/adhesive/coating, tensile tests and shear tests for sealants and elastomeric foam adhesives, indentation tests and scratch tests for characterizing coating adhesion.

## 22.2 Blister Tests

The blister test is a method to determine the fracture (adhesion) energy between a substrate and a flexible adherend, which could consist of a plate or membrane adhered to the substrate or could simply be an adhesive layer or coating. The blister test was first introduced by Dannenberg for characterizing paint adhesion (Dannenberg 1961; Maugis 1999), although the more familiar form was introduced by Williams (1969). Blister tests are typically loaded by pressurizing the cavity between the substrate and flexible adherend and monitoring the growth of the debond as a function of applied pressure and, in some cases, time. Blister tests can be advantageous for some systems, including when pressurization may mimic actual application conditions, when relevant environments can be used as the pressurization media, and to avoid the need for mechanically gripping for loading. A wide range of blister configurations has been proposed and used, including some which are illustrated in Fig. 1.

In the standard blister test, the flexible adherend is assumed to behave as a plate, with compliance based solely on plate bending. Assuming that the pressure-deflection relationship is linear, the fracture energy is easily obtained by determining the deflected shape at a given pressure using simple plate theory, resulting in:

**Fig. 1** Illustrations of several blister test configurations

$$\mathcal{G} = \frac{3p^2(1-\nu^2)a^4}{32Eh^3} \quad (1)$$

where  $\mathcal{G}$  is the applied strain energy release rate,  $p$  is the pressure,  $\nu$  is the Poisson's ratio of the plate,  $a$  is the radius of the debond,  $E$  is the modulus of the plate, and  $h$  is the thickness of the plate (Anderson et al. 1977). When the thickness of the flexible adherend is very large compared to the debond radius, the assumption of plate bending is no longer valid, and the solution approaches that of a penny-shaped crack between two bodies (Anderson et al. 1977). This results, for example, in

$$\mathcal{G} = \frac{3p^2a}{2\pi E} \quad (2)$$

for the the case of a semi-infinite, incompressible adherend bonded to a rigid substrate. On the other hand, when the thickness of the flexible adherend is very thin, the resistance to deflection comes not from plate bending but primarily from membrane stretching, resulting in the membrane blister specimen (Gent and Lewandowski 1987). The membrane deflection solution is inherently nonlinear and more involved, and becomes dependent on the residual stress present within the membrane.

For the membrane blister, the hole radius  $a_0$  (or in some cases, a larger debond initiated during fabrication) is given as the initial decohesion radius, and the membrane is inflated and effectively peeled off at the radius  $a$  ( $>a_0$ ). The relationship between the central deflection  $\delta$  and the pressure  $p$  of a circular membrane with no residual stress is given by (Hencky 1915)

$$\delta = C \left( \frac{pa^4}{Eh} \right)^{1/3} \quad (3)$$

where  $C$  is a constant dependent on the Poisson's ratio (e.g.  $C = 0.662$  for  $\nu = 0.3$  and  $C = 0.595$  for  $\nu = 0.5$ ). The energy release rate  $\mathcal{G}$  for this geometry is given by (Gent and Lewandowski 1987)

$$\mathcal{G} = \frac{5CD}{4} \left( \frac{p^4a^4}{Eh} \right)^{1/3} = \frac{5D}{4} p\delta \quad (4)$$

where  $D = 0.518$  for  $\nu = 0.3$  and  $0.519$  for  $\nu = 0.5$ . As pressure is gradually increased, debonding is expected to occur at a critical pressure  $p_c$  for a debonding energy of  $\mathcal{G}_c$

$$p_c = \left( \frac{4w}{5CD} \right)^{3/4} \frac{(Eh)^{1/4}}{a_0} \quad (5)$$

at a critical central deflection of

$$\delta_c = \left( \frac{4wC^3}{5DEh} \right)^{1/4} a_0 \quad (6)$$

In all of these test configurations, debonding can often be induced between the adherend and substrate by injecting a gas (for example, nitrogen) or a liquid (e.g. water) under pressure through a small hole in the substrate, as shown in Fig. 2. This membrane form of the blister test has certain advantages in that mechanical testing is sometimes possible even for thin films which are, in general, difficult to evaluate with other mechanical testing approaches due to the soft or delicate nature of the film. Fracture mechanics theory can be applied to evaluate the fracture energy, and with appropriate analysis, accurate measures of debond energy can be obtained. Another advantage is the fact that the test geometry is similar to that in actual usage for coatings or paint, i.e., the evaluation of the film is possible in a geometry relevant to actual applications.

While the blister test provides several advantages for the quantitative evaluation of the fracture energy, there are disadvantages. For example, in order to put holes to pressurize the film, fabrication processes of drilling or etching are often needed, and securing an appropriate initial configuration that results in desired delamination without tearing or bursting the membrane can be involved. In some cases, an auxiliary adherend can be adhered on top of the membrane to reinforce it, though this influences the resulting deformation and energy analysis. For complex hole structures, such as the island and peninsula blister tests, discussed later, the process of undercutting the membrane can be even more complex. In addition, the blister test is limited to sufficiently flexible films like polymer coatings. For hard films, brittle fracture of the film can occur prior to the delamination under the applied pressure. Again, for such cases, a backing or auxiliary adherend can be added to reinforce the fragile coating, however, often resulting in a successful means to evaluate adhesion.

In order to overcome such disadvantages, the blister test has been extended by several researchers. The inverted blister test (Fernando and Kinloch 1990; Jiang and Penn 1990; Fernando et al. 1993) has been developed to reduce the likelihood of cohesive failure or film bursting. Figure 3 schematically shows the inverted blister test. A sufficiently tough and flexible substrate of film geometry is delaminated from the coating or the adhesive adhered firmly onto the support plate, instead of delamination of the coated thin film from the substrate in the standard blister test. The island blister test (Allen and Senturia 1989), the peninsula blister test (Dillard and Bao 1991), and the constrained blister test (Chang et al. 1989) have been proposed. These tests are schematically shown in Fig. 1. In the island blister test, a small “inner island” induces larger driving force for the propagation of the delamination front than that on the periphery (the crack

**Fig. 2** Geometry of the membrane blister test. Fluid is injected through a small hole of radius  $a_0$  under a pressure  $p$  and the membrane of thickness  $h$  is deflected by  $\delta$  and peeled off at radius  $a$

**Fig. 3** Geometry of the inverted blister test

initiation point for the standard blister test), which results in effective delamination at the interface between the film and the substrate island. The peninsula blister test is an extension of the the island blister test, developed to improve the stability in that it is a constant energy release rate specimen. Both tests tend to induce high values of applied energy release rate because of the very localized debonding fronts (Lai and Dillard 1994; Liechti and Shirani 1994; Lai and Dillard 1996; Xu et al. 2006). In the constrained blister test, a transparent rigid cover plate prevents the film from bursting while permitting observation of the delamination front (Chang et al. 1989; Lai and Dillard 1990a, b). Theoretical treatment of some of these tests can also be found in Williams (1997).

Although pressurization of circular or other confined cavities are popular for blister tests, mechanical loading has also been reported as with the shaft-loaded blister (Wan and Mai 1996) and is sometimes simpler to implement in the laboratory. Simple linear versions of blister tests are also popular. The central debonded region of a strip bonded along much of its length to a rigid substrate can be displaced from the substrate, inducing a peeling action. This configuration, known as the pull-off (Gent and Kaang 1986), strip blister (Liechti and Liang 1992), or V-peel (Wan 1999) test by various authors, is simple to perform and results in a particularly simple solution when the flexible adherend deformation is controlled by membrane stretching:

$$\mathcal{G} = \frac{3F\theta}{8b} \quad (7)$$

where  $F$  is the applied force,  $\theta$  is the peeling angle in radians, and  $b$  is the width of the strip. One advantage of this geometry is that the relatively shallow debonding angles reduce plastic bending in the adherends, often resulting in practical or measured peel energies that are closer to the actual debond energy (Kinloch et al. 1994; Moidu et al. 1995, 1998b; Kinloch and Williams 2002; Kinloch et al. 2006).

There are other variations of the blister test and the literature abounds with a range of solutions, so special care should be used for when applying the equations reported in the literature for various blister configurations. In particular, solutions often apply to either block-like (or semi-infinite), plate-like, or membrane-like behavior, as discussed above, so the relative thickness of the flexible substrate to the debond size is of critical importance. Transition regions have been considered by several

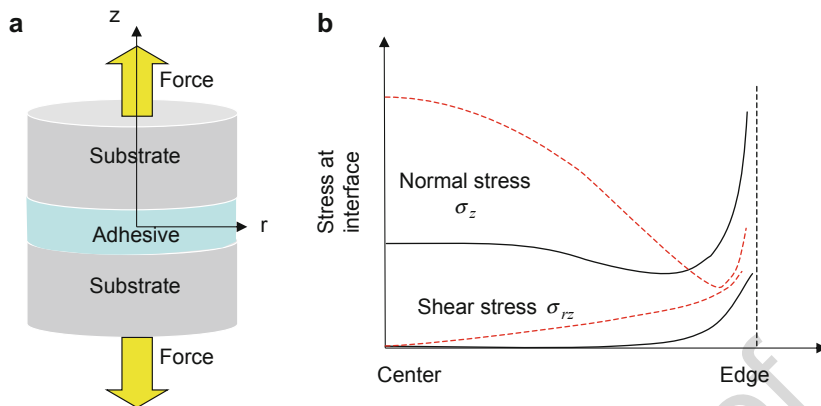

authors (Anderson et al. 1977; Wan and Lim 1998). The transition from plate bending to membrane stretching has received some attention and becomes important when deflections become relatively large (say on the order of the flexible adherend thickness (Wan and Lim 1998). Finally, the presence of residual stress within membrane-like adherends can significantly affect deflections and energy release rate (Dillard and Bao 1991; Wan et al. 2003). Such residual stresses often arise when processing the materials to make specimens, and must be considered and characterized to achieve meaningful experimental results.

## 22.3 Sealants and Elastomeric/Foam Adhesives

Sealants share many similarities with other adhesives, but are often distinguished by their ability to fill gaps and undergo large strains while maintaining a sealing function, forming a barrier or protective layer against water, air, and other intruding media. There are a number of unique challenges for sealant formulation, joint design, and long term durability, however (Klosowski and Wolf 2015). Elastomer adhesives and foam pressure sensitive adhesive tapes are other types of adhesives, but also are used in thick bondline form. Many of the test methods and analysis procedures covered elsewhere in adhesion texts (Anderson et al. 1977; Kinloch 1987; Adams et al. 1997; Pocius 1997; Dillard 2002) and this handbook can be adapted to evaluate these softer and often thicker material systems, though complications can arise and test method adaptations are often employed. Here, the tensile or butt joint test, shear test, tensile adhesion test, and peel test are briefly reviewed with relevance to such materials.

Figure 4a shows the geometry for the tensile butt joint test, also known as the poker-chip or button test. Two rigid cylinders are bonded end to end with the adhesive or sealant of interest, and the joint is tested by applying tensile forces to the cylinders, measuring the load at break and, in some cases, the load-displacement curves as well as. Alignment of these specimens can be problematic, as slight eccentricity or misalignment can significantly affect the stress state uniformity and the resulting rupture load (Anderson et al. 1988). Though the test method looks quite simple, special care is also required for the data analysis. In practice, the stress distribution at the adhesive-substrate interface is not uniform (see Fig. 4b), but depends on the elasticity (modulus and Poisson's ratio Normalized) of the cylinders and the adhesive, and also strongly depends on the aspect ratio (thickness/diameter), especially for elastomeric adhesives. A range of solutions can be found, depending on the material and geometric parameters (Lindsey 1967; Anderson et al. 1977; Adams et al. 1978; Shephard 2002). Because of the significant difference in modulus between the substrate and adhesive layer, large triaxial tensile stresses arise within the bond. Assuming the adherends may be considered rigid, the strain can range widely, falling between the bound imposed for highly confined, uniaxial strain conditions approached as the thickness to diameter ratio approaches zero, and the uniaxial stress solution (i.e. very large adhesive thickness to diameter ratio), as respectively given by

**Fig. 4** (a) Geometry of a specimen of tensile test for butt joint. (b) stress distribution at the interface between adhesive and substrate (*solid lines* for smaller Poisson's ratio adhesive, *dashes lines* for elastomeric adhesive)

**Fig. 5** Geometry of a specimen of shear test for (a) the single-lap joint, and (b) the double-lap joint

$$\frac{(1 + \nu)(1 - 2\nu)}{(1 - \nu)} \frac{\sigma_x}{E} \leq \epsilon_x \leq \frac{\sigma_x}{E} \quad (8)$$

This shows that for highly constrained systems, Poisson's ratio also becomes very important, as small deviations from ideal elastomer ( $\nu = 1/2$ ) behavior can dramatically affect the resulting apparent stiffness of the joint (Lai et al. 1992). Specialized precision experimental methods to measure such Poisson's ratios or bulk moduli (Rightmire 1970; Yu et al. 2001; Dillard et al. 2008; Tizard et al. 2012; Motamed et al. 2014) may be needed for some modeling purposes of highly constrained elastomers.

Figure 5 illustrates two types of the shear tests, nominally used to measure the apparent shear strength (ASTM-D1002-99 1999; Packham 2005). In the single-lap joint, an adhesive is sandwiched between two plates and shearing is applied by tensile loading until failure occurs. Though this test has advantages in that the method is quite simple and typical of many joint configurations, complexities associated with load eccentricity, bending moments, and terminal regions result in non-uniform normal and shear stress states along the length of the bond (Goland and Reissner 1944; ASTM-D4896-95 2001), effects that are exaggerated by the larger bondline thickness of elastomeric material systems discussed in this section.

**Fig. 6** Geometry of a specimen of tensile adhesion test for sealants, elastomers, or foam adhesives

In order to reduce the rotation and peeling resulting from the eccentricity, the double lap joint has sometimes been advocated. The double-lap joint essentially consists of two single-lap joints, and although peeling is reduced by the symmetric configuration, it is not eliminated and can continue to dominate failure (Borgmeier and DeVries 2000).

Figure 6 is a schematic of the tensile adhesion test, where the adhesive is filled into the space between two adherends and two spacers. In the tensile adhesion test, after the spacers are removed from the specimen, the adhesive may be extended by external loading. When a given elongation (i.e., 25%, 100%, etc.) is reached, the specimen may be fixed for a period of time (ex. 24 hours) with spacers, and any resulting failure type (cohesive or adhesive) is recorded. Cyclic straining, including in the presence of environment, is a common means to load such specimens (ASTM-C719-14 2014) for durability assessment.

Finally, yet another common characterization method for many adhesives, including sealants, are a variety of peel tests. 180° peel tests are particularly common for sealant testing because of the very simple fixturing requirement, though 45°, 90°, and other angles are also used. Reinforcing wire or fabric is often embedded in the sealant to provide enough integrity to prevent peel arm rupture, and also to minimize peel arm straining, which can significantly affect the measured peel force and resulting debonding energy calculations. Stretching of the peel arm requires additional input work, which is typically accomplished through larger crosshead movement, albeit with smaller required forces (Lindley 1971). Although commonly tested at fixed displacement rates (ASTM-C794 2010), these tests can be loaded at a range of rates, temperatures, and humidities, for example, to assess long term performance through viscoelastic superposition methods. Dead loads can also be applied to obtain long-term failure rate information.

Elastomeric foam tapes produced by several manufacturers are finding applications in a wide range of non-structural and even semi-structural applications, including supporting road signs, facades, ceilings, and some load-bearing supports, as well as in the assembly of some transportation vehicles and trailers. Combining a relatively thick, highly dissipative and flexible layer with adequate adhesion offers opportunities for significant energy dissipation, potentially resulting in damage-tolerant solutions where design stress levels are relatively small. Some of these products can be used as alternatives to more traditional sealants, including for mounting windows in commercial buildings. Representative studies of such materials can be found in Townsend et al. (2011a, b, 2012).

## 22.4 Indentation Tests

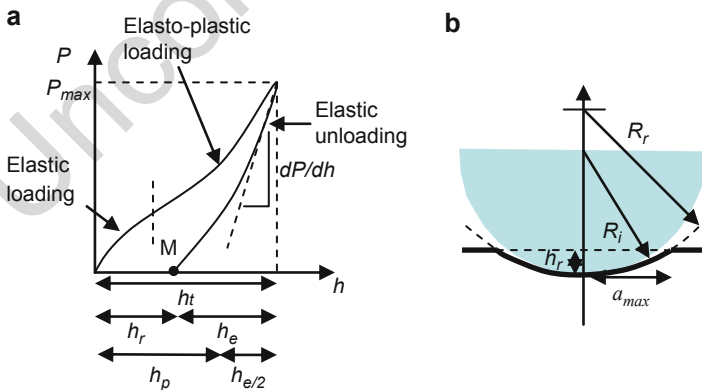

Indentation tests can be used to determine the **hardness** and the elastic modulus of a material (Tabor 2000), and in some cases, the interfacial fracture resistance of thin coatings (Ritter et al. 1989, 1992). Several tests are proposed using different types of indenters such as spherical, three-sided pyramidal, or four-sided Vickers, and the tests are performed not only on a macroscopic scale but also on a microscopic one; measurement of the hardness at very small scales is called nanoindentation. Advantages of the indentation test include that only a small sample is needed, minimal specimen preparation is required, and in some cases even portable equipment can be used to measure the mechanical properties of the material.

Figure 7 shows a schematic for an indentation test of a flat specimen with a spherical indenter. The depth of penetration of a rigid spherical indenter beneath the specimen is  $h_t$  at full load  $P_{\max}$ . When the load is removed, assuming no reverse plasticity, the unloading is elastic and at complete unloading, there is a residual impression of depth  $h_r$ . If the load  $P_{\max}$  is reapplied, then the reloading is elastic through a distance  $h_e = h_t - h_r$  according to the Hertz equation:

$$P = \frac{4}{3}E^*R^{1/2}h_e^{3/2} \quad (9)$$

where  $E^*$  is the composite elastic modulus

$$\frac{1}{E^*} = \frac{1 - \nu^2}{E} + \frac{1 - \nu'^2}{E'} \quad (10)$$

**Fig. 7** Load-Displacement curve for an elastic-plastic specimen loaded with a spherical indenter (radius  $R_i$ ) showing both loading and unloading response. Upon loading, there is an initial elastic response followed by elasto-plastic deformation. Upon unloading, the specimen shows elastic response and comes back to the residual displacement  $h_r$  with the residual impression of radius  $R_r$ .

where  $E$ ,  $E'$ ,  $\nu$  and  $\nu'$  correspond to Young's moduli and Poisson's ratio for the substrate and indenter, respectively and

$$\frac{1}{R} = \frac{1}{R_i} - \frac{1}{R_r} \quad (11)$$

with  $R_i$  and  $R_r$  being the indenter radius and the radius of residual impression, respectively.

Using these equations with the known indenter parameters ( $E^*$ ,  $\nu'$ , and  $R_i$ ) and measured radius of residual impression  $R_r$ , the elastic modulus of the material  $E$  can be determined. The hardness  $H$  can also be quantified by

$$H = \frac{P_{\max}}{\pi a_{\max}^2} \quad (12)$$

where  $a_{\max}$  is the contact radius at maximum load.

Microindentation tests are performed to measure the hardness and the elastic modulus of small specimens with low applied loads. One of the most difficult problems in the microindentation test is to determine the contact radius (Fischer-Cripps 2000). In this case, the contact radius is estimated by the following equation.

$$a_{\max} = \sqrt{2R_i h_p - h_p^2} \cong \sqrt{2R_i h_p} \quad (13)$$

where  $h_p = h_t - h_e/2$  is the the plastic depth, as defined in Fig. 7. Oliver and Pharr (1992) proposed a method to determine the plastic depth as

$$h_p = h_t - \frac{3}{4} \frac{P_{\max}}{dP/dh}. \quad (14)$$

the derivative  $dP/dh$  is calculated by the initial slope of the load-displacement curve at the unloading phase (see Fig. 7).

The use of indentation tests to measure coating adhesion has received wide attention, including for very thin coatings (Oliver and Pharr 2010). Delamination can result from a combination of shearing and tensile stresses developing across the interface. Indentation can induce high stresses across the interface in the vicinity of the interface, but also can induce a compressive in-plane residual stress within the coating, which can contribute to the debonding process through buckling-driven delamination (DeBoer and Gerberich 1996a, b; deBoer et al. 1997a). Overlayers or superlayers can also be added to provide additional stored energy to drive the delamination at the desired interface (Bagchi et al. 1994). A related test, the notched coating adhesion test (Chang et al. 1997; Dillard et al. 1999), involves indentation with a razor blade to sever the coating and induce local debonding, which can then be propagated by subsequent mechanical straining of the substrate. This test has also been used to assess structural adhesive durability as the diffusion times are much shorter for open-faced coatings rather than bonded adhesive joints (Chang et al. 1997;

Moidu et al. (1998a). Other experimental approaches are able to use residual stress alone to propagate debonding, both for tensile (Farris and Bauer 1988) and compressive coating stress states (Hutchinson et al. 2000). Comprehensive theoretical treatments of stresses and fracture of layered and coated systems can be found in Hutchinson and Suo (1992) and Freund and Suresh (2010).

## 22.5 Scratch Tests

The scratch test is a method to determine the adhesion strength of a coated layer, and many embodiments of this method have been proposed, including a number with commercially available instruments designed for this purpose. In the scratch test, as schematically shown in Fig. 8, an indenter or stylus is translated across a coated substrate, typically at a constant velocity under an applied normal force of increasing magnitude. Stresses are introduced at the interface between coating and substrate, and at a critical load, delamination of the coating occurs. Benjamin and Weaver (1963) performed a simple analysis for the scratch test by using the following equations.

$$F = \frac{AH}{\sqrt{R^2 - H^2}} \quad (15)$$

and

$$A = \sqrt{\frac{W}{\pi H}} \quad (16)$$

where  $A$  is the radius of the contact circle,  $R$  is the radius of the stylus tip,  $W$  is the applied normal load,  $H$  is the indentation hardness of the substrate, and  $F$  is the lateral force. Though they tried to evaluate the coating adhesion by the normal load  $W$  and the lateral force  $F$  at which the the coating is removed from the substrate, there existed several difficulties such as, delamination of the coating before removal, thinning of the film instead of removal, complex elasto-plastic deformation of both coating and substrate, and so on. As with many other coating adhesion tests, real complications make the analysis difficult unless simplifying assumptions are appropriate. In order to improve the scratch test, more sophisticated apparati have been developed. The normal

**Fig. 8** Schematic of the scratch test, in which a coated substrate is moved to the left against a fixed stylus

load is not only controlled to determine the critical load  $W_c$  required to initiate delamination, also the optical microscopy for the monitoring the scratch process and acoustic spectroscopy for detecting acoustic emissions have been employed.

Microscratch and nanoscratch tests have been discussed widely, including in deBoer et al. (1997b). Sarin (1995) developed an alternate version of the scratch test, turning the experiment on its side and performing a micro-scratch test on the cross section of the sample, as shown in Fig. 9. After the edge of the cross section is precisely polished, the scratch test is carried out on a microscopic scale. As a result, the failure mode can be isolated and determined at the coating/substrate interface. In fact, for a titanium carbide (TiC) film coated onto a silicon nitride/titanium carbide (Si<sub>3</sub>N<sub>4</sub> + TiC) ceramic composite, he could generate a crack along the coating/substrate interface and thus obtained a delamination failure mode.

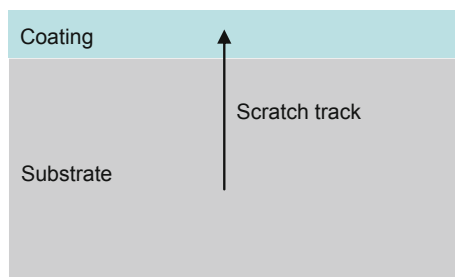

While the scratch test is advantageous for its simplicity in the geometry and ease of the sample preparation, there are several disadvantages. The test is often limited to hard, brittle coatings or nonlinear elasto-plastic deformation complications arise, where the failure mode of the scratch test is not well understood (Bull 2001). Furthermore, the test is very sensitive to the material and the surface geometry or topography of the stylus (Oroshnik and Croll 1978).

However, the scratch test is one of the most popular adhesion tests in both industry and academic research. This comes from the fact that this technique is applicable to the evaluation of a wide range of systems, and commercial equipment is available to perform a variety of functions, such as surface roughness measurement, the evaluation of mechanical properties of the coating, and so on. In particular, the scratch test appears useful for many situations involving hard and brittle coatings. For softer coating, though this test is difficult to extract a true delamination mode from, it is still useful as a complementary test of other techniques. For further information, refer to Lacombe (2006) and references therein.

## 22.6 Tack

Tack is surprisingly complex, with quantitative values often involving a combination of conforming, wetting, bonding, and removal phenomena. Based on the concept of quantifying the adhesion resulting after application of light and momentary pressure,

**Fig. 9** Scratch test using microindenter. The indenter is driven across the substrate and the adhesive on the cross section

tack is intended to measure the aggressiveness of a polymer surface. Tack is widely measured on pressure sensitive adhesives (PSA), but is also of interest in probing the degree of cure or consolidation as other adhesives move from their liquid application state to their solid use state, and for other applications involving adhesion development at interfaces. An underlying concern for tack measurements is that although the intention is to measure the ability of the adhesive to quickly wet and hold a substrate, tack tests inherently involve debonding. Thus, the bonding process is confounded by the debonding process that also occurs upon separation. This involves the creation of new surfaces as cavitation and fibrillation occur, as well as significant rheological dissipation as materials stretch, draw, and break.

Tack is measured by a number of different techniques, ranging from an individual's perception of the "thumb appeal" of an adhesive to sophisticated characterization of the loads and deformations and failure mechanisms involved in bonding and debonding process. Primary tack measurement techniques include probe tack tests, loop tack, quick stick, and rolling ball techniques. These techniques are illustrated schematically in Fig. 10.

The probe tack test involves bringing a probe of desired shape into contact with the adhesive with a prescribed force and duration, then withdrawing the probe at a fixed displacement rate. Some units involve a mechanically driven punch that rises to lift a weight to which a PSA tape has been affixed. The weight can be selected to provide the desired initial contact force and pressure. The probe then drops at a fixed rate, as a load cell records the force. More versatile test frames have also been used to apply controlled force application and probe removal to a wide range of specimens. Although peak values of removal force have typically been recorded and used in quantifying tack, additional information can be obtained from the load deformation trace, such as illustrated in Fig. 11. Other metrics that may be of interest include the area under the force removal curve, the amount of deformation at which the peak force occurs, or the deformation required to completely sever the bond. A range of probe configurations have been used, but flat cylindrical punches of several

**Fig. 10** Illustrations of several test methods used to characterize tack of pressure sensitive adhesives: (a) flat probe tack, (b) loop tack, and (c) rolling ball tack

**Fig. 11** Illustration of force vs time trace for a probe tack test of a pressure sensitive adhesive as the probe is compressed to make contact, held for a fixed dwell time, then removed

millimeters in diameter are common, with rounded tips and other configurations used for certain applications.

Zosel (1998) has made wide use of these probe tack techniques characterize the tack of pressure sensitive adhesives as a function of substrate roughness, contact time, contact pressure, and other factors. His work has clearly shown that the drop in load from its initial peak is often due to the onset of internal cavitation within the adhesive layer. The onset of cavitation limits the peak force, but leads to fibrillation which dissipates significant amounts of energy, increasing the energy required to sever the bond. Creton and coworkers have developed sophisticated techniques for carefully aligning the contact, photographing the resulting failure modes, and relating this behavior to material properties (Lakrout et al. 1999). They have also shown that the rate-dependent peak force is related to the frequency-dependent modulus of the adhesive, with lower modulus adhesives exhibiting the onset of cavitation at lower applied loads (Gent and Wang 1991).

The rolling ball tack test involves rolling a ball down an incline and characterizing tack by the ability of the adhesive to arrest the forward motion of the rolling ball. In essence, the ball is placed a given height above a horizontal table supporting the adhesive layer; the potential energy of the ball is converted to kinetic energy as the ball rolls down an incline to the plane containing the adhesive layer, and this energy is then dissipated, primarily through viscoelastic processes, as the ball is brought to a stop. Assuming an ideal conversion of potential energy (the mass of the ball times its height above the plane) to kinetic energy, this energy is equivalent to the distance the ball travels on the adhesive layer times some average dissipative force. One caveat of the rolling ball test is that the rates of bonding and debonding can be significantly larger than encountered in most other tack tests, a fact that can significantly affect the perceived tack of rate-dependent viscoelastic materials.

Other tack tests common for PSAs include the loop tack and quick stick test. The loop tack test involves bringing a loop of adhesive tape, sticky side out, into contact with a rigid adherend of specified length. After contact with what are typically very small contact pressures when the backing is flexible, the crosshead is reversed and the loop is removed from the substrate. The initial portion of the test is similar to a

peel test at just over  $90^\circ$ , albeit one that is conducted without the bonding step normally used to prepare peel test specimens. As the debonds approach one another, the stiffness of the backing becomes more significant, and the loop tack begins looking and acting more like a probe test. Here, the backing stiffness again becomes important in that it controls the size of the contact that remains at final separation; thicker and stiffer backings lead to greater contact areas at final separation, resulting in larger peak force measurements. Some users report using the peak force when recording loop tack results, while others report using the plateau that results during the initial peeling process. These are clearly very different phenomena that are controlled by different mechanisms, again suggesting the complexity of performing and interpreting tack tests in general and loop tack tests in particular (Plaut and Ritchie 2004). The PSTC procedure known as the quick stick test is related to initial phase of the loop tack test. A tape is laid on a horizontal surface, without applying external mechanical pressure, and the strip is removed by pulling on one end. Again, this test resembles a  $90^\circ$  peel test.

---

## 22.7 CTE, SFT, and Residual Stresses

Residual stresses are of significant importance in many adhesive applications. In some applications, including for structural adhesive joints, the residual stresses induced within a bond can be larger than stresses induced by mechanical loading the joint experiences within its service life. Because residual stresses can represent locked-in stresses that are present at all times, their duration can become a factor in joint life. Also, because they can be ever present, residual stresses can make adhesive layers and coatings more susceptible to environmental damage, including environmental stress cracking (Dillard et al. 1995).

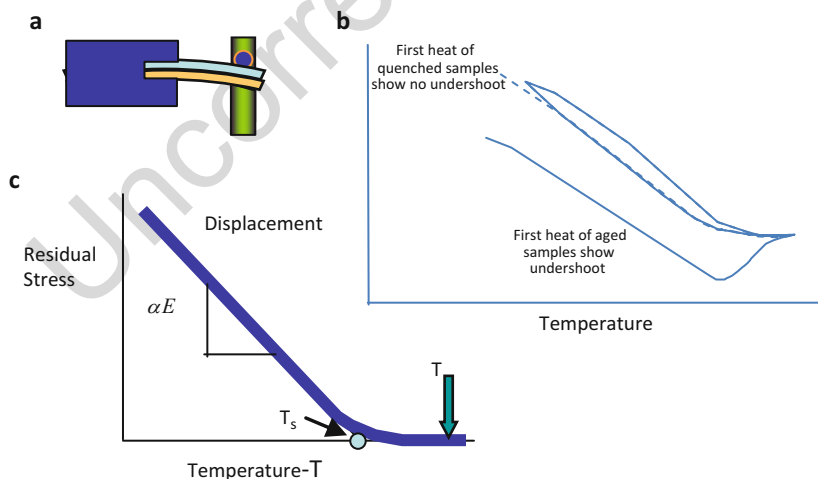

The coefficient of thermal expansion can be measured through several methods, the most direct being through linear or volumetric dilatometry. Thermal mechanical analyzers (TMA) are ideally suited for such measurements, as their components are made of very low expansion materials such as quartz. With precise temperature control, they are able to accurately measure linear dimensional changes as a function of temperature. They are often equipped to measure other properties such as softening temperature, etc. in addition to the coefficient of thermal expansion as a function of temperature.

While the coefficient of thermal expansion is nominally a property of the bulk adhesive, the residual stress, often the term of interest for design, is a property of a bonded joint or structure. One of the simplest means to measure the residual stress in an adhesive layer or coating is with the use of the bimaterial curvature technique. For several centuries, people have known that when two dissimilar beams are bonded together at the interface and subjected to a temperature change, a curvature will result. This curvature is a function of the relative moduli and thicknesses of the two beams or plates, the difference or mismatch in their CTEs, and the temperature change to which they are exposed. The resulting stresses are easily determined but

are quite nonuniform (Timoshenko 1925). A very significant simplification occurs when the thickness of one layer is significantly smaller than the other. For example, if a softer polymeric adhesive is applied as a thin coating on a stiffer substrate, the resulting curvature becomes a function of the residual stress within this coating layer. For appropriate geometries then, characterizing the curvature of bimaterial strips provides a direct measure of the residual stress experienced within the adhesive or coating layer. Dating back to the work of Stoney (1909):

$$\sigma = \frac{E_s t_s^2}{6(1 - \nu_s)h\rho} \quad (17)$$

where  $\sigma$  is the equal biaxial stress in the thin film,  $h$  is the thickness of the film,  $E_s$ ,  $t_s$ , and  $\nu_s$  are the modulus, thickness, and Poisson's ratio of the thick substrate, and  $\rho$  is the radius of curvature. Several improvements have been proposed to refine the equation to cover a broader range of specimen configurations (Freund et al. 1999; Yu et al. 2003). This can be applied to thermal, hygral (Li et al. 2012), or other swelling mechanisms as well. Such tests are easily performed in commercial dynamic mechanical analyzers (DMA), which boost excellent force and displacement resolution in a carefully controlled temperature chambers (Case et al. 2005). Figure 12 illustrates applications of this technique in which a bimaterial strip is cantilevered at one end and the deflection of the other end is measured. Knowing the geometry of the specimen and the moduli of substrate and adhesive layer, one can determine the difference in coefficient of thermal expansion between the substrate and adhesive as well as the stress-free temperature.

**Fig. 12** Illustration of bimaterial curvature technique to measure coefficient of thermal expansion and stress-free temperature of adhesive layer showing: (a) test sample, (b) representative deflection results, and (c) residual stress predictions

## 22.8 Conclusions

This chapter describes a few examples of the special tests to measure the mechanical properties of the membranes, films, adhesives, coating, sealants, and foam/elastomeric adhesives. The major conclusions are the following:

1. A wide range of blister tests have been developed and utilized to characterize adhesion, and in some cases, moduli and other properties of adhering membranes and adherends.
2. For mechanical tests of thick samples sandwiched between two substrates such as sealants, elastomeric or foam adhesives, shear tests and tensile adhesion tests have been commonly applied.
3. Indentation tests are performed to evaluate the elastic modulus and the hardness of the coating, and in some cases, interfacial fracture energies associated with coating adhesion.
4. In the scratch tests, a stylus is driven across a coated surface under a normal load. The critical load is determined by the first appearance of the failure. While the test can be applied for hard and brittle coating, quantitative evaluation for the soft and ductile coating is more complex.
5. Several tack tests, such as probe tack, loop tack, quick stick and rolling ball tack tests are used to evaluate the aggressiveness of a polymer surface.
6. The coefficient of thermal expansion (CTE) and the stress-free temperature (SFT) can be important in engineering design and are often measured to estimate residual stresses in adhesives.

nonlinearity considerations, rubber elasticity, singularity methods, bulk adhesive as composite material, damage models, the effects of cure and processing conditions on the mechanical behavior, and the concept of the “interphase.”

## 23.1 Introduction

Most adhesives are polymer-based materials and exhibit viscoelastic behavior. Some adhesives are elastomer materials and also exhibit full or partial rubberlike properties. The word “elastic” refers to the ability of a material to return to its original dimensions when unloaded, and the term “mer” refers to the polymeric molecular makeup in the word “elastomer.” In cases where brittle material behavior prevails, and especially, when inherent material flaws such as cracks, voids, and disbonds exist in such materials, the use of the methods of fracture mechanics are called for. For continuum behavior, however, the use of damage models is considered appropriate in order to be able to model the progression of distributed and non-catastrophic failures and/or irreversible changes in material’s microstructure, which are sometimes described as “elastic limit,” “yield,” “plastic flow,” “stress whitening,” and “strain hardening.” Many adhesive materials are composite materials due to the presence of secondary phases such as fillers and carriers. Consequently, accurate analysis and modeling of such composite adhesives require the use of the methods of composite materials.

A complete approach to modeling adhesives and sealants, therefore, needs to include considerations for deformation theories, viscoelasticity, bulk adhesive as composite material, damage models, and the effects of cure and processing conditions on the mechanical behavior.

## 23.2 Classical Models

### 23.2.1 General Deformation Theories

The deformation theory was first introduced by Hencky (1924), and can be described in the form:

$$\epsilon_{ij} = \left( \frac{\sigma_{kk}}{9K} \right) \delta_{ij} + \psi S_{ij}. \quad (1)$$

where  $S_{ij}$  is the deviatoric stress tensor. Equation 1 reduces to the elastic stress–strain relations when  $\psi = 1/2 G$ , where  $G$  is the elastic shear modulus. If the scalar function  $\psi$  is defined as

$$\psi = \left( \frac{1}{2G} \right) + \Omega \quad (2)$$

then Eq. 1 can be interpreted in the form

$$\epsilon_{ij} = \epsilon_{ij}^E + \epsilon_{ij}^V + \epsilon_{ij}^P \quad (3)$$

where

$$\epsilon_{ij} = \left( \frac{\sigma_{kk}}{9K} \right) \delta_{ij} + \left( \frac{S_{ij}}{2G} \right) + \Omega S_{ij} \quad (4)$$

and

$$\epsilon_{ij}^P = \Omega S_{ij} \quad (5)$$

with  $\Omega$  being a scalar function of the invariants of the stress tensor, and the superscripts E, V, and P representing elastic, viscoelastic, and plastic behaviors, respectively.

Consequently, the relation

$$\epsilon = \left( \frac{\sigma}{E} \right) + \Lambda \sigma \quad (6)$$

is obtained for uniaxial tension on the basis of Eqs. 4 and 5 with  $\Lambda = 2\Omega/3$ .

Ramberg and Osgood (1943) used a special form of Eq. 6 with  $\Lambda = K\sigma^{n-1}$  to result in:

$$\epsilon = \left( \frac{\sigma}{E} \right) + K\sigma^{n'} \quad (7)$$

where K and  $n'$  are material constants.

They reported that Eq. 7 could be used successfully to describe uniaxial tension and compression behavior of various metal alloys. Equation 7 was later modified by McLellan (1969) to accommodate strain rate effects. McLellan interpreted the terms E, K, and  $n'$  of Eq. 7 as material functions with the function E representing viscoelastic behavior and functions K and  $n'$  representing work-hardening characteristics. The terms E, K, and  $n'$  were all described as functions of the strain rate ( $d\epsilon/dt$ ) so that rigidity, stress, and plastic flow, respectively, were all affected by variations in the strain rate.

Renieri et al. (1976) used a bilinear form of rate-dependent Ramberg–Osgood equation to describe the stress–strain behavior of a thermosetting adhesive in the bulk tensile form. The bilinear behavior was obtained when  $\log \epsilon_p$  was plotted against  $\log \sigma$ , where  $\epsilon_p$  represents the second term on the right-hand side of Eq. 7. The model adhesive they used was an elastomer-modified epoxy adhesive with and without carrier cloth. They made several modifications on the form of the equation previously used by McLellan. First, the plastic strain  $\epsilon_p$  was assumed to be a function of the over-stress above the elastic limit stress (the development of over-stress approach will be presented subsequently) and second, the stress levels  $\sigma^*$  defining the intersection point

**Fig. 1** A stress–strain diagram identifying upper and lower stress-whitening stress limits,  $\sigma_U$  and  $\sigma_{L,0}$ , respectively, as well as the visually observed stress-whitening stress. The modulus of elasticity,  $E$ , and the elastic limit stress,  $\theta$  for the bulk adhesive tested are  $3.3 \times 10^5$  and  $3.5 \times 10^3$  psi (2276 and 24 MPa), respectively

for the bilinear behavior were found to occur slightly below the stress-whitening stress values. The equations they developed in this fashion are given as:

$$\epsilon = \frac{\sigma}{E}, \quad 0 < \sigma < \theta \quad (8.1)$$

$$\epsilon = \left(\frac{\sigma}{E}\right) + K_1[\sigma - \theta]^{n_1} \quad \theta < \sigma < \sigma^* \quad (8.2)$$

$$\epsilon = \left(\frac{\sigma}{E}\right) + K_2[\sigma - \theta]^{n_2} \quad \sigma^* < \sigma < Y \quad (8.3)$$

where  $\theta$  is the elastic limit stress (yield stress) in simple tension,  $Y$  is the maximum stress, and  $K_1$ ,  $K_2$ ,  $n_1$ , and  $n_2$  are strain rate–dependent material functions. Renieri et al. (1976) reported that the adhesive material properties were different before and after stress whitening due to changes in material behavior, and therefore bilinear equations of the form (Eq. 8) were needed to describe such behavior. Brinson et al. (1975) determined that for the adhesive with the carrier cloth the parameter  $n$ , Eq. 7, varied much less with strain rate in comparison to the adhesive without the carrier cloth. They concluded that the bilinear forms they proposed, Eq. 8, accurately predicted the rate-dependent behavior of their model adhesive.

Figures 1 and 2 show the application of the model described above to the stress–strain and stress-whitening behaviors of a bulk thermosetting epoxy film

**Fig. 2** A dual bilinear fit stress–strain diagram identifying upper and lower stress-whitening stress limits,  $\sigma_U$  and  $\sigma_{Lo}^*$ , respectively, as well as the visually observed stress whitening stress. The modulus of elasticity,  $E$ , and the elastic limit stress,  $\theta$  for the bulk adhesive tested are  $3.3 \times 10^5$  and  $3.5 \times 10^3$  psi (2276 and 24 MPa), respectively

adhesive containing a nonwoven nylon mat, as obtained by Sancaktar and Beachtle (1993). In this application, two intersection points are identified by intersecting two pairs of bilinears, each of which containing a common slope line as part of the bilinear sets (Fig. 2). This procedure was called “dual bilinear fit” by Sancaktar and Beachtle (1993). These intersection points define upper and lower stress-whitening stress limits shown in Fig. 1.

Ramberg–Osgood-type equations were also used to describe shear behavior of structural adhesives. Zabora et al. (1971) used a rate-dependent form of the Ramberg–Osgood equation to describe the shear behavior of structural adhesives in the bonded form.

Simple power function–type relations may be utilized in an empirical fashion to describe nonlinear elastic behavior of structural adhesives in tensile and shear modes when their mechanical behavior is found to be relatively rate insensitive. For example, Sancaktar and Schenck (1985) used a power function relation given by

$$\tau = K\gamma^r \quad (9)$$

where  $\tau$  and  $\gamma$  are shear stress and strain, respectively, to represent the nonlinear elastic shear behavior of a thermoplastic polyimidesulfone adhesive in the bonded form. Sancaktar and Dembosky (1986) showed that when the stress–strain curve has a well-defined initial elastic region and a yield point,  $\tau_y$ , then a bimodal relation given by

$$\gamma = \frac{\tau}{G}, \quad \tau < \tau_y \quad (10.1)$$

$$\gamma = B\tau^m \quad \tau > \tau_y \quad (10.2)$$

can be utilized more appropriately.

### 23.2.2 Rubber Elasticity

Vulcanized rubber materials typically have more than 200% elongation in a tensile test and are capable of returning rapidly and forcibly to their original dimensions when load is removed. This elastic response is due to the three-dimensional cross-linked network molecular structure they have. An elastomer, on the other hand, typically has elongation rates of 100% or more and a significant amount of resilience. Resilience is represented by the area under the elastic portion of the stress-strain curve, and therefore refers to a material's ability to undergo elastic deformations.

#### Estimation of Rubber Material Properties

Tension in a stretched ideal rubber arises from the entropy contribution. The change in entropy between the stretched state (S) and unstretched state ( $S_0$ ) is related to the number of conformations in the corresponding states with the relation:

$$S - S_0 = k \left[ \ln \left( \frac{W}{W_0} \right) \right] \quad (11)$$

where  $k$  = the Boltzmann constant =  $1.3804 \times 10^{-16}$  dyn-cm/K, and  $W_0$  and  $W$  are the number of initial (unstretched) and the final (stretched, and reduced) possible conformational states, respectively. Evaluation of the number of possible conformational states leads to:

$$S - S_0 = - \left( \frac{1}{2} \right) N_0 k \left\{ \left( \frac{L}{L_0} \right)^2 + 2 \left( \frac{L_0}{L} \right) - 3 \right\} \quad (12)$$

where  $N_0$  = the number of network chains in sample of initial length and cross-sectional area  $L_0$  and  $A_0$ , respectively. In the stretched state, the length and the cross-sectional area become  $L$  and  $A$ , respectively.

In the rubbery state, the material is assumed to be incompressible, so that:

$$L_0 A_0 = LA \quad (\text{i.e., } V = \text{constant}). \quad (13)$$

For ideal rubber, force can be related to temperature,  $T$ , and the entropy differential with the relation:

$$F = -T \left( \frac{dS}{dL} \right)_T \quad (14)$$

144 Consequently, differentiation of Eq. 12 results in:

$$F = \left( \frac{N_0 k T}{L_0} \right) \left\{ \left( \frac{L}{L_0} \right) - \left( \frac{L_0}{L} \right)^2 \right\}. \quad (15)$$

145 Division of Eq. 15 by the instantaneous cross-sectional area (A) yields the true  
146 stress ( $\sigma_T$ ) equation for ideal rubber:

$$\sigma_T = \frac{F}{A} = nRT \left\{ \left( \frac{L}{L_0} \right)^2 - \left( \frac{L_0}{L} \right) \right\} \quad (16)$$

147 where  $n$  = the number of moles of network chains per unit volume (i.e.,  $\text{cm}^3$ ) =  $d/M_C$ ,  
148 where  $d$  = the density ( $\text{g}/\text{cm}^3$ ),  $M_C$  = the number average molecular weight between  
149 successive points of cross-linkage, and

$$n = N_0 / (A_0 L_0) N_{AV}. \quad (17)$$

150 Division of Eq. 15 by initial cross-sectional area ( $A_0$ ) yields the engineering stress  
151 ( $\sigma$ ) equation for ideal rubber:

$$\sigma = \frac{F}{A_0} = nRT \left\{ \left( \frac{L}{L_0} \right) - \left( \frac{L_0}{L} \right)^2 \right\}. \quad (18)$$

152  
153 If a cross-linked network is produced from originally linear rubber molecules by  
154 the addition of " $n_c$ " moles of tetrafunctional cross-linking agent per  $\text{cm}^3$  of rubber,  
155 then each cross-link originates four network chains, and each chain belongs to two  
156 cross-links. Consequently, there are  $2 n_c$  moles of network chains per  $\text{cm}^3$  in the  
157 cross-linked network, that is,  $2 n_c = n = d/M_C$ .

158 For any portion of the stress-strain curve, the isothermal Young's modulus (E) is  
159 defined as

$$E = L \left( \frac{d\sigma_T}{dL} \right)_T = \left( \frac{d\sigma_T}{e_T} \right)_T \quad (19)$$

160 and substitution in Eq. 16 results in:

$$E = nRT \left\{ 2 \left( \frac{L}{L_0} \right)^2 + \left( \frac{L_0}{L} \right) \right\}. \quad (20)$$

A remarkable aspect of Eq. 20 is that it gives Young's modulus as a function of extension (or strain) which conflicts with the customary definition for elastic modulus.

For small magnitudes of strains approximating the condition  $L = L_0$ , Eq. 20 yields:

$$E(\Delta L \sim 0) = 3nRT = \frac{3dRT}{M_C}. \quad (21)$$

### Constitutive Elastic Rubber Behavior

The incremental work,  $dW_1$ , done by the stress  $\sigma_1$  is

$$dW_1 = \sigma_1 L'_2 L'_3 (dL_1) \quad (22)$$

where  $(L'_i)$  are the new dimensions of a volumetric material element.

Therefore,

$$\frac{dW_1}{L_1 L_2 L_3} = \sigma_1 \lambda_2 \lambda_3 d\lambda_1 \quad (23)$$

where "extension ratio" or "stretch ratio":

$$\lambda = \frac{L}{L_0}. \quad (24)$$

Superposition of the contributions from  $\sigma_2$  and  $\sigma_3$  results in

$$\frac{dW}{V_0} = dU_0 = \sigma_1 \lambda_2 \lambda_3 d\lambda_1 + \sigma_2 \lambda_1 \lambda_3 d\lambda_2 + \sigma_3 \lambda_1 \lambda_2 d\lambda_3 \quad (25)$$

where  $V_0$  is the initial volume and  $U_0$  is the strain energy density.

Differentiation of the strain energy density results in:

$$\frac{dU_0}{d\lambda_1} = \sigma_1 \lambda_2 \lambda_3 \Rightarrow \sigma_1 = \left( \frac{1}{\lambda_2 \lambda_3} \right) \left( \frac{dU_0}{d\lambda_1} \right) \quad (26)$$

The stretch ratio invariants,  $(I'_1, I'_2, I'_3)$ , are defined as follows:

$$I'_1 = \lambda_{xx}^2 + \lambda_{yy}^2 + \lambda_{zz}^2 = \lambda_1^2 + \lambda_2^2 + \lambda_3^2 \quad (27)$$

$$\begin{aligned} I'_2 &= \lambda_{xx}^2 \lambda_{yy}^2 + \lambda_{yy}^2 \lambda_{zz}^2 + \lambda_{zz}^2 \lambda_{xx}^2 - \lambda_{xy}^4 - \lambda_{yz}^4 - \lambda_{zx}^4 \\ &= \lambda_1^2 \lambda_2^2 + \lambda_2^2 \lambda_3^2 + \lambda_3^2 \lambda_1^2 \end{aligned} \quad (28)$$

$$I'_3 = \lambda_{xx}^2 \lambda_{yy}^2 \lambda_{zz}^2 + 2\lambda_{xy}^2 \lambda_{yz}^2 \lambda_{zx}^2 - \lambda_{xx}^2 \lambda_{yz}^4 - \lambda_{yy}^2 \lambda_{zx}^4 - \lambda_{zz}^2 \lambda_{xy}^4 = \lambda_1^2 \lambda_2^2 \lambda_3^2 \quad (29)$$

The strain energy density,  $U_0$ , is a function of the stretch ratio invariants:

$$U_0 = U_0(I'_1, I'_2, I'). \quad (30)$$

For an incompressible material,

$$\frac{V}{V_0} = I'_3 = 1 \quad (31)$$

Substitution in Eq. 26 yields:

$$\begin{aligned} \sigma_1 &= \left( \frac{1}{\lambda_2 \lambda_3} \right) \left( \frac{dU_0}{d\lambda_1} \right) \\ &= \left( \frac{1}{\lambda_2 \lambda_3} \right) \left\{ \left[ \left( \frac{dU_0}{dI'_1} \right) \left( \frac{dI'_1}{d\lambda_1} \right) \right] + \left[ \left( \frac{dU_0}{dI'_2} \right) \left( \frac{dI'_2}{d\lambda_1} \right) \right] + \left[ \left( \frac{dU_0}{dI'_3} \right) \left( \frac{dI'_3}{d\lambda_1} \right) \right] \right\}. \end{aligned} \quad (32)$$

Noting that,  $(dI'_1/d\lambda_1 = d\lambda_1; dI'_2/d\lambda_1 = 2\lambda_1(\lambda_2^2 + \lambda_3^2), \text{ and } dI'_3/d\lambda_1 = 2\lambda_1\lambda_2^2\lambda_3^2,)$  substitution yields:

$$\sigma_1 = \left( \frac{2}{\lambda_1 \lambda_2 \lambda_3} \right) \left\{ \left( \frac{dU_0}{dI'_1} \right) \lambda_1^2 + \left( \frac{dU_0}{dI'_2} \right) \lambda_1^2 (\lambda_2^2 + \lambda_3^2) + \left( \frac{dU_0}{dI'_3} \right) \lambda_1^2 \lambda_2^2 \lambda_3^2 \right\}. \quad (33)$$

If the work–strain energy relation is used to determine, say,  $\sigma_1$ , the pressure must be added since for an incompressible solid, pressure,  $p$ , does not contribute to strain energy as there is no volume change. Therefore,

$$\sigma_1 = \left\{ \left( \frac{1}{\lambda_2 \lambda_3} \right) \left( \frac{dU_0}{d\lambda_1} \right) + p \right\}. \quad (34)$$

### Mooney–Rivlin Equations for Rubber Elasticity

With this model, the strain energy density function is assumed to be a linear function of  $(I'_1)$  and  $(I'_2)$ , that is,

$$U_0 = \left( \frac{\Phi}{2} \right) (I'_1 - 3) + \left( \frac{\Psi}{2} \right) (I'_2 - 3) \quad (35)$$

where  $\Phi$  and  $\Psi$  are material constants. Therefore,

$$\sigma_i = \lambda_i^2 \Phi - \left( \frac{\Psi}{\lambda_i^2} \right) + p. \quad (36)$$

A relation between the Mooney–Rivlin parameters,  $\Phi$  and  $\Psi$ , and the stretch components can be obtained as follows: Consider the first stress invariant,  $J_1$ ,

$$J_1 = \sigma_1 + \sigma_2 + \sigma_3$$

$$= \Phi(\lambda_1^2 + \lambda_2^2 + \lambda_3^2) - \Psi \left\{ \left( \frac{1}{\lambda_1^2} \right) + \left( \frac{1}{\lambda_2^2} \right) + \left( \frac{1}{\lambda_3^2} \right) \right\} + 3p \quad (37)$$

189 but  $J_1 = 3p \Rightarrow$

$$\Phi(\lambda_1^2 + \lambda_2^2 + \lambda_3^2) = \Psi \left\{ \left( \frac{1}{\lambda_1^2} \right) + \left( \frac{1}{\lambda_2^2} \right) + \left( \frac{1}{\lambda_3^2} \right) \right\}. \quad (38)$$

190  $\sigma_3$  is zero for the condition of plane stress, and therefore:

$$p = \left( \frac{\Psi}{\lambda_3^2} \right) - \lambda_3^2 \Phi. \quad (39)$$

191 For incompressible materials, the condition  $\lambda_1^2 \lambda_2^2 \lambda_3^2 = 1$  holds, resulting in  
192  $\lambda_3^2 = 1/\lambda_1^2 \lambda_2^2$  and

$$p = - \left( \frac{\Phi}{\lambda_1^2 \lambda_2^2} \right) + \lambda_1^2 \lambda_2^2 \Psi. \quad (40)$$

193 Substitution yields

$$\sigma_1 = \lambda_1^2 \Phi - \left( \frac{\Psi}{\lambda_1^2} \right) + \left\{ - \left( \frac{\Phi}{\lambda_1^2 \lambda_2^2} \right) + (\lambda_1^2 \lambda_2^2 \Psi) \right\}. \quad (41)$$

194 Therefore,

$$\sigma_1 = [\Phi + \Psi \lambda_2^2] \left\{ \lambda_1^2 - \left( \frac{1}{\lambda_1^2 \lambda_2^2} \right) \right\} \quad (42)$$

195 and

$$\sigma_2 = [\Phi + \Psi \lambda_1^2] \left\{ \lambda_2^2 - \left( \frac{1}{\lambda_1^2 \lambda_2^2} \right) \right\} \quad (43)$$

196 For a tensile (uniaxial) test, the conditions  $\sigma_2 = 0$  and  $\lambda_2 = \lambda_3$  are valid.  
197 Furthermore, if incompressible material behavior is assumed, the conditions  $\lambda_1 \lambda_2$   
198  $\lambda_3 = 1$  and  $\lambda_2 = \lambda_3 = 1/\sqrt{\lambda_1} = 1/\sqrt{\lambda_1}$  also become valid. Therefore,

$$\sigma_1 = \lambda_1^2 \left[ \Phi + \left( \frac{\Psi}{\lambda_1} \right) \right] \left[ 1 - \left( \frac{1}{\lambda_1^3} \right) \right]. \quad (44)$$

199 Typically, for many polymers, comparison of the Mooney–Rivlin parameters,  $\Phi$   
200 and  $\Psi$ , reveal the relationship:  $0 < \Psi < (0.2)\Phi$ .

For small strains, the relation  $\lambda = (1 + \epsilon)$  holds, and substitution in Eq. 44 results in:

$$\sigma_1 = ((1 + \epsilon_1)^2 \Phi - \left[ \frac{\Phi}{(1 + \epsilon_1)} \right] + \Psi(1 + \epsilon_1) - \left[ \frac{\Psi}{(1 + \epsilon_1)^2} \right]). \quad (45)$$

Simplification of Eq. 45 by approximation results in:

$$\sigma_1 \cong 3(\Phi + \Psi)\epsilon_1. \quad (46)$$

204

### 23.2.3 Viscoelasticity Considerations

#### Linear Viscoelasticity

The differential forms of the fundamental constitutive relations are given as:

$$P\{S_{kl}\} = 2Q\{\epsilon_{kl}\} \quad (47)$$

$$P'\{\sigma\} = Q'\{\epsilon\} - Q''\{AT\} \quad (48)$$

where A is the thermal expansion function, T is the temperature,  $S_{kl}$  and  $\epsilon_{kl}$  are stress and strain deviators, respectively, and the differential operators are defined as:

$$P = \sum_{i=0}^u a_i(x, t, T) \frac{\partial^i}{\partial t^i} \quad (49)$$

$$Q = \sum_{i=0}^v b_i(x, t, T) \frac{\partial^i}{\partial t^i} \quad (50)$$

$$P' = \sum_{i=0}^{u'} a'_i(x, t, T) \frac{\partial^i}{\partial t^i} \quad (51)$$

$$Q' = \sum_{i=0}^{v'} b'_i(x, t, T) \frac{\partial^i}{\partial t^i} \quad (52)$$

$$Q'' = \sum_{i=0}^{v''} b''_i(x, t, T) \frac{\partial^i}{\partial t^i} \quad (53)$$

$$Q''\{AT\} = \int_{T_0}^{T(x, t)} Q'''\{\alpha(T')\} dT \quad (54)$$

$$Q''' = \sum_{i=0}^{v'''} b'''_i(x, t, T) \frac{\partial^i}{\partial t^i} \quad (55)$$

In Eqs. 49 through 55, the terms  $(a_i, a'_i, b_i, b'_i, b''_i, \text{ and } b'''_i)$  are material properties and the integers  $u, u', v, v', v'', \text{ and } v'''$  reflect the complexity of the material behavior, and  $t$  represents time. In Eq. 54, the quantity  $\alpha$  represents the coefficient of thermal expansion.

The same constitutive relations can also be represented in integral equation form given by:

$$\sigma(x, t) = \int_{-\infty}^t E_V(x, t, t') \left[ \frac{\partial \epsilon(x, t')}{\partial t'} \right] dt' - \int_{-\infty}^t E_{VT}(x, t, t') \frac{\partial [AT(x, t')]}{\partial t'} dt' \quad (56)$$

and

$$S_{kl}(x, t) = 2 \int_{-\infty}^t E(x, t, t') \frac{\partial \epsilon_{kl}(x, t')}{\partial t'} dt' \quad (57)$$

where  $E_V$  and  $E_{VT}$  are the relaxation moduli as functions of time and time and temperature, respectively. As shown by Flügge (1975), the assumptions of elastic dilatational behavior or no volume change are frequently used in three-dimensional analyses of polymeric materials. As for distortion operations, however, any mechanical model (Maxwell, Kelvin, three-parameter solid, etc.) can be used.

## Linear Viscoelastic Mechanical Models in One-Dimension

### Kelvin Model

The Kelvin model (Fig. 3) exhibits solid-like behavior, because the behavior of the dashpot is restricted by the spring.

The constitutive equation for the Kelvin model is given by:

$$\left( \frac{d\epsilon}{dt} \right) + \left( \frac{E}{\mu} \right) \cdot \epsilon = \frac{\sigma}{\mu} \quad (58)$$

where  $\mu$  is the coefficient of viscosity in solid form.

**Fig. 3** The Kelvin model

229 The creep condition can be described with the application of the Heaviside step  
 230 function,  $H(t)$ :

$$\sigma(t) = \sigma_0 H(t) \quad 0 < t, \quad (59)$$

231 to result in the creep equation governing with the initial condition  $\epsilon_0 = 0$ , at  $t = 0$ :

$$\epsilon = \left(\frac{\sigma_0}{E}\right) \left\{1 - e^{-(E/\mu)t}\right\} \quad (60)$$

232 Therefore, the Kelvin model exhibits “delayed elasticity” with the creep strain  
 233 approaching its final value gradually (Fig. 4).

234 In order to understand the relaxation behavior predicted by the Kelvin model, it can  
 235 be assumed that the strain is fixed at  $t = t_1$  subsequent to a creep test, that is,  $\epsilon$   
 236  $(t_1) = \epsilon_1 = \text{const}$ . Therefore, the Kelvin model constitutive equation yields the relation:

$$\left(\frac{E}{\mu}\right) \cdot \epsilon = \frac{\sigma}{\mu} \quad (61)$$

237 which, with the condition  $d\epsilon/dt = 0$ , results in the relation:

$$\sigma = E \cdot \epsilon = \sigma_0 \left\{1 - e^{-(t_1/t_R)}\right\} < \sigma_0 \quad (62)$$

238 where  $t_R = (\mu/E)$  is the relaxation time. Therefore, when the strain is fixed, the stress  
 239 is immediately relaxed by a certain amount, and then remains at this value, that is,  
 240 relaxation is incomplete.

#### 241 Maxwell Model

242 The Maxwell model (Fig. 5) exhibits fluidlike behavior, due to the presence of the  
 243 fluid element, the dashpot, which is not restricted by the solid spring element.  
 244 Because of this reason, it is suitable for noncross-linked polymers.

**Fig. 4** Delayed elasticity with Kelvin model's creep behavior

**Fig. 5** The Maxwell model

The constitutive equation for the Maxwell model is given by:

$$\left(\frac{d\epsilon}{dt}\right) = \frac{(d\sigma/dt)}{E} + \frac{\sigma}{\mu} \quad (63)$$

For the creep condition, Eq. 59, along with the initial condition,  $\epsilon_0 = \sigma_0/E$ , at  $t = 0$ , results in the governing equation for creep behavior:

$$\epsilon(t) = \left(\frac{\sigma_0}{\mu}\right)t + \left(\frac{\sigma_0}{E}\right). \quad (64)$$

This equation describes unbounded creep. It allows unlimited deformation under finite stress, which describes typical fluid property.

The creep recovery behavior of the Maxwell model shown in Fig. 6 reveals that just prior to releasing the load, the following relation is valid:

$$\epsilon(t) = \left(\frac{\sigma_0}{\mu}\right) \cdot t + \left(\frac{\sigma_0}{E}\right). \quad (65)$$

At the instant the stress is released, the strain will decrease by the amount,  $\sigma_0/E$ , (linear material). After this instantaneous change in strain, the spring (E) will not undergo any additional deformation.

For the relaxation condition, use of the relation:

$$\epsilon(t) = \epsilon_0 H(t) \quad 0 < t \quad (66)$$

along with the initial condition,  $\sigma(0) = \sigma_0$ , at  $t = 0$ , results in the governing equation for relaxation, which represents the stress behavior during a relaxation test:

$$\sigma(t) = \sigma_0 \cdot e^{-(t/t_R)}. \quad (67)$$

The limiting conditions for this relaxation behavior can be calculated as follows:  $t \rightarrow 0 \Rightarrow (\sigma(t) \rightarrow \sigma_0)$ , as well as the “elastic after effect”:  $t \rightarrow \infty \Rightarrow (\sigma(t) \rightarrow 0)$ .

Substitution of the Maxwell model relaxation time,  $t_R = (\mu/E)$ , into Eq. 67 results in:

**Fig. 6** The creep recovery behavior of the Maxwell model

$$\sigma(t = t_R) = \frac{\sigma_0}{e} (e = \exp(1) = 2.72). \quad (68)$$

Note that by identifying the time it takes for the stress level to relax to the value,  $\sigma_0/e$ , it is possible to determine the (solid) material viscosity coefficient,  $\mu$ , if the Young's modulus,  $E$ , for the material is available.

### 23.2.4 Interrelationship Between the Tensile and Shear Properties

The constitutive equations proposed for characterization of solid polymer materials in the tensile mode can be reformulated for the case of pure shear. One approach is to replace tensile stress and strain variables by their shear counterparts.

It is usually desirable to run a simple bulk tensile test program and subsequently predict (calculate) shear properties from their tensile counterparts. This approach requires a clearly defined relationship between shear and tensile elastic limit and yield variables and material properties. The elastic limit and yield stress values can be related between tensile and shear conditions by using an appropriate failure criterion, such as maximum normal stress, maximum shear stress, and distortion energy criteria. A material parameter that needs to be converted in addition to the usual elastic properties is the viscosity coefficient. This can be done by using Tobolsky's (1960) assumption of equivalent relaxation times in shear and tension. Application of this assumption results in the relation:

$$\mu_S = \mu_T/2(1 + \nu) \quad (69)$$

where  $\mu_S$  and  $\mu_T$  refer to the viscosity coefficients in shear and tension, respectively, and  $\nu$  is Poisson's ratio. An application of this procedure for a linear viscoelastic (over-stress) model was shown by Sancaktar and Brinson (1980).

### 23.2.5 Time–Temperature Superposition

The time–temperature superposition principle (TTSP) is used to extend the creep and relaxation data obtained at higher temperatures to values at lower temperatures and longer times in the same strain and stress ranges. Provided that no structural changes occur in the material at high temperatures, TTSP can be used for amorphous and semicrystalline thermoplastics and thermosets for extrapolation purposes. In order to apply this principle, one should first construct a “master curve,” where the complete compliance–time or relaxation modulus–time behavior is plotted at a constant temperature. For the “master curve,” a reference temperature  $T_0$  is chosen. As shown by Ahlonis et al. (1972), the relation for the compliance observed at any time  $t$  and temperature  $T_0$  is given in terms of the experimentally observed compliance values at different temperatures  $T$  as:

$$D(T_0, t) = \left[ \frac{\rho(T)T}{\rho(T_0)T_0} \right] D(T, t/a_T) \quad (70)$$

where

$$D(t) = \frac{\epsilon(t)}{\sigma} \quad (71)$$

and  $\rho(T)$  is the temperature dependent density. An illustration of this procedure is shown in Fig. 7, where adjustments for any change in the material density are ignored.

A similar relation for the relaxation modulus is given as:

$$E(T_0, t) = \left[ \frac{\rho_0(T_0)T_0}{\rho(T)T} \right] E(T, a_T t) \quad (72)$$

where

$$E(t) = \frac{\sigma(t)}{\epsilon}. \quad (73)$$

The term  $a_T$  is a time shift factor which can be obtained with the application of the Williams–Landel–Ferry (WLF) equation, reported by Ferry (1961).

For most polymeric materials, the polymer's glass transition temperature ( $T_g$ ) is chosen as the reference temperature for accurate results. Even though Ferry (1961) reports that the above equations have not been proven to be valid below the  $T_g$ , data showing its application for  $T < T_g$  is available in the literature. Examples of applications to structural adhesives in the bulk form were given by Renieri et al. (1976) and Keuner et al. (1982).

The application of the TTSP can be extended into the nonlinear viscoelastic region, as shown by Darlington and Turner (1978). Examples on the establishment of rate–temperature superposition based on WLF equation as applied to peeling problems have been given by Kaelble (1964, 1969), Hata et al. (1965), and Nonaker (1968). Nakao (1969) and Koizumi et al. (1970) report superposition based on Arrhenius' equation.

**Fig. 7** An illustration of time–temperature (t-T) superposition procedure for shifts in creep compliance,  $D(t)$ . Adjustments for any change in the material density are ignored

## 23.3 Advanced Models

### 23.3.1 Nonlinear Viscoelasticity

Equations 47, 48 and 56, 57 can also be used to describe nonlinear material behavior provided that  $a_i$ ,  $b_i$ , etc., and  $E$ ,  $E_V$  are functions of stresses, strains, their derivatives, and their invariants in addition to the functional variables shown.

On the basis of their observations on polymers, composites, and adhesives, Hiel et al. (1983), Rochefert and Brinson (1983), and Zhang et al. (1985) report that the extent of nonlinearity is dependent on both the stress level and the timescale. Constitutive relations having the form of Eqs. 56 and 57 are in agreement with this observation. Schapery (1966, 1969a, b) reports that stress- and strain-dependent material properties of nonlinear constitutive equations have a thermodynamic origin. For example, the one-dimensional constitutive relation

$$\epsilon = g_0 D(0) \sigma + g_1 \int_0^t \Delta D(\phi - \phi') \left[ \frac{d(g_2 \sigma)}{d\tau} \right] d\tau \quad (74)$$

includes the variables  $g_0$ ,  $g_1$ , and  $g_2$ , which reflect stress dependence of the Gibbs free energy. In Eq. 74,  $D(0)$  is the initial value of the linear viscoelastic creep compliance,  $\Delta D(\phi)$  is the transient component, and the quantities

$$\phi = \phi(t) = \int_0^t dt' / a_\sigma \quad (75)$$

and

$$\phi' = \phi(\tau) = \int_0^\tau dt' / a_\sigma \quad (76)$$

are reduced time parameters and depend on the shift function  $a_\sigma$ . “ $a_\sigma$ ” is a function of stress and change with entropy production and free energy changes (Peretz and Weitsman 1982).

An equation similar to Eq. 74 can be written with strain as the independent state variable. In this equation, the strain-dependent properties  $h_0$ ,  $h_1$ ,  $h_2$ , and  $a_\epsilon$  reflect the changes in the Helmholtz free energy.

In using nonlinear mechanical models, in addition to utilizing nonlinear elastic and shear thickening or thinning dashpot elements, a perturbation technique can also be used to incorporate nonlinear behavior. This is accomplished by adding small perturbation terms which are functions of the current level of elastic strain and strain rate to the elastic and viscous coefficients, respectively. This method was originally

proposed by Davis (1964) and later applied by Renieri et al. (1976) in material characterization of bulk adhesives.

Further discussions on nonlinear viscoelastic theory are given by Green and Adkins (1960) and Hilton (1975).

### 23.3.2 Empirical Description of Creep Behavior

The constitutive equations obtained with the use of mechanical models can be solved for the creep condition given by

$$\sigma(t) = \sigma_0 H(t) \quad (77)$$

with  $\sigma_0$  and  $H(t)$  describing the level of constant stress and the unit step function, respectively, to result in a creep equation. In some cases, however, empirical relations describing time-dependent strain functions are preferred over this method for practical reasons. Actual creep data can be fitted with such functions to yield accurate analysis in conjunction with equations of the form 56, 57, or 74.

A variety of mathematical forms have been proposed to describe the creep behavior of adhesives and polymers in an empirical fashion. The simplest procedure is called the log-log method based on the assumption that the logarithm of the secondary creep rate is linearly related to the logarithm of the stress level at which the creep occurs. This assumption results in a creep relation which is a linear function of time but nonlinear function of stress in the secondary range. An application of this method to polymeric materials was given by Sancaktar et al. (1987).

The creep relation which is most commonly used in the literature is the "power-law" compliance given by

$$D(t) = D_0 + D_1 t^{n''} \quad (78)$$

where  $D_0$  is the instantaneous compliance, and  $D_1$  and  $n''$  are material constants. Note that Eq. 78 allows time reduction by a stress-dependent shift factor to describe stress-enhanced creep. Equations of this form were used by researchers such as Weitsman (1981) and Ravi-Chandar and Knauss (1984) for viscoelastic stress analysis and fracture mechanics considerations (respectively) of adhesives and polymeric materials.

Various methods have been proposed to determine the parameters  $D_0$ ,  $D_1$ , and  $n''$  of Eq. 78. For example, Findley and Peterson (1958) subtract the instantaneous strain from the total strain and plot the transient strain on log-log paper. A comparison and discussion of different methods was given by Dillard and Hiel (1985).

As shown by Sancaktar (1991), Figs. 8 and 9 illustrate the variation of adhesive shear stress at the overlap edges of double lap joints as predicted by linear and nonlinear viscoelastic analyses. In Fig. 8, the linear analysis was performed using the Maxwell model with different relaxation times,  $t_R$ , and the nonlinear analysis was

**Fig. 8** Variation of adhesive shear stress at the overlap edges of double lap joints as predicted by linear and nonlinear viscoelastic analyses. The linear analysis was performed using the Maxwell model with different relaxation times,  $t_R$ , and the nonlinear analysis was performed using Eq. 78 with a stress-dependent shift factor. The joint dimensions used in analysis are also shown with  $\delta$ ,  $L$ , and  $d$  representing adhesive thickness, overlap length, and the main plate thickness, respectively.  $E_s$  and  $G_a$  represent the Young's modulus for the substrate and the shear modulus for the adhesive, respectively

performed using Eq. 78 with a stress-dependent shift factor. Figure 9 illustrates the ability to obtain matching results between the two models by using the Maxwell model with variable relaxation time,  $t_R$ , as given by Sancaktar (1991).

Additional methods and discussions on constitutive equations for creep were given by Gittus (1975).

### 23.3.3 Increases in Joint Strength Due to Rate-Dependent Viscoelastic Adhesive Behavior

Due to their viscoelastic nature, most adhesives exhibit rate-dependent material behavior, which can be modeled, for example, by using mechanical model characterization.

In order to describe the rate dependence of limit stress and elastic limit strain for polymeric and adhesive materials in the bulk form, Renieri et al. (1976) and Sancaktar and Brinson (1980) utilized a semiempirical approach proposed by Ludwik (1909) in the form:

**Fig. 9** Variation of maximum adhesive shear stress in double lap joints based on nonlinear viscoelastic analysis, using Eq. 78 with a stress-dependent shift factor, and linear viscoelastic analysis, using the Maxwell model with variable relaxation time,  $t_R$

$$\tau_{ult} = \tau' + \tau'' \log \left[ \frac{(d\gamma/dt)}{(d\gamma'/dt)} \right] \quad (79)$$

where  $\tau_{ult}$  is the ultimate shear stress,  $d\gamma/dt$  is the initial elastic strain rate, and  $\tau'$ ,  $\tau''$ , and  $d\gamma'/dt$  are material constants.

Renieri et al. (1976) and Sancaktar and Brinson (1980) used the same form of Eq. 79 to describe the variation of elastic limit shear stress ( $\tau_{el}$ ) and strains ( $\gamma_{el}$ ) with initial elastic strain rates. These expressions may be written as:

$$\tau_{el} = \phi' + \phi'' \log \left[ \frac{(d\gamma/dt)}{(d\gamma'/dt)} \right] \quad (80)$$

and

$$\gamma_{el} = \zeta' + \zeta'' \log \left[ \frac{(d\gamma/dt)}{(d\gamma'/dt)} \right] \quad (81)$$

where  $\phi'$ ,  $\phi''$ ,  $\zeta'$ , and  $\zeta''$  are material constants. Sancaktar et al. (1984) and Sancaktar (1985) later showed applicability of Eqs. 79 through 81 for adhesives in the bonded form and also proposed superposition of temperature effects on these equations.

As reported by Ward and Hadley (1993), the theoretical basis of Eq. 79 can be found in the Eyring theorem, according to which the mechanical response of an adhesive is a

process that has to overcome a potential barrier, ( $\Delta E$ ). This barrier decreases not only with increasing stress but also with increasing temperature. Based on the Eyring theorem, the relationship between a limit stress, say  $\tau_{el}$ , and the strain rate can be written as:

$$\frac{d\gamma}{dt} = A \exp \left[ \frac{(\tau_{el} V - \Delta E)}{RT} \right] \quad (82)$$

where  $A$  is a pre-exponential factor,  $R$  is the gas constant, and  $V$  is the activation volume.

Equation 82 can be expressed in logarithmic form as:

$$\tau_{el} = \left\{ \frac{\Delta E}{V} \right\} + \frac{\{2.303RT \log[(d\gamma/dt)/A]\}}{V} \quad (83)$$

Sharon et al. (1989) applied Eq. 83 to describe rate- and temperature-dependent variation of four structural adhesives in the bulk form. They used the shift factor  $[\log(1/A)] \times 10^{-3}$  on the temperature ( $^{\circ}\text{C}$ ) to describe the effect of rate.

If the energy barrier term  $\Delta E/V$  of Eq. 83 is also affected by temperature, then one needs two shift factors in Eqs. 79 through 81 to describe rate-temperature effects on limit stress-strain equations:

$$\tau_{el} = \{a_{T1}\}\theta' + \left\{ \{a_{T2}\}\theta'' \log \left[ \frac{d\gamma/dt}{d\gamma'/dt} \right] \right\} \quad (84)$$

and

$$\gamma_{el} = \{b_{T1}\}\zeta' + \left\{ \{b_{T2}\}\zeta'' \log \left[ \frac{d\gamma/dt}{d\gamma'/dt} \right] \right\} \quad (85)$$

where  $a_{Ti}$  and  $b_{Ti}$  are shift factors as functions of temperature. Figure 10 illustrates an application of Eq. 84 by Sancaktar et al. (1984), showing the variation of elastic limit shear stress with initial elastic strain rate and environmental temperature for an epoxy adhesive film with polyester knit fabric carrier cloth. The adhesive was tested in the bonded lap shear mode.

In order to analyze the effects of rate and temperature on the interfacial strength of bonded joints, one can initially use a simple energy approach in the following manner: A critical energy level,  $W_c$ , is used to represent interfacial failure. In the presence of adhesive, substrate, and interphase (a distinct material layer between the substrate and the adhesive layer which transmits the rigid substrate's energy to the adhesive layer), the combined elastic energy can be written as:

$$V_a \left\{ \left( \frac{1}{2} \right) \epsilon_{\text{adhesive}}^2 E_{\text{adhesive}} \right\} + V_{ip} \left\{ \left( \frac{1}{2} \right) \epsilon_{\text{interphase}}^2 G_{\text{interphase}} \right\} + V_s \left\{ \left( \frac{1}{2} \right) \epsilon_{\text{substrate}}^2 E_{\text{substrate}} \right\} = W_c \quad (86)$$

**Fig. 10** Variation of elastic limit shear stress with initial elastic strain rate and environmental temperature, and comparison with Ludwik’s equation for an epoxy adhesive film with polyester knit fabric carrier cloth. The adhesive was tested in the bonded lap shear mode

where  $V_a$ ,  $V_{ip}$ , and  $V_s$  represent volume fractions of the adhesive layer, interphase, and the substrate, respectively. If Eq. 86 is considered in conjunction with Eq. 85 to include rate–temperature effects, then it can be easily deduced that higher  $W_c$  levels are obtained at high rate and/or low temperature levels since the proportion of elastic strains increases with increasing elastic limit strains due to high rate and/or low temperature levels.

### 23.3.4 Reductions in Stress Concentration Due to Viscoelastic Adhesive Behavior

If the adhesive material exhibits viscoelastic behavior, then the high stress magnitudes observed at the overlap end region of bonded joints are expected to diminish in time due to the creep process. For example, Weitsman (1981) utilized the nonlinear viscoelastic “power-law” response, which describes a stress-enhanced creep process to illustrate time-dependent reductions in shear stress peaks along the adhesive layers of symmetric double lap joints. Sancaktar (1991) later illustrated the applicability of the correspondence principle to the same problem with the use of Maxwell chain to approximate the continuous change in the relaxation time and to coincide with the results calculated using nonlinear viscoelastic theory, as shown in Figs. 8 and 9.

### 23.3.5 Singularity Methods

Theoretically, geometrical singularities exist at sharp interface corners. The strength of such singularities depends on the local geometry, including the actual corner

radius, and the material properties. Barsoum (1989) considered the cases of elastic adhesive at a rigid corner, and nonlinearly hardening adhesive at a square rigid corner. He showed that for an elastic adhesive, the obtuse angle notch gives a much weaker singularity and, hence, a greater failure load.

Assuming linear elasticity, Groth (1988) proposed an exact solution for the adhesive stresses at an interface corner in the form of a power series:

$$\sigma_{ij} = \sum_{k=1}^{\infty} K_k H_{ij}^k(\phi) \zeta^{\lambda_k} + \text{Continuous part} \quad (87)$$

where  $\sigma_{ij}$  is the stress tensor,  $\zeta = r/h$  is a nondimensional radial distance from the singularity,  $(H_{ij}^k)$  are functions depending on the geometry angle  $\Phi$  of the corner,  $K_k$  constitutes generalized stress intensity factors, and  $\lambda_k$  defines the strength of singularities governed by the eigenvalues of the  $\lambda_k$  in the open interval  $\text{Re}(\lambda_k) < 1$ . Due to restrictions on finite strain energy at the singularity, values of  $\text{Re}(\lambda_k) \geq 1$  are not allowed. Obviously, based on Eq. 87, more than one singular term may influence the stress field close to an interface corner. Dempsey (1995) showed that in addition to the power-type singularities, that is,  $O(r^{-\lambda})$  as  $r \rightarrow 0$ , and  $\lambda$  representing the strength of singularity, power-logarithmic-type singularities, that is,  $O(r^{-\lambda} \ln r)$  as  $r \rightarrow 0$ , may occur for homogeneous boundary conditions of composite wedge problems.

Stress singularities at butt joint interface corners were discussed by Reedy and Guess (1995) and Sawa et al. (1995).

### 23.3.6 Bulk Adhesive as Composite Material

Since most adhesives contain secondary phase materials such as fillers and carrier cloth, they should be treated as composite materials in constitutive modeling. The interesting aspect in such treatment is the fact that such secondary phase constituents form adhesive bonds with the adhesive matrix in small scale. Consequently, localized non-catastrophic failures within the bulk adhesive consisting of interfacial separations are expected to cause constitutive behavior changes for the adhesive bulk. Such behavior can be properly described by using “damage mechanics models,” some of which will be described later in this chapter within the context of adhesive materials.

It is known that particle size, shape, and volume fraction all affect the mechanical behavior of filled polymers. For example, electrically and thermally conductive adhesives which usually contain dispersed metal particles of varying aspect ratios, but usually within the micron size range, require the methods of Eshelby (1959) for characterization. These types of adhesives sometimes require directional properties. Kerner (1956), Hashin and Shtrikman (1963), Budiansky (1965), and Hill (1965) provided methods for calculation of elastic moduli for isotropic materials filled with spherical particles. Methods for elastic moduli of unidirectional reinforced polymers

with infinitely long fibers were given by Hill (1964) and Chow and Hermans (1969). Bulk and shear moduli for disk- and needle-shaped inclusions were considered by Wu (1966) and Walpole (1969).

As reported by Ashton et al. (1969), Halpin and Tsai introduced approximate equations for square fiber reinforcement by reducing Hermans' (1967) solution using numerical solutions of elasticity theory. Equations for slender rigid inclusions at low concentrations were developed by Russel and Acrivos (1973). As for effective thermal expansion coefficient of filled polymers, the effects of filler geometry and constituent material properties have been studied by Kerner (1956).

Using the generalized approach of Eshelby, Chow (1978a) derived relations for the bulk modulus, transverse and longitudinal Young's moduli, and the two effective shear moduli,  $G_{12}$  and  $G_{13}$ , of the filled polymer containing aligned ellipsoidal particles at finite concentration. Chow (1978b) also derived relations for the linear and volumetric thermal expansion coefficients for filled polymers containing aligned ellipsoidal inclusions at finite concentration. He concluded that in such filled systems, the volumetric expansion varies only slightly with the aspect ratio of the ellipsoid, while longitudinal and transverse linear expansions show strong dependence on the particle shape. All the modulus calculations developed by Chow are based on the following assumptions: (1) The filler particles are well bonded to the matrix, and consequently, the isostrain condition at the particle/matrix interface can be used to develop the method. (2) The shapes of particles are uniform ellipsoids with the aspect ratio  $C_p$ , representing the ratio of the major to minor axes. (3) The particles are distributed with their corresponding axes aligned.

Wei (1995) and Sancaktar and Wei (1998) applied the elastic moduli and thermal expansion coefficient relations developed by Chow in describing the material behavior of electronically conductive (filled) adhesives in order to be able to determine, accurately, the thermal mismatch stresses which occur between the adhesive and the substrates in the bonded form. Both finite element analysis and closed form solutions were used for stress analysis.

The results given by Chow are consistent with the well-known rule of mixtures used in long fiber-reinforced composites. When the aspect ratio,  $C_p$ , of the particle is  $C_p > 50$ , the moduli are not a function of  $C_p$ . Therefore, for larger  $C_p$ , the composite's behavior is more like that of long fiber-reinforced composite. For intermediate aspect ratio cases, i.e.,  $1 < C_p < 50$ , Sancaktar and Wei (1998) proposed an approximation of Chow's elastic moduli formulas by utilizing the method used for randomly oriented short fibers in predicting the behavior of particle filled adhesives, so that the composite material can be treated as isotropic, as suggested by Agarwal and Broutman (1990).

As for the thermal expansion coefficient, the isotropy assumption was accomplished simply by using one-third of the volumetric thermal expansion coefficient, as suggested by Lipatov et al. (1991). It should be noted, however, that in special cases of conductive adhesive applications, directional conduction may be required, in which case the use of non-isotropic, directional material properties would be necessary.

The constitutive models cited above for predicting filled polymer behavior all assume perfect adhesive bond between the fillers and the polymer matrix. As such

filled polymers are loaded, however, failure of adhesive bonds is expected in proportion to the applied force and the duration of its application. This, in turn, is expected to result in changes in the constitutive properties of the filled polymer adhesive. Lipatov et al. (1991) reported a decrease in the modulus of elasticity of a filled elastomer at separation of filler particles from the binder and described it with the approximate formula

$$\frac{E_x}{E_f} = \exp^{-4.3(V_x)} \quad (88)$$

where  $E_f$  is the initial elastic modulus for the filled polymer with unbroken bonds,  $V_x$  is the volume fraction of unbonded filler, and  $E_x$  is the composite's elastic modulus when the fraction,  $V_x$ , of the filler particles are no longer bonded to the matrix.

Garton et al. (1989) discussed stiff polar molecular additives which interact strongly with the (thermoplastic or thermoset) matrix polymer adhesive, thus decreasing the composite free volume,  $f$ , as given by the equation

$$f = V_1 f_1 + V_2 f_2 + k V_1 V_2 \quad (89)$$

where  $V_1$  and  $V_2$  are the volume fractions of the polymer matrix and additive, respectively,  $f_1$  and  $f_2$  are the corresponding fractional free volumes, and  $k$  is an interaction parameter. The composite properties – bulk elastic modulus, bulk strength (to a lesser degree) – as well as bonded joints properties of strength and stiffness are reported by Garton et al. (1989) to increase with reductions in composite free volume.

In another study, Sancaktar and Kumar (2000) obtained increases in the lap joint strength by selectively rubber toughening the high stress concentration regions of the adhesive overlap. This novel approach to increase the lap joint strength by using functionally gradient adhesive introduced a method different from the traditional methods of either increasing the lap joint area or altering the joint geometry. For the different configurations of adhesive arrangements tried, the trends obtained in finite element analysis matched the trends obtained by tensile shear testing.

### 23.3.7 The Concept of the Interphase

There is strong interrelationship between the properties of the adhesive and the substrates in shaping the final joint behavior. A more accurate prediction of the joint behavior can be obtained by including a distinct “interphase” region in modeling the overall joint behavior. Earlier, in Sect. 3.3, the interphase was defined as “a distinct material layer between the substrate and the adhesive layer which transmits the rigid substrate's energy to the adhesive layer.” An early discussion of this concept was provided by Sharpe (1972). This concept becomes especially relevant as efficient methods for inducing mechanically distinct surface topography and chemically distinct interlayers emerge. The use of excimer pulse lasers for surface treatment

and topography inducement on metal adherends, shown by Sancaktar et al. (1995), cure and post-cure of interphase regions around carbon fibers embedded in epoxy matrix via resistive electric heating by the fiber, shown by Sancaktar and Ma (1992), microwave curing of carbon-epoxy composites, which produce “interfacial strengths higher than that achievable in thermally cured system,” as shown by Agrawal and Drzal (1989), and the production of a transcrystalline region in crystalline polymers upon solidifying when in contact with a substrate, as shown by Hata et al. (1994), all provide examples of current methods used to create distinct interphases. Another main reason for the presence of an interphase region is the chemical primer (sizing) applied to the adherend surfaces to improve adhesion. The diffusion of this sizing into the adhesive matrix can create a concentration gradient. There are other possible mechanisms which could lead to an interphase region. Some examples are: possible polymeric diffusion into the substrate during the adhesion process, selective adsorption of one or more of the components in the matrix before curing, and the presence of free volume differences between the bulk polymer and the polymer near the substrate–matrix boundary, possibly created by thermal stresses. Figure 11 shows different “interphases” between an epoxy-based, approximately 80% wt silver flake-filled electrically conductive adhesive and different substrates.

Adequate analysis and understanding of the interphase between an adherend and an adhesive is critical for the design of efficient bonded structures and composite materials. In adhesion science and technology circles, it is a well-accepted fact that the mechanical properties of the (polymeric) adhesive material are altered in regions close to the adherend due to the adhesion process. For example, Knollman and Hartog (1985) reported approximately 10% reduction in the adhesive bulk shear modulus, in an interphase region comprising approximately 20% of the bulk adhesive thickness. Consequently, a satisfactory mechanical analysis on the adherend–adhesive interaction should include a finite thickness interphase with its own material properties rather than assuming an interface with unknown properties or very high strength and negligible thickness. Modeling of the adhesive–adherend interphase becomes especially relevant

**Fig. 11** Illustration of “interphases” between an epoxy-based, approximately 80% wt silver flake-filled electrically conductive adhesive and stainless steel and piezoelectric substrates. The flake size is approximately 7  $\mu\text{m}$

in understanding and design of composite materials with “tailored” interphases which increase the toughness of the composite material. The adherend surfaces have distinct topographies, which result in a collection of miniature joints in micron, and even nanoscale when bonded adhesively. The methods of continuum mechanics can be applied to this collection of miniature joints by assuming continuous or a combination of continuous/discontinuous interphase zones.

Using the case of a carbon fiber embedded in epoxy matrix, Sancaktar and Zhang (1990) and Sancaktar et al. (1992) reported that nonlinear viscoelastic behavior of the matrix and the interphase may have a profound effect on the mechanism of stress transfer.

Sancaktar’s analytical model involves a cylindrical interphase surrounding an elastic fiber of finite length. The interphase region has nonlinear viscoelastic material properties. The region surrounding the interphase (which can be assumed to be the bulk of the adhesive matrix) is also assigned nonlinear viscoelastic properties, which are different from those of the interphase. The nonlinear viscoelastic material behavior of the interphase zone and the matrix is represented using a stress-enhanced creep. Different interphase diameter values and different material properties for the interphase and the matrix are used to determine their effects on the interfacial shear stress. Results of this analysis reveal that depending on the relative magnitudes of interphase and matrix viscoelastic material properties, it is possible to have stress reductions or increases along the fiber and, hence, the critical fiber length obtained will also vary accordingly, as illustrated in Fig. 12. This result reveals that not only the quality of adhesion but also the material properties of the bulk matrix and the interphase, all of which can be affected by cure conditions, can affect the critical fiber length, a concept introduced by Kelly and Tyson (1965) to gage the fiber–matrix interfacial strength.

The analytical and experimental results presented so far reveal the possibility for mutual reduction between rate, temperature, and interphase thickness, as shown by Sancaktar et al. (1992). The application of fiber sizing typically results in thicker interphases, and the cross-head rate,  $v$ , can be related to the shear strain rate,  $d\gamma/dt$ , and the interphase thickness,  $\delta$ , with the relation:

$$v = f\left(\frac{d\gamma}{dt}\right) \cdot g(\delta). \quad (90)$$

Therefore, based on classic shear lag analysis (also based on definition of shear strain), it can be shown that for a fixed strain rate (function) the effect of increased cross-head rate can be induced by increasing the interphase thickness (i.e., application of fiber sizing). Indeed, the experimental results reveal shorter fragment lengths for increased cross-head rate and/or presence of fiber sizing. Based on this premise, the following superposition relations can be written for the interfacial strength,  $\tau_c$ :

$$\tau_c(T, v, \delta) = \tau_c(T_0, a_T v, \delta) \quad (91)$$

$$\tau_c(T, v, \delta) = \tau_c(T_0, v, \delta/a_T) \quad (92)$$

**Fig. 12** The variation of the maximum shear stress with time and matrix transient creep compliance based on a nonlinear viscoelastic stress analysis of a cylindrical interphase zone for maximum transferred load. The nonlinear analysis was performed using Eq. 78 with a stress-dependent shift factor.  $D_0$  and  $D_1$  are the interphase instantaneous and transient creep compliances,  $\delta$  is the interphase thickness, and the subscripts m and f indicate matrix and fiber, respectively

630 and,

$$\tau_c(T, v, \delta) = \tau_c(T_0, v/a_\delta, \delta_0) \quad (93)$$

631 where  $T$  is the temperature,  $T_0$  is a reference temperature, such as room temperature,  
 632  $\delta_0$  is an interphase thickness used as reference, and  $a_T$  and  $a_\delta$  are shift factors  
 633 reflecting the effects of changes in temperature and interphase thickness, respec-  
 634 tively, in comparison with reference values.

635 In order to represent the composite behavior of the adhesive/adherend interphase,  
 636 where the polymeric adhesive is mechanically interlocked to the surface projections  
 637 of a metal adherend, Sancaktar (1996) proposes a “smeared” modulus zone.  
 638 Although deformation within the bulk adhesive is likely viscoelastic, simple elastic  
 639 relationships probably suffice, to describe deformation within the topographic sur-  
 640 face region. Therefore, simple elastic relationships are used to relate strain gradient  
 641 within those regions to topography.

642 The equivalent elastic modulus,  $G_{IP}$ , for the mechanically interlocked interphase  
 643 is calculated by assuming an “isostress” condition for the interphase, illustrated in  
 644 Fig. 13. In other words, the adhesive and the adherend surface (projections) are  
 645 subjected to the same level of shear stress,  $\tau_{IP}$ , at the interphase, while the composite

**Fig. 13** The state of isostress shear at the interphase

interfacial shear strain,  $\gamma_{IP}$ , is a volumetric weighted average of the adhesive and adherend strains, that is,

$$\gamma_{IP} = (V_{fA})(\gamma_A) + (V_{fS})(\gamma_S). \quad (94)$$

In Eq. 94,  $\gamma_A$  and  $\gamma_S$  are the adhesive and substrate shear strains at the interphase and  $V_{fA}$  and  $V_{fS}$  are the volume fractions of the adhesive and the substrate surface (projections) at the interphase. Assuming that the adhesive essentially fills the voids, the adhesive volume fraction can be equated to the sum of the void volume fractions of each lamina.

With the assumption that the deformations in both the adhesive and the adherend are elastic, the interphase shear modulus can be defined as:

$$G_{IP} = \tau_{IP} / \gamma_{IP}. \quad (95)$$

Using Eqs. 94 and 95 and Hooke's law to represent adhesive and adherend's material behavior, the following expression can be obtained for the interphase shear modulus:

$$G_{IP} = \frac{G_S G_A}{V_{fA} G_S + V_{fS} G_A} = \frac{G_S G_A}{V_{fS} (G_S - G_A) + G_A} \quad (96)$$

where  $G_A$  and  $G_S$  are the elastic moduli for the adhesive and the adherend, respectively.

Failure at the interphase is more likely with higher strain gradients,  $d\gamma_{IP}/dz$ . Of course, in the limit, a strain discontinuity defines failure based on mechanics principles. Based on this premise, a mathematical expression can be obtained to gage the possibility of failure using the shear moduli of the adhesive and the adherend along with the adhesive volume fraction,  $V_{fA}$ , at the interphase. For this purpose, differentiation of Eq. 95 along the interphase thickness direction (z-direction) results in

$$\frac{dG_{IP}}{dz} = -\tau_{IP}\gamma_{IP}^{-2} \left( \frac{d\gamma_{IP}}{dz} \right). \quad (97)$$

An equivalent expression can be obtained by differentiating Eq. 96 with respect to z:

$$\frac{dG_{IP}}{dz} = -\frac{G_S G_A (G_S - G_A)}{[V_{fA}(G_S - G_A) + G_A]^2} \left( \frac{dV_{fA}}{dz} \right). \quad (98)$$

An expression relating the shear strain gradient,  $d\gamma_{IP}/dz$  at the interphase to the volume fraction,  $V_{fA}$ , and the differential volume fraction  $dV_{fA}/dz$ , of the adherend voided during surface preparation can now be obtained by equating Eqs. 97 and 98. Both parameters are experimentally determinable, as discussed by Sancaktar (1996).

Interfaces usually constitute a weak link in the chain of load transfer in bonded joints. Also, the discontinuity of the material properties causes abrupt changes in stress distribution, as well as causing stress singularities at the edges of the interfaces. It is very desirable to optimize the substrate surface topography at the interfaces to maximize the load-bearing capacity of bonded joints and to improve their deformational characteristics.

During the second half of the twentieth century, a considerable amount of research work has been published related to the interface stress distributions focusing on flat surfaces between two different materials except when the effects of surface roughness were investigated. In general, stress distributions, stress concentrations, singularities, and surface roughness effects were studied. These studies, however, were not extended to the development of a general methodology to include surface topography effects for varying configurations which can be represented by different mathematical functions.

An investigation by Sancaktar and Narayan (1999) on adhesively bonded scarf joints revealed that the angle between the bonded interface and the loading direction had a significant influence on the stress distributions at the interface. Their analysis revealed that the distributions of stresses became more uniform along the adhesive layer when scarf angles varying from lap joint to butt joint in an increasing order of scarf angle were considered. The transverse and shear stress distributions were in a decreasing order for scarf angle increments of  $15^\circ$  between  $30^\circ$  and  $90^\circ$ , while a reverse trend was observed for the normal stress distributions. The peak normal stress was minimum for the  $30^\circ$  scarf joint; on the other hand, the magnitudes of transverse and shear stresses were minimum when a butt joint was used. Uniformly

distributed external shear loading on the joints led to higher stresses in lap joints, while 75° scarf joints had the lower values.

Sancaktar and Narayan (1999) stated that an attention to the type of stress (i.e., normal, transverse or shear) provided information relevant to the type of failure (i.e., brittle- or ductile-type failures). The authors also introduced newly defined design parameters: stress times substrate volume, stress divided by substrate volume, and stress (strain) gradients along and across the adhesive joint, as a general methodology to compare adhesive joints for design optimization.

In highly deformable adhesives, most of which are elastomeric in nature, such as those used in pressure sensitive tape and tack applications, a high amount of deformation results in cavitation of the material under dilatation. High dilatation may lead to cavitation in localized regions of the adhesive layer starting at a microscopic scale.

It is also desirable to know the magnitudes of shear and normal stresses individually since some adhesives are weak in shear loading (ductile adhesives) while others are weak in normal stress loading (brittle adhesives).

High levels of stresses result in crack propagation in brittle adhesives and cavitation induced failures in deformable adhesives. Furthermore, not only the magnitudes but also the gradients of stresses and strains become an important issue in optimizing the joint strength. Large strain gradients at adhesive–substrate interfaces may result in bond failure.

The magnitude of strain gradients depends on the volume fractions of the adhesive and substrate materials within the effective bond region defined by the geometry of the surface topography. The effect of bonded substrate volume, corresponding to the volume of substrate projections beyond a common baseline on the substrate, on the strain gradients across the adhesive layer can be found by relating the volume fraction gradients to the strain gradients. For this purpose, the composite behavior of the adhesive/adherend interphase, where the polymeric adhesive is mechanically interlocked into the surface projections of an adherend can be utilized to determine an equivalent composite modulus, as suggested by Sancaktar (1996) and discussed above.

Mechanical adhesion depends on surface topography, which can be considered a collection of many geometrical forms. Therefore, mechanical adhesion depends on the stress states of different adhesive joint geometries on the scale of the surface topography, which may include many lap, butt, and scarf joints in the “interphase” region. To address this issue, Ma et al. (2001) compared the stress distributions in adhesive joints as functions of varying geometrical interfaces described mathematically in polynomial or other functional forms, as well as the material properties of the adhesive and the adherend or two different substrates joined by an infinitesimally thin adhesive layer. For this purpose, a mathematical procedure was developed to utilize the complementary energy method, by minimization, in order to obtain an approximate analytical solution to the 3-D stress distributions in bonded interfaces of dissimilar materials. In order to incorporate the effects of surface topography, the interface was expressed as a general surface in Cartesian coordinates, that is,  $F(x, y, z) = 0$ , and the results verified by comparison with

Finite element analysis (FEA). Their methodology involved the following steps: (1) Choose the appropriate stress functions,  $\Phi_{mn}$ , to satisfy stress boundary conditions and utilize equilibrium conditions to relate the stress functions to the stress distribution functions. (2) Use stress interface boundary conditions to reduce the unknown variables in the stress distribution functions obtained. (3) Define a function ( $II$ ) as the sum of complementary energy ( $I$ ) and the penalty function  $\left( R \sum_{i=1 \dots 3}^{y=f(x,z)} (u_i^A - u_i^B)^2 \right) \cdot (R)$  is chosen such that it is the largest positive number which causes the total system complementary energy to change by only 0.1%. (4) Use the remaining unknown variables to minimize the function ( $II$ ) formed in step 3, using the Newton quadratic method, and solve all the unknown variables to obtain the complete stress distribution functions.

The continuity of displacements was enforced at the interface area, approximately, using the fundamental theorem for surface theory of differential geometry, described by Struik (1950), instead of directly using displacements. This way, the integrations of displacements were avoided, and the stress distributions could be calculated more accurately.

For example, for a flat interface (on  $x$ - $z$  plane), such as a butt joint, they utilized the following stress functions:

$$\Phi_{xx}^A = \left( z^2 - \frac{1}{4} \right)^2 \left( y - \frac{1}{2} \right)^2 f_1(x, y, z) \quad (99)$$

$$\Phi_{yy}^A = \left( z^2 - \frac{1}{4} \right)^2 \left( x^2 - \frac{1}{4} \right)^2 f_2(x, y, z) \quad (100)$$

$$\Phi_{zz}^A = \left( x^2 - \frac{1}{4} \right)^2 \left( y - \frac{1}{2} \right)^2 f_3(x, y, z) \quad (101)$$

$$\Phi_{xy}^A = \left( x^2 - \frac{1}{4} \right) \left( z^2 - \frac{1}{4} \right)^2 \left( y - \frac{1}{2} \right) f_4(x, y, z) \quad (102)$$

$$\Phi_{xz}^A = \left( x^2 - \frac{1}{4} \right) \left( z^2 - \frac{1}{4} \right) \left( y - \frac{1}{2} \right)^2 f_5(x, y, z) \quad (103)$$

$$\Phi_{yz}^A = \left( x^2 - \frac{1}{4} \right)^2 \left( z^2 - \frac{1}{4} \right) \left( y - \frac{1}{2} \right) f_6(x, y, z) \quad (104)$$

$$\Phi_{xx}^B = \left( z^2 - \frac{1}{4} \right)^2 \left( y + \frac{1}{2} \right)^2 f_7(x, y, z) \quad (105)$$

$$\Phi_{yy}^B = \left( z^2 - \frac{1}{4} \right)^2 \left( x^2 - \frac{1}{4} \right)^2 f_8(x, y, z) \quad (106)$$

$$\Phi_{zz}^B = \left(x^2 - \frac{1}{4}\right)^2 \left(y + \frac{1}{2}\right)^2 f_9(x, y, z) \quad (107)$$

$$\Phi_{xy}^B = \left(x^2 - \frac{1}{4}\right) \left(z^2 - \frac{1}{4}\right)^2 \left(y + \frac{1}{2}\right) f_{10}(x, y, z) \quad (108)$$

$$\Phi_{xz}^B = \left(x^2 - \frac{1}{4}\right) \left(z^2 - \frac{1}{4}\right) \left(y + \frac{1}{2}\right)^2 f_{11}(x, y, z) \quad (109)$$

$$\Phi_{zz}^B = \left(x^2 - \frac{1}{4}\right)^2 \left(z^2 - \frac{1}{4}\right) \left(y + \frac{1}{2}\right) f_{12}(x, y, z). \quad (110)$$

Functions ( $f_n(x, y, z)$ ) are of the type:

$$g_{n1} \sinh(x) \sinh(z) + g_{n2} \sinh(x) \cosh(z) + g_{n3} \cosh(x) \sinh(z) + g_{n4} \cosh(x) \cosh(z)$$

where ( $g_{ni}$ ) are polynomials of ( $h_{ni1} + h_{ni2}x + h_{ni3}z$ ), and ( $h_{ni1}$ ), ( $h_{ni2}$ ), and ( $h_{ni3}$ ) are polynomials of ( $a_{n1j} + \dots + a_{n1jm}y^{m-1}$ ). The selection of ( $\sinh x$ ), ( $\cosh x$ ), ( $\sinh z$ ), ( $\cosh z$ ), and  $y$  facilitated numerical calculations.

A typical distribution for the normal stress,  $\sigma_{yy}$ , common to both substrates A and B at the bonded interface of a three-dimensional flat interface between these substrates is shown in Fig. 14. This stress is calculated by the novel mathematical procedure based on differential geometry and the penalty function as described by Ma et al. (2001), and summarized above. Figure 15 shows the transverse stresses  $\sigma_{xx}$ , on substrates A and B at the bonded interface, illustrating the discontinuity of this stress across the interface, as sometimes called the “stress jump.” Again, these stresses are calculated by the novel mathematical procedure based on differential geometry and the penalty function as described by Ma et al. (2001), and summarized above.

### 23.3.8 Damage Models

The incremental theory of plasticity assumes that the strains depend on the entire history of loading. The total increments of deviatoric strain  $\Delta \epsilon_{ij}$  is composed of a viscoplastic component

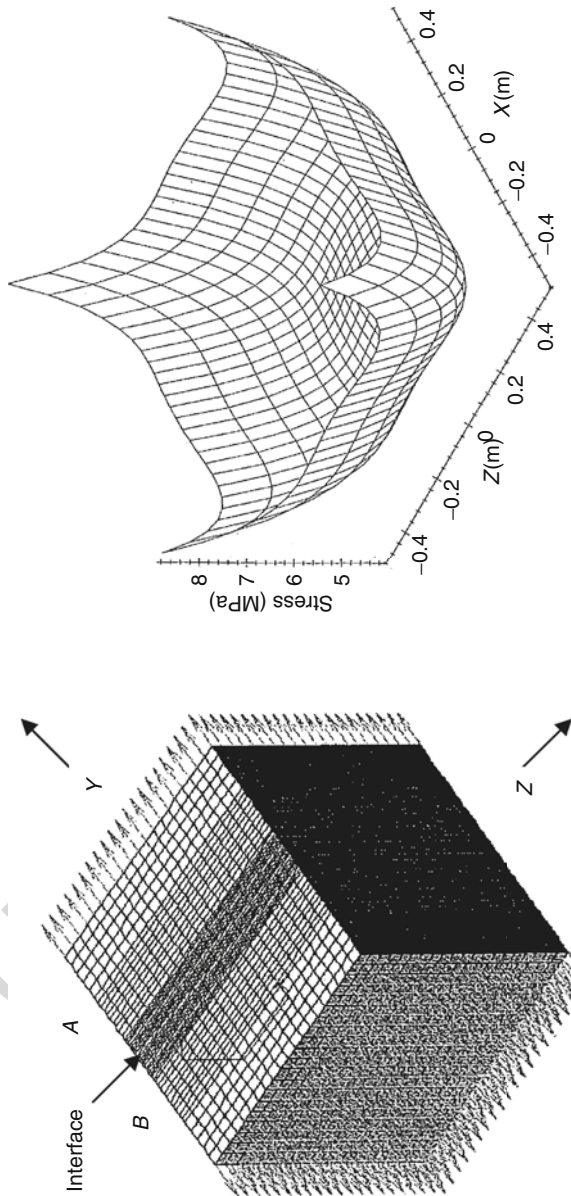

$$\Delta \epsilon_{ij}^P = d\lambda S_{ij} \quad (111)$$

where  $d\lambda$  is a variable depending on the loading history, and an elastic component

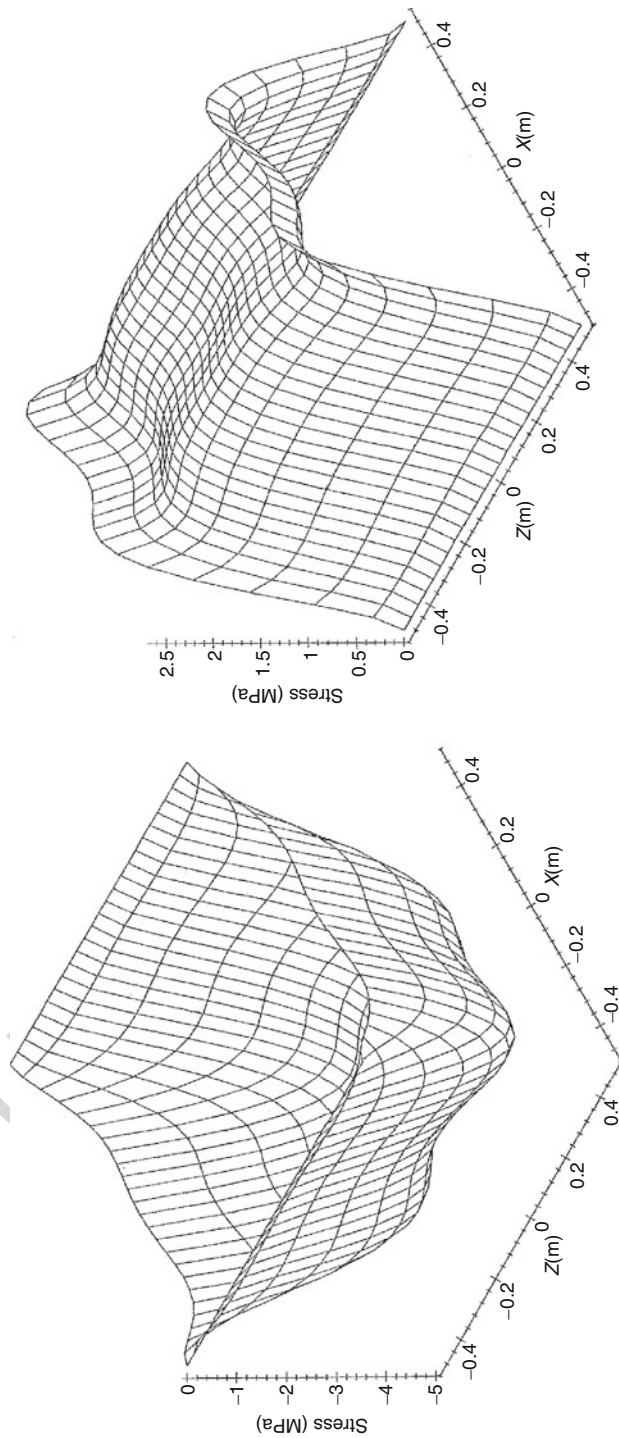

$$d\epsilon_{ij}^E = \left( \frac{dS_{ij}/dt}{2G} \right) \quad (112)$$

so that

**Fig. 14** A three-dimensional flat interface between two substrates A and B, loaded as shown and analyzed by FEA with the mesh pattern shown (left). A typical distribution for the normal stress,  $\sigma_{yy}$ , common to both substrates A and B at the bonded interface is shown on the right, as calculated by a novel mathematical procedure based on differential geometry and the penalty function

**Fig. 15** The transverse stresses  $\sigma_{xx}$  on substrates A (left) and B (right) at the bonded interface, illustrating the discontinuity of this stress across the interface, as sometimes called the “stress jump,” calculated by a novel mathematical procedure based on differential geometry and the penalty function

$$\frac{d\epsilon_{ij}}{dt} = \frac{d\epsilon_{ij}^E}{dt} + \frac{d\epsilon_{ij}^P}{dt}. \quad (113)$$

Obviously, a yield criterion is needed to determine the actual magnitudes of plastic strain increments. This theory was first proposed by Prandtl (1925) and Reuss (1930).

Several constitutive forms were proposed to describe the viscoplastic term of Eq. 113 by various researchers. Among these, Sokolovsky (1948) used the assumption that the viscoplastic component is a function of the over-stress above the yield point. On the basis of his experimental observations, Sokolovsky determined that the over-stress should be defined above the elastic limit, as a function  $F(\sigma - \theta)$ , so that

$$\epsilon = \frac{\sigma}{E}, \sigma \leq \theta. \quad (114.1)$$

$$\epsilon = \left(\frac{\sigma}{E}\right) + F \frac{(\sigma - \theta)}{E}, \sigma > \theta. \quad (114.2)$$

The over-stress idea can be incorporated into the viscoelastic mechanical models by means of adding sliding elements to describe yield or termination points. With such an application, equations containing viscosity terms are obtained in a form similar to (24.114). For example, Brinson et al. (1975), Renieri et al. (1976), Sancaktar and Brinson (1979, 1980), Sancaktar (1981), Sancaktar and Padgilwar (1982), Sancaktar et al. (1984), and Sancaktar and Schenck (1985) used the modified Bingham model developed by Brinson (1974) to describe the shear and tensile material behavior of structural adhesives in the bulk and bonded forms:

$$\sigma = E\epsilon \quad \sigma \leq \theta \quad (115.1)$$

$$\frac{d\epsilon}{dt} = \frac{d\sigma}{dt} + \frac{(\sigma - \theta)}{\mu} \theta < \sigma \leq Y \quad (115.2)$$

$$\sigma = Y \quad \sigma \geq Y. \quad (115.3)$$

The model describes linear elastic behavior below the elastic limit  $\theta$ , linear viscoelastic behavior between  $\theta$ , and the maximum stress  $Y$  and perfectly plastic behavior above  $Y$ . When the sliding element is activated at  $\sigma = \theta$ , the model becomes essentially a Maxwell element, as illustrated in Fig. 16.

A similar application was also reported first by Chase and Goldsmith (1974) and later by Sancaktar (1981), Sancaktar and Padgilwar (1982), Sancaktar et al. (1984), and Sancaktar and Schenck (1985), in modifying a three-parameter solid model with a sliding element to describe the mechanical behavior of polymeric materials and adhesives. Figure 17 shows stress-strain-strain rate behavior of LARC-3 carrier-cloth supported solid film adhesive and comparison with the Chase-Goldsmith

**Fig. 16** The modified Bingham model and its comparison with the Maxwell model.  $t_R = \mu/E$  = relaxation time and  $t_0$  is the time to reach elastic limit

model. LARC-3, a linear condensation polyimide adhesive, was made at NASA Langley Research Center by adding a 2:1 molar ratio of 3,3',4,4'-benzophenone tetracarboxylic dianhydride (BTDA) (0.010 mol)/pyromellitic dianhydride (PMDA) (0.005 mol) to 3,3'-diaminobenzophenone (DABP) (0.015 mol) in 429 of diglyme.

The Chase-Goldsmith model constitutive equations are given as (see Fig. 18):

$$\sigma = E\epsilon \leq \sigma_{\text{static}} \quad (116.1)$$

$$\frac{d\epsilon}{dt} = \left( \frac{(d\sigma/dt)}{E_1} \right) + \frac{(\sigma - \sigma_{\text{static}})}{\mu'} \sigma \geq \sigma_{\text{static}} \quad (116.2)$$

where

$$\sigma_{\text{static}} = \left[ \frac{E_1}{(E_1 + E_2)} \right] (Y + E_2\epsilon) \quad (117)$$

**Fig. 17** Stress–strain–strain rate behavior of LARC-3 adhesive bonded in symmetric-single lap configuration, and comparison with the Chase–Goldsmith model

813 and

$$\mu' = \left[ \frac{E_1}{(E_1 + E_2)} \right] \mu. \tag{118}$$

814

815 To obtain the constant strain rate relation, the above constitutive equation is  
816 solved using the condition,  $d \epsilon / dt = R = \text{constant}$ , to result in:

**Fig. 18** The Chase–Goldsmith model

$$\sigma = \left[ \frac{E_1}{(E_1 + E_2)} \right] \{ (Y + \mu' R + E_2 \epsilon (1 - \exp[-\alpha(\epsilon - \epsilon_Y)])) \} + \left\{ Y + \left[ \frac{E_1 E_2}{(E_1 + E_2)} \right] (\epsilon - \epsilon_Y) \right\} \exp[-\alpha(\epsilon - \epsilon_Y)] \quad (119)$$

where

$$\epsilon_Y = \frac{Y}{E_1} \quad (120)$$

$$\alpha = \frac{E_1}{\mu' R}. \quad (121)$$

Previous investigations by Sancaktar and Brinson (1979, 1980), Sancaktar (1981), and Sancaktar and Padgilwar (1982) on toughened structural adhesives with and without a carrier (Metlbond 1113 and 1113-2 solid film adhesives, respectively) showed that the bonded adhesive behavior was predominantly affected by the presence of inherent flaws and the ensuing fracture processes due to their presence. Figure 19 shows the variability of the shear stress–strain behavior in the symmetric-single lap joint form for similar specimens tested under monotonic loading. Prior to testing, a neutron radiography examination of the joints shown in Fig. 19 revealed that the variations in the stress-strain behavior were results of inherent flaws (voids) in the bond line, which constituted approximately 6–8% of the bond area. With brittle adhesives, the presence of inherent flaws may lead to fracture processes and catastrophic failures.

**Fig. 19** Symmetric single lap adhesive stress–strain response of Metlbond-1113 film adhesive with synthetic carrier cloth and containing inherent flaws prior to testing. The dashed line represents the stress–strain behavior predicted for the same testing rate based on the bulk adhesive data

An isothermal theory of separation in (thermoplastic or pressure sensitive) polymer-solid adhering systems based on drawing of filaments is given by Good and Gupta (1988).

Ganghoffer and Schultz (1996) stated that the influence of damage on the mechanical behavior is specified through the concept of strain equivalence. They propose that the constitutive law for the damaged material is given by that of the virgin material if the stress tensor  $\sigma$  is replaced by the effective stress tensor  $\sigma/(1 - d)$  with the term,  $d$ , representing the extent of damage between the virgin state,  $d = 0$  and complete failure,  $d = 1$ .

Another example of empirical damage modeling in joints bonded using silver flake-filled electrically conductive adhesives was given by Gomatam and

Sancaktar (2006a, b), who introduced a comprehensive fatigue life predictive model for single lap joints subjected to variable loading (2006b). For the purpose of formulating a fatigue life predictive model, a linear relationship is established first between the maximum cyclic load  $P_{\max}$  (or maximum principal stress,  $\sigma_{\max}$ , as suggested by Gomatam (2002), and Gomatam and Sancaktar (2004)) and the number of cycles  $N$ :

$$P_{\max} = C' + m'N \quad (122)$$

where  $(C')$  and  $(m')$  are the intercept and slope for this linear relation, respectively.

For the purpose of the analytical fatigue life predictive model, two separate analytical equations were proposed depending on the intensity (severe or moderate) of the load-ratio first applied, at a maximum cyclic load level. The total fatigue life,  $N_{\text{Total}}$ , under severe-to-moderate condition was predicted by the relation

$$N_{\text{Total}} = n_s + \frac{\Delta C}{m_M} - (C_s - P) \left( \frac{1}{m_s} - \frac{1}{m_M} \right) \left( 1 - \frac{n_s}{N_s} \right). \quad (123)$$

The total fatigue life under moderate-to-severe condition, on the other hand, was predicted by

$$N_{\text{Total}} = n_M + N_s \left( 1 - \frac{n_M}{N_M} \right). \quad (124)$$

The term  $\Delta C$ , in Eqs. 123 and 124, is defined as:

$$\Delta C = C_M - C_s, \quad (125)$$

where  $C_M$  and  $C_s$  are the intercepts, and  $m_M$  and  $m_s$  are the slopes for the linear relationships between the maximum cyclic load  $P_{\max}$  (or maximum principal stress,  $\sigma_{\max}$ ) and the number of cycles  $N$  under moderate and severe conditions, respectively.  $n_M$  and  $n_s$  are the number of cycles applied under moderate and severe conditions, respectively.

As illustrated in Fig. 20, in going from moderate-to-severe conditions, the predicted remaining life for the sample under the severe condition,  $N_s[1 - (n_M/N_M)]$ , is simply added to the number of cycles under moderate conditions ( $n_M$ ), based on experimental predictions without making any slope corrections, Eq. 124. In going from severe-to-moderate condition, however, a slope correction,  $[C_s - P] \{ (1/m_s) - (1/m_M) \} [1 - (n_s/N_s)]$ , is also made, in order to make the severe and moderate load–number of cycles ( $P$ – $N$ ) curves parallel, and shift the intercepts to add the remaining life,  $\Delta C/m_M$ , to that already used up under severe condition (i.e.,  $n_s$ ). These particular methodologies were chosen based on experimental observations. Utilizing the above equations, the total fatigue life of the joints subjected to varying loading conditions, namely, severe-to-moderate and moderate-to-severe were computed for a set of test cases, in addition to experimentally determined values, for the

**Fig. 20** Illustration of the cumulative fatigue damage model

purpose of model validation. Comparison between the experimental and predicted values validated the accuracy and efficiency of the proposed model.

In order to render the model usable with different stress components ( $\sigma_{xx}$ ,  $\sigma_{yy}$ ,  $\sigma_{zz}$ ,  $\tau_{xy}$ ,  $\tau_{yz}$ ,  $\tau_{xz}$ ) instead of the maximum cyclic load values, Gomatam (2002) utilized the maximum and minimum principal and von Mises stresses obtained from non-linear elastoplastic finite element analyses to calculate the ratios of peak stress values obtained at corresponding maximum load levels. These stresses were then compared to the intercept ratios obtained from the P–N curves at given environmental conditions. This comparison procedure revealed the maximum principal stress as the appropriate parameter to be used in the form of stress-number of cycles (S–N) curves, that is,

$$\sigma_{\max} = C + mN \quad (126)$$

where  $C$  and  $m$  are, respectively, the intercept and slope values based on maximum principal stress. The mathematical basis for the maximum principal stress to replace the maximum cyclic load in Eq. 122 was illustrated by performing fatigue tests under three different maximum load,  $P_{\max}$ , conditions, and considering the following relations:

$$\frac{C'_3}{C'_1} = \frac{C_3}{C_1}, \quad (127)$$

and

$$\frac{C'_2}{C'_1} = \frac{C_2}{C_1} \quad (128)$$

where  $(C'_1, C'_2, C'_3)$  relate to Eq. 122, and  $C_1, C_2, C_3$  relate to Eq. 125.

In order to account for environmental effects, such as elevated temperature and humidity, a superposition method was applied for fatigue life prediction by shifting the slopes and the intercepts between different environmental conditions. For this purpose, design charts were formulated based on experimental data. These design charts comprise two parts, one for shifting the slope and the other for shifting the intercept between different environmental conditions. Once the slopes and the intercepts are determined, Eqs. 122 and 125 would yield the fatigue life of the joint at the new environmental condition, as illustrated in Fig. 21 (Gomatam and Sancaktar 2006b).

The proposed model was also extended to bonded cases with varying stress states. For this purpose, a nonlinear elastoplastic finite element analysis (FEA) for ambient condition, and a nonlinear thermoelastoplastic FEA for elevated temperature conditions were performed using two different lap joint geometries and boundary conditions to represent two distinct states of stress. Utilizing the FEA results, relations between the stress components, slopes, and intercepts were established. The intercepts were found to be inversely proportional to the maximum stresses, and the slopes directly proportional to a shear stress component. Thus, by using these relations along with knowledge of the stress states for only two joint configurations, the slope and intercept for any other lap joint with unknown P–N ( $\sigma - N$ ) behavior could be computed, from which the fatigue life of the joint could be predicted.

### 23.3.9 The Effects of Cure and Processing Conditions on the Mechanical Behavior

Cure and processing conditions have strong effects on the resulting mechanical properties of structural adhesives in the bulk and bonded forms.

**Fig. 21** The shifting mechanism, shown by horizontal arrows, implemented for the purpose of predicting fatigue life of joints subject to a stress ratio ( $R$ ), and maximum cyclic load of  $P_{max}$ , from one test environment (28 °C, or 50 °C, or 90 °C) to another at the same stress ratio, and maximum cyclic load, RT indicates room temperature

Variation of various mechanical properties of an epoxy adhesive with or without a carrier cloth as functions of cure temperature, time, and cooldown conditions, and their effects on bulk tensile properties were studied by Sancaktar et al. (1983), Jozavi and Sancaktar (1989a, b, c), and Sancaktar (1995), with the work by Jozavi and Sancaktar (1989c) providing information on the effects of cure conditions on the relaxation behavior of bulk thermosetting adhesives. A comparison of the degree of cure with bulk strength was given by Jozavi and Sancaktar (1988). The effects of the cure parameters on the stress-whitening behavior were given by Jozavi and Sancaktar (1989a, b). The effects on the bonded joint behavior were discussed by Shaw and Tod (1989), Sancaktar and Ma (1992), and Turgut and Sancaktar (1992). In general, mechanical properties are improved with increases in cure temperature and time and with slow cooldown. Such increases, however, have an upper limit, and further increases in cure parameter magnitudes lead to deterioration in adhesive mechanical properties. Consequently, in general, the variation of mechanical properties are bell-shaped functions, showing an initial increase with decreasing slope followed by a decreasing trend, when plotted against the cure parameters.

Additional information on the effects of cure conditions were provided by Sinclair (1992).

In the case of particle-filled adhesive systems, such as electrically conductive adhesives, the viscosity,  $\mu$ , during processing and cure is a function of filler volume fraction,  $\Phi$ , shear rate,  $d\gamma/dt$ , and resin conversion level,  $\alpha$ . The development of viscosity from a chemorheological point of view is important as it relates to the wetting and diffusive characteristics of the adhesive during its cure. These characteristics ultimately determine the viability of the interphase and, therefore, the overall adhesive bond. A comprehensive model may be represented by combining the following models: the power law describing the shear rate effect (Wildemuth and Williams 1985), Castro-Macosko model describing the conversion effect (Castro et al. 1984), and Liu model describing the filler volume fraction effect (Liu 2000). Such a combined model takes the form:

$$\mu\left(\phi, \frac{d\gamma}{dt}, \alpha\right) = A \cdot (\phi_m - \phi)^{-2} \cdot \left(\frac{d\gamma}{dt}\right)^{C_0+C_1\cdot\alpha} \cdot \left[\frac{\alpha_{gel}}{(\alpha_{gel} - \alpha)}\right]^{D+E\cdot\alpha} \quad (129)$$

where  $A$ ,  $C_0$ ,  $C_1$ ,  $D$ , and  $E$  are model constants that can be determined by multivariable nonlinear regression analysis of isothermal data. The maximum filler volume fraction,  $\Phi_m$ , and conversion at gel point,  $\alpha_{gel}$ , values are usually known for typical thermosets.

Zhou and Sancaktar (2008) incorporated the isothermal temperature effects to obtain a general-form comprehensive model in the form:

$$\mu\left(T, \phi, \frac{d\gamma}{dt}, \alpha\right) = A \cdot \exp\left(\frac{B}{T}\right) \cdot (\phi_m - \phi)^{-2} \cdot \left(\frac{d\gamma}{dt}\right)^{C_0+C_1\cdot\alpha} \cdot \left[\frac{\alpha_{gel}}{(\alpha_{gel} - \alpha)}\right]^{D+E\cdot\alpha} \quad (130)$$

where  $B$  is the activation temperature and other coefficients are same as in Eq. 129.

In order to model realistic adhesive processing, usually with a broad temperature range, nonisothermal tests usually need to be undertaken. The comprehensive isothermal chemoviscosity model, based on Eq. 130, can then be extended to nonisothermal temperature cure cycle through nonlinear regression analysis of nonisothermal data.

In fact, nonisothermal temperature cure is a different process from isothermal cure. The reaction kinetics, total reaction order, and even the reaction energy for epoxy systems may not be constant and same, but process dependent. Therefore, modifications need to be made to reflect the effects of such a difference.

An improvement in the model predictability is expected by allowing parameters  $D$  and  $E$  in Eq. 130 to change with temperature during nonisothermal cure. Furthermore, both of these parameters also show some variation with the volume fraction ( $\Phi$ ) and shear rate ( $(d\gamma/dt)$ ). A modified comprehensive model was thus proposed as follows (Zhou and Sancaktar 2008):

$$\mu\left(T, \phi, \frac{d\gamma}{dt}, \alpha\right) = A \cdot \exp\left(\frac{B}{T}\right) \cdot (\phi_m - \phi)^{-2} \cdot \left(\frac{d\gamma}{dt}\right)^{C_0 + C_1 \cdot \alpha} \cdot \left[\frac{\alpha_{\text{gel}}}{(\alpha_{\text{gel}} - \alpha)}\right]^{D^* + E^* \cdot \alpha} \quad (131)$$

where

$$D^* = D_0 + D_1 \cdot \left(\frac{d\gamma}{dt}\right) + D_2 \cdot \phi + D_3 \cdot T \quad (132)$$

$$E^* = E_0 + E_1 \cdot \left(\frac{d\gamma}{dt}\right) + E_2 \cdot \phi + E_3 \cdot T \quad (133)$$

with  $D_i$  and  $E_i$  values to be determined by data fitting.

## 23.4 Prediction of Limit (Threshold) and Failure Stresses

In predicting limit (threshold) conditions, such as the elastic limit, yield, and failure conditions, classical failure criteria, such as the maximum normal stress criterion, maximum shear stress criterion and the distortion energy (von Mises) criterion can be employed.

If the yield strength,  $\sigma_y$ , of the material is the same under tensile and compressive conditions, that is,  $\sigma_{yc} = \sigma_{yt}$ , the von Mises failure criteria, which is based on (deviatoric) distortion energy considerations, provides accurate predictions of yield:

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_1 - \sigma_3)^2 = \text{constant} = 2\sigma_y^2. \quad (134)$$

The left-hand side of Eq. 134 is related to the second invariant,  $(J'_2)$  of the stress deviator tensor by the relation:

$$6J'_2 = (\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_1 - \sigma_3)^2 \quad (135)$$

If the condition,  $\sigma_{yc} > \sigma_{yt}$ , prevails, then the hydrostatic pressure,  $p$ , also affects the yield process. A given stress tensor,  $\sigma_{ij}$ , can be written as:

$$\sigma_{ij} = p + \sigma_{\text{deviatoric}},$$

and the hydrostatic pressure,  $p$ , is defined as:

$$p = (1/3)[\sigma_1 + \sigma_2 + \sigma_3] \quad (136)$$

Therefore, by using Eqs. 134–136, the von Mises yield criterion can be modified to the form:

$$\begin{aligned} 2(\sigma_{yc} - \sigma_{yt})[\sigma_1 + \sigma_2 + \sigma_3] + [(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_1 - \sigma_3)^2] \\ = 2\sigma_{yc}\sigma_{yt}. \end{aligned} \quad (137)$$

Conditions resulting in the creation of free volume, such as crazing (stress whitening) and cavitation relate to the magnitude of the hydrostatic stress. Level of the critical (or crazing) strain,  $\epsilon_{CR}$  at such occurrences can be predicted using the relation:

$$\epsilon_{CR} = C + (D/p) \quad (138)$$

where  $C$  and  $D$  are temperature and rate-dependent material constants, and  $p$  is the hydrostatic stress.

## 23.5 Conclusion

Constitutive modeling of adhesives and sealants include considerations for deformation theories and viscoelasticity with linearity and nonlinearity considerations, rubber elasticity, singularity methods, bulk adhesive as composite material, damage models, and the effects of cure and processing conditions on the mechanical behavior. However, the concept of the “interphase” must always be kept in mind for accurate predictions in mechanical behavior of surfaces and joints bonded with adhesives and sealants. Interfaces may constitute a weak link in the chain of load transfer in bonded joints. Also, the discontinuity of the material properties causes abrupt changes in stress distribution, as well as causing stress singularities at the edges of the interfaces. In most engineering joints the adherend surfaces have distinct topographies, which result in a collection of miniature joints in micron, and even nanoscale when bonded adhesively. If the interphase is not considered as a

discrete collection of individual chemical bonds, the methods of continuum mechanics can still be applied to this collection of miniature joints by assuming continuous or a combination of continuous/discontinuous interphase zones. Thus, the displacement at the interphase need not be continuous at every location. The analysis of a miniature joint contributing to the overall adhesion in a macro joint can be performed in a fashion similar to that for the macro joint itself, which is usually studied with the employment of the methods of linear or nonlinear elasticity, viscoelasticity, plasticity, fracture, damage, and/or failure mechanics.

### Abstract

This chapter presents analytical approach for determining stress and strength of adhesively bonded joints. Selected applications of adhesively bonded joints are discussed first, and then mathematical models for stress analysis of these joints are outlined. Various closed-form solutions for adhesive stresses and edge bending moment for balanced single-lap joints are presented and compared. The method for finding analytical solutions for asymmetric and unbalanced adhesive joints is also discussed. Explicit expressions for mode I and mode II energy release rates for cohesive failure and interfacial debonding are presented for asymmetric joints with a semi-infinite length subjected to general load combinations.

## 24.1 Introduction

Adhesive bonding technology is increasingly being used in practical structures due to its load-transferring performance. It can be used to effectively join similar and dissimilar thin sheets of materials via forming superb load-bearing structural joints (Adams et al. 1997; Tong and Steven 1999). It can behave superior to mechanical fastening in joining composite parts due to relatively smooth stress distribution compared to highly localized stress concentration in mechanically fastened joints. It is finding wider applications in many industries. For example, in aerospace and automotive industries, it is used to connect thin-walled structural parts; in civil engineering, it is used to reinforce concrete structures by bonding composite materials; and in intelligent structural systems, it is used to bond functional materials to host structures.

Figure 1 depicts some of the typical joint configurations to join structural panel components.

When adhesive bonding is used to repair or strengthen structural defects, such as cracks and ballistic damage, single-sided, double-sided, scarf and step repair configurations, as shown in Fig. 2, are usually used.

Reinforced concrete (RC) beams with adhesively bonded fiber-reinforced polymer (FRP) as shown in Fig. 3a have also been widely used in civil engineering. In this case, the fiber-reinforced polymer plate plays the role of bridging the cracks in the concrete beams, thus slowing down or arresting the crack propagation. Figure 3b

**Fig. 1** Common joint configurations: (a) single-lap joint; (b) double-lap joint; (c) L-joint; (d) T-joint

**Fig. 2** Composite repair configurations: (a) single-strap joint; (b) double-strap joint; (c) scarf joint; (d) step joint

**Fig. 3** Adhesive bonding technology used in civil engineering and intelligent structure systems: (a) FRP-plated RC beam; (b) PZT smart plate

illustrates a piezoelectric (PZT) smart plate, in which PZT patches are adhesively bonded to the plate surface to control its structural performance.

Figures 1, 2, and 3 illustrate that lap-type adhesive joints are common configurations used in practical structures. Although lap-type joints have the features of two-dimensional (2D) geometry, their stress analysis usually involves three-dimensional (3D) stresses and strains; hence it is a 3D problem in nature. Numerical methods, such as finite element analysis (FEA) (see ► Chap. 25, “Numerical Approach: Finite Element Analysis”), have been used to solve 3D problems of adhesively bonded structures. However, simple and closed-form solutions are important in terms of identifying fundamental characteristics and key parameters. Analytical solutions can also be useful in preliminary design stage as they can offer in timely fashion, simple, quick, and meaningful answers. Therefore, considerable efforts have been devoted to the development of analytical approach for determining stress and strength of an adhesively bonded joint. Hence, this chapter focuses on presentation of basic mechanics models and analytical solutions for selected adhesively bonded joints.

In order to derive closed-form explicit solutions for adhesively bonded joints/structures, it is important to develop appropriate mechanics models that take into account fundamental characteristics and key parameters. It is a compromise between the including of selected physical behavior and likelihood of admissible explicit solutions, and this balance plays a vital role in the development of analytical solution methods.

A lap-type joint often consists of one or more adhesive layer(s) sandwiched between two or more beams/plates usually referred to as adherends. An adherend usually has a thickness smaller than the other in-plane dimension(s), and when the aspect ratio, that is, in-plane dimension-to-thickness ratio, is sufficiently large, it is reasonable to model the adherends as a beam or plate. As the theory for beam-like structures have been well established, adherends in most adhesively bonded structures can be simplified as beam- or plate-like structures. An adhesive layer typically has a thickness of a fraction of a millimeter, for example, a bondline thickness of approximately 0.2 mm is common in secondarily bonded aerospace or automobile structures. The stress state in the adhesive layer is rather complex in 3D or 2D nature when the adherends are modeled as plates or beams, respectively. However, in practice, an adhesive is very thin compared to an adherend; therefore, the adhesive layer is generally modeled by an infinite number of springs or an interface by assuming that the only adhesive normal (thickness direction) and shear stresses exist, and they remain constant across the bondline thickness and only vary along the bondline length. This approximation leads to a mechanics model (referred as 1D model) that permits analytical solutions for stresses in an adhesively bonded joint.

In this chapter, analytical models and solutions for adhesively bonded joints treated as beam-like structures are presented.

## 24.2 Classical Analytical Analysis of Single-Lap Joints

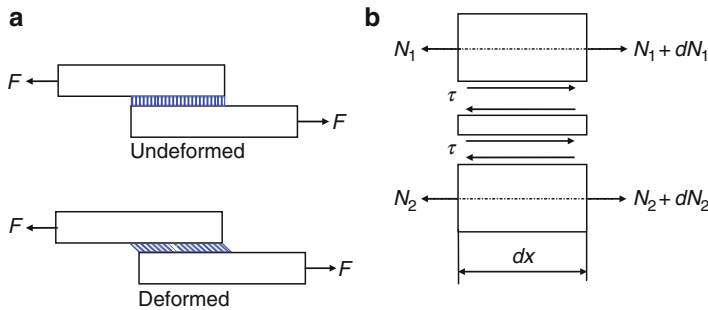

The simplest geometric configuration of adhesively bonded structures is probably the single-lap joint (SLJ), which has been widely used as a standard test specimen to calibrate adhesive properties and has been shown to be representative and challenging in identifying fundamental characteristics and key parameters in bonded lap joints.

### 24.2.1 Adhesive Stress

#### Average Shear Stress Model

This model treats the adherend as a rigid bar and the adhesive as continuous shear spring, which is based on the assumption that the adherends are so stiff that they do not deform and only the adhesive deforms as it is so soft, as shown in Fig. 4a. In this model, the adhesive shear stress uniformly distributes within the adhesive and is given by:

$$\tau = F/(2c) \quad (1)$$

**Fig. 4** Stress analysis of the adhesive based on the one parameter elastic medium: (a) an average shear stress model; (b) free body diagrams of the shear lag model

where  $F$  is the applied tensile force per unit width and  $(2c)$  is the overlap length; the unit width of a beam has been assumed. In this chapter, the unit width and plane stress state are assumed for brevity. The results can be easily extended to plane strain state by changing the related parameters. Also, the composite adherends with the symmetric lay-ups are assumed. The results can be directly applied to joints with isotropic adherends.

### Shear Lag Model

Volkersen (1938) proposed a shear lag model, in which the adherend was modeled as a rod undergoing axial or longitudinal deformation only and the adhesive as a continuous shear spring. As shown in Fig. 4b, the equilibrium and constitutive equations for adherends 1 and 2 are:

$$\frac{dN_1}{dx} + \tau = 0; \frac{dN_2}{dx} - \tau = 0 \quad (2)$$

$$N_i = A_{di} \frac{du_i}{dx} \quad (i = 1, 2) \quad (3)$$

where  $A_d$  is the extensional stiffness and subscript  $i$  ( $i = 1, 2$ ) denotes adherend 1 and 2. The adhesive shear stress is defined as:

$$\tau = \frac{G_a}{t_a} (u_2 - u_1) \quad (4)$$

where  $G_a$  and  $t_a$  are the shear modulus and thickness of the adhesive.

The shear stress can be found by solving Eqs. 2, 3, and 4 and is given by:

$$\tau = \left( \frac{\beta_v F}{2} \right) \left[ \frac{\cosh \beta_v x}{\sinh \beta_v c} - \frac{(1 - \psi) \sinh \beta_v x}{(1 + \psi) \cosh \beta_v c} \right] \quad (5)$$

where  $\beta_v = \sqrt{\frac{(1 + \psi) G_a}{t_a A_{d1}}}$  and  $\psi = \frac{A_{d1}}{A_{d2}}$

This solution clearly shows that the shear stress is not uniform along the bondline length direction and peaks at the adhesive ends. The maximum shear stress occurs at one end and is given by:

$$\tau_{\max} = \left( \frac{\beta_v F}{2} \right) \left[ \frac{\cosh \beta_v c}{\sinh \beta_v c} - \frac{(1 - \psi) \sinh \beta_v c}{(1 + \psi) \cosh \beta_v c} \right] \text{ when } \psi \geq 1 \quad (6a)$$

OR

$$\tau_{\max} = \left( \frac{\beta_v F}{2} \right) \left[ \frac{\cosh \beta_v c}{\sinh \beta_v c} + \frac{(1 - \psi) \sinh \beta_v c}{(1 + \psi) \cosh \beta_v c} \right] \text{ when } \psi \leq 1 \quad (6b)$$

For a relatively long overlap, the maximum shear stress can be approximately written as:

$$\begin{aligned} \tau_{\max} &= \frac{\psi \beta_v F}{1 + \psi} \text{ when } A_{d1} \neq A_{d2} \\ \text{or : } \tau_{\max} &= \frac{1}{2} \beta_v F \text{ when } A_{d1} = A_{d2} \end{aligned} \quad (6c)$$

In Eq. 6c,  $\sinh \beta_v c \approx \cosh \beta_v c$  is assumed, which is sufficiently accurate in most adhesive joints used in engineering.

### Adhesive-Beam Model

Goland and Reissner (1944) proposed an adhesive-beam model for the single-lap joint shown in Fig. 5a, in which a two-parameter elastic medium and Euler beams are used to model the adhesive and adherends, respectively.

The free body diagrams of an infinitesimal element are shown in Fig. 6a, and the equilibrium equations of adherends 1 and 2 are:

$$\begin{cases} \frac{dN_1}{dx} + \tau = 0; & \frac{dQ_1}{dx} + \sigma = 0; & \frac{dM_1}{dx} + \frac{t_1}{2} \tau - Q_1 = 0 \\ \frac{dN_2}{dx} - \tau = 0; & \frac{dQ_2}{dx} - \sigma = 0; & \frac{dM_2}{dx} + \frac{t_2}{2} \tau - Q_2 = 0 \end{cases} \quad (7)$$

where  $t_1$  and  $t_2$  are the thicknesses of adherends 1 and 2,  $t_2 = t_1$  is for the balanced joints, and  $\tau$  and  $\sigma$  are the adhesive shear and peel stresses, defined by:

$$\tau = \frac{G_a}{t_a} \left[ (u_2 - u_1) + \left( \frac{t_1}{2} \frac{dw_1}{dx} + \frac{t_2}{2} \frac{dw_2}{dx} \right) \right]; \sigma = \frac{E_a}{t_a} (w_2 - w_1) \quad (8)$$

in which  $E_a$  is Young's modulus of the adhesive.

By using the Euler beam theory, Eqs. 7 and 8, the governing equations for adhesive stresses can be derived as:

**Fig. 5** A single-lap joint: (a) configuration; (b) deformation and forces in cross sections *I* and *II* of the deformed single-lap joint; (c) forces at the overlap edges; (d) SLJ with alignment tabs

$$\frac{d^3 \tau}{dx^3} - \beta_c^2 \frac{d\tau}{dx} = 0; \frac{d^4 \sigma}{dx^4} + 4\beta_\sigma^4 \sigma = 0 \quad (9)$$

146 in which

$$\beta_c^2 = \alpha_a \beta_\tau^2; \beta_\tau = \sqrt{\frac{8G_a}{A_{d1}t_a}}; \beta_\sigma = \frac{\sqrt{2}}{2} \times \sqrt[4]{\frac{2E_a}{D_1 t_a}}; \alpha_a = \frac{1}{4}(1 + \alpha_k); \alpha_k = \frac{4A_{d1}t_1^2}{D_1} \quad (10)$$

147 where  $D_1$  is the bending stiffness of adherends 1 and 2 and  $\alpha_a$  and  $\alpha_k$  reflect the  
148 influences of composite lay-ups. For isotropic adherends,  $\alpha_a = 1$  and  $\alpha_k = 3$ .

149 Solving Eq. 9 with the boundary conditions shown in Fig. 5b, c yields:

$$\begin{cases} \tau = \frac{\beta_c(Ft_1 + 2\alpha_k M_k) \cosh \beta_c x}{8\alpha_a t_1 \sinh \beta_c c} + \frac{\alpha_k(Ft_1 - 2M_k)}{8\alpha_a t_1 c} \\ \sigma = B_{\sigma 1} \sinh \beta_\sigma x \sin \beta_\sigma c + B_{\sigma 4} \cosh \beta_\sigma x \cos \beta_\sigma c \end{cases} \quad (11)$$

150 where

**Fig. 6** Stress analysis of the adhesive based on a two-parameter elastic medium: (a) free body diagrams of a **linear** overlap; (b) free body diagrams of a **nonlinear** overlap

$$\begin{cases} B_{\sigma 1} = \frac{2\beta_{\sigma}[M_k\beta_{\sigma}(\sinh \beta_{\sigma}c \cos \beta_{\sigma}c + \cosh \beta_{\sigma}c \sin \beta_{\sigma}c) + V_k \sinh \beta_{\sigma}c \sin \beta_{\sigma}c]}{\sinh 2\beta_{\sigma}c + \sin 2\beta_{\sigma}c} \\ B_{\sigma 4} = \frac{2\beta_{\sigma}[M_k\beta_{\sigma}(\sinh \beta_{\sigma}c \cos \beta_{\sigma}c - \cosh \beta_{\sigma}c \sin \beta_{\sigma}c) + V_k \cosh \beta_{\sigma}c \cos \beta_{\sigma}c]}{\sinh 2\beta_{\sigma}c + \sin 2\beta_{\sigma}c} \end{cases} \quad (12)$$

As  $\sinh \beta_{\sigma}c > 1$  and  $\sinh \beta_c c > 1$  in most cases, the maximum shear and peel stresses occur at the adhesive edges and can be simplified as:

$$\tau_{\max} = \frac{Ft_1(\beta_c c + \alpha_k) + 2\alpha_k M_k(\beta_c c - 1)}{8\alpha_a t_1 c}; \sigma_{\max} = \beta_{\sigma}^2 \left( M_k + \frac{V_k}{\beta_{\sigma}} \right) \quad (13)$$

It is noted that the stress analysis of Goland and Reissner (1944) is for adhesively bonded isotropic joints, and an extension to composite joints is presented here.

### Adhesive Models Based on Two-Dimensional Elastic Theory

When an adhesive layer is relatively thick, the above adhesive model of assuming constant shear and peel strains may not be effective. In fact, shear and peel strains are not constant, and the axial strain may not be ignored even if the adhesive is very thin (e.g.,  $<0.2$  mm) (Ojalvo and Eidinoff 1978; Luo and Tong 2004). In addition, the constant adhesive model does not satisfy the boundary condition of free shear stress at an adhesive end.

To capture stress variation through the adhesive thickness and free edge stress in the adhesive ends, models based on the 2D elastic theory have been used. Allman (1977) and then Chen and Cheng (1983) assumed linear variation of peel stress and constant shear stress across the adhesive thickness. Ojalvo and Eidinoff (1978) and then Carpenter (1980) adopted linear variation of shear stress and constant peel stress through the thickness. Luo and Tong (2004) chose linear and higher-order variations of shear, peel, and axial normal stresses across the adhesive thickness.

Adams and Mallick (1992) and then Zhao and Lu (2009) developed analytical models for the adhesively bonded joints using 2D elasticity, in which both adhesive and adherends are described as elastic media. Their models can be applied to joints with thick adhesive. Analytical solutions of adhesively bonded composite joints for this model are unavailable or too complicated.

When the adhesive is thin (e.g.,  $<0.3$  mm), the adhesive model with constant shear and peel stresses can be used to describe overall structural performance of adhesively bonded joints. Since the adhesive stresses are not constant across the thickness even for very thin adhesive, the adhesive shear and peel stresses should be deemed as an approximation to those in the adhesive midplane.

## 24.2.2 Load Update and Bending Moment Factor

Due to load eccentricity in the SLJ of Fig. 5a, large deflections must be considered, as shown in Fig. 5b. This means that the bending moment  $M_k$  and the shear force  $V_k$  at the overlap ends need to be updated with structural deformation. This geometric nonlinearity can be characterized by the bending moment factor or edge moment factor  $k$  and is defined as:

$$M_k = k \frac{(t_1 + t_a)}{2} F \quad (14)$$

It is noted that  $t_a$  is ignored in the definition of edge moment factor  $k$  in Goland and Reissner (1944). They presented the uncoupled formulation for determining the joint edge force update and adhesive stresses in Part I and Part III of their work. In Part I, the large deflections of both outer adherends and overlap were considered with the overlap being treated as an entire beam. Deflections of the left outer adherend and the overlap of the SLJ in Fig. 5 are:

$$w_3 = A \sinh \beta_k x_3 + \frac{(t_1 + t_a)x_3}{2(l+c)}; w_o = B \sinh \beta_o x_o + \frac{(t_1 + t_a)x_o}{2(l+c)} \quad (15)$$

in which

$$\beta_k = \sqrt{\frac{F}{D_1}}; \quad \beta_o = \sqrt{\frac{F}{D_o}} \quad (16)$$

where  $D_o$  is the bending stiffness of the entire overlap and  $A$  and  $B$  are the integration constants to be determined by the continuity conditions at intersection  $I$ . The joint edge forces  $M_k$  and  $V_k$  can be found by using  $M_k = -D_1 w_3''(l)$  and  $V_k = -D_1 w_3'''(l)$ . The edge moment factor is given by:

$$k = \frac{1}{1 + (\beta_k/\beta_o)\tanh \beta_o c \coth \beta_k l} \quad (17)$$

or :  $k = \frac{1}{1 + (\beta_k/\beta_o)\tanh \beta_o c}$  when  $\coth \beta_k l \approx 1$

## 24.3 Other Analytical Solutions for Single-Lap Joints

### 24.3.1 Adhesive Stress with the Effects of Transverse Shear and Geometric Nonlinearity

In the classical adhesive-beam model proposed by Goland and Reissner (1944), the equilibrium equations are derived from Fig. 6a by using the Euler beam to model the isotropic adherends. That is, the overlap geometric nonlinearity, transverse shear, and normal stiffness of the adherends are not modeled. In adhesively bonded composite structures, such as single-lap joints and single-sided patch repairs, geometric nonlinearity and transverse shear stiffness can significantly affect the adhesive stresses due to large deflection and relatively lower transverse stiffness of composites. Therefore, geometric nonlinearity and transverse stiffness should be considered.

When the geometric nonlinearity is considered, the associated free body diagrams are illustrated in Fig. 6b. To model transverse stiffness of the adherends, the Timoshenko or higher-order beam theory needs to be used to model the adherends (Srinivas 1975; Renton and Vinson 1975; Carpenter 1991; Yang and Pang 1993; Luo and Tong 2008; Yousefsani and Tahani 2013). In the analytical formulations conducted by Luo and Tong (2008), the following variables are introduced:

$$\begin{cases} 2u_s = u_2 + u_1; & 2w_s = w_2 - w_1; & 2\phi_s = \phi_2 - \phi_1 \\ 2u_a = u_2 - u_1; & 2w_a = w_2 + w_1; & 2\phi_a = \phi_2 + \phi_1 \\ 2N_s = N_2 + N_1; & 2Q_s = Q_2 - Q_1; & 2M_s = M_2 - M_1; & 2V_s = V_2 - V_1 \\ 2N_a = N_2 - N_1; & 2Q_a = Q_2 + Q_1; & 2M_a = M_2 + M_1; & 2V_a = V_2 + V_1 \end{cases} \quad (18)$$

where subscripts  $1$  and  $2$  indicate adherends 1 and 2; subscripts  $s$  and  $a$  denote the symmetric and anti-symmetric deformations; and the variables have the usual meanings used in Timoshenko beam theory.

The equilibrium equations derived by considering the geometric nonlinearity of Fig. 6b are (Luo and Tong 2007, 2008):

$$\begin{cases} \frac{dN_1}{dx} + \tau = 0; & \frac{dQ_1}{dx} + \sigma + \tau\phi_1 = 0; & \frac{dM_1}{dx} + \frac{t_1}{2}\tau - Q_1 = -N_1\phi_1 \\ \frac{dN_2}{dx} - \tau = 0; & \frac{dQ_2}{dx} - \sigma - \tau\phi_2 = 0; & \frac{dM_2}{dx} + \frac{t_1}{2}\tau - Q_2 = -N_2\phi_2 \end{cases} \quad (19)$$

219 When the Timoshenko beam is used to model the adherends, the adhesive shear  
220 and peel stresses can be expressed as:

$$\tau = \frac{2G_a}{t_a} \left( u_a + \frac{t_1}{2} \phi_a \right); \sigma = \frac{2E_a}{t_a} w_s \quad (20)$$

221 The governing equations taking into account the geometric nonlinearity of the  
222 overlap and the transverse shear stiffness of the adherends can be derived by using  
223 Eqs. 18, 19, and 20 and the constitutive equations of the Timoshenko beam, and they  
224 are given by (Luo and Tong 2008):

$$\begin{cases} \frac{d^3 u_a}{dx^3} - \frac{\beta_\tau^2}{4} \left( \frac{du_a}{dx} + \frac{t_1}{2} \frac{d^2 w_a}{dx^2} \right) = 0 \\ \frac{d^4 w_a}{dx^4} - \frac{\alpha_k \beta_\tau^2}{2t_1} \left( \frac{du_a}{dx} + \frac{t_1}{2} \frac{d^2 w_a}{dx^2} \right) - \frac{\beta_k^2}{2} \frac{d^2 w_a}{dx^2} = 0 \end{cases} \quad (21)$$

$$\frac{d^2 u_s}{dx^2} = 0; \frac{d^4 w_s}{dx^4} - 4\beta_{ng}^2 \frac{d^2 w_s}{dx^2} + 4\beta_{ng}^4 w_s = 0 \quad (22)$$

225 where

$$\beta_{ng}^2 = \left( \beta_g^2 + \frac{\beta_k^2}{8} \right); \beta_{ng}^4 = \left( \beta_\sigma^4 + \frac{\beta_k^2 \beta_g^2}{2} \right); \beta_g = \frac{1}{2} \times \sqrt{\frac{2E_a}{G_{k1} t_a}} \quad (23)$$

226 in which  $G_{k1}$  is the shear stiffness of adherends 1 and 2.

227 When the boundary conditions are prescribed, analytical solutions of Eqs. 21  
228 and 22 can be obtained. Luo and Tong (2008) derived the analytical solutions for  
229 given forces at overlap edges. For composite SLJs, the analytical solutions of  
230 Eq. 21 are:

$$\begin{cases} u_a = A_{a2} \cosh \beta_{a1} x + A_{a4} \cosh \beta_{a2} x + A_{a7} \\ w_a = B_{a1} \sinh \beta_{a1} x + B_{a3} \sinh \beta_{a2} x + B_{a6} x \end{cases} \quad (24)$$

231 where

$$\beta_{a1}, \beta_{a2} = \frac{1}{2} \left[ \beta_c^2 + \frac{\beta_k^2}{2} \pm \sqrt{\beta_c^4 + \left( 1 - \frac{1}{2\alpha_a} \right) \beta_c^2 \beta_k^2 + \frac{\beta_k^4}{4}} \right] \quad (25)$$

232 The analytical solutions of Eq. 22 for composite SLJs are:

$$\begin{cases} u_s = \frac{F}{2A_{d1}}x \\ w_s = \frac{B_{s1}^-}{B_{s2}^+} \sinh \beta_{s1}^- x \sin \beta_{s2}^- x + \frac{B_{s4}^-}{B_{s4}^+} \cosh \beta_{s1}^- x \cos \beta_{s2}^- x & \Delta < 0 \\ w_s = \frac{B_{s1}^+}{B_{s2}^+} \cosh \beta_{s1}^+ x + \frac{B_{s4}^+}{B_{s4}^+} \cosh \beta_{s2}^+ x & \Delta > 0 \end{cases} \quad (26)$$

233 where

$$\begin{cases} \Delta = \beta_{ng}^4 - \beta_{n\sigma}^4 \\ \beta_{s1}^- = \sqrt{\beta_{n\sigma}^2 + \beta_{ng}^2}; \quad \beta_{s2}^- = \sqrt{\beta_{n\sigma}^2 - \beta_{ng}^2} & \Delta < 0 \\ \beta_{s1}^+ = \sqrt{2} \sqrt{\beta_{ng}^2 + \sqrt{\beta_{ng}^4 - \beta_{n\sigma}^4}}; \beta_{s2}^+ = \sqrt{2} \sqrt{\beta_{ng}^2 - \sqrt{\beta_{ng}^4 - \beta_{n\sigma}^4}} & \Delta > 0 \end{cases} \quad (27)$$

234 It can be shown that, for the case of thick adherend, thin adhesive and low  
235 transverse shear stiffness of the adherends,  $\Delta > 0$ ; otherwise,  $\Delta < 0$ . In general,  
236  $\Delta < 0$  for isotropic adherends made of steel and aluminum, and  $\Delta > 0$  for composite  
237 adherends due to the lower transverse shear stiffness. As  $t_a \rightarrow 0$ ,  $\Delta > 0$ ; it becomes a  
238 problem of interface fracture or delamination (Luo and Tong 2009b, c).  $\Delta = 0$  is a  
239 special case, whose solutions can be obtained by letting  $\Delta \rightarrow 0$  in the solutions for  
240  $\Delta < 0$  or  $\Delta > 0$ .

241 By using Eqs. 20, 24, and 26, adhesive stresses can be directly obtained, and the  
242 details can be found in Luo and Tong (2008). In most cases,  $\beta_{a1}^2 \approx \beta_c^2 \gg \beta_{a2}^2$ ,  $\beta_g^2$   
243  $\gg \beta_k^2$ , and  $\beta_\sigma^2 \gg \beta_k^2$ . When these approximations are used, the analytical solutions  
244 can be simplified. The simplified adhesive stresses at the adhesive ends are:

$$\tau_{\max} = \frac{[2\alpha_k M_k + Ft_1(1 - r_k)]\beta_{a1}c \coth \beta_{a1}c}{8\alpha_a t_1 c} + \frac{\alpha_k (Ft_1 - 2M_k)\beta_{a2}c \coth \beta_{a2}c}{8\alpha_a t_1 c} \quad (28)$$

$$\sigma_{\max} = \begin{cases} \beta_\sigma^2 \left[ M_k + \left( \frac{\beta_{s1}^-}{\beta_\sigma^2} \right) V_k \right] & \Delta < 0 \\ \beta_\sigma^2 \left[ M_k + \left( \frac{\beta_{s1}^+ + \beta_{s2}^+}{2\beta_\sigma^2} \right) V_k \right] & \Delta > 0 \end{cases} \quad (29)$$

245 The adhesive stresses of a single-lap joint reach maximum at the edges, which are  
246 important in assessing the adhesive joint strength. The expressions of maximum  
247 adhesive stresses obtained using different analytical models are summarized in  
248 Table 1.

$$\text{where } r_k = \frac{\beta_k^2}{2\beta_c^2}$$

249  
250 It can be shown that when  $\beta_k \rightarrow 0$ , the maximum adhesive stresses in nonlinear  
251 analysis degenerate to those in linear analysis. It is noted that different strategies can  
252 be used to obtain analytical solutions of adhesively bonded composite joints with  
253 and without considering geometrical nonlinearity. When the linear overlap is  
254 assumed, it is handy to express the governing equations in terms of the adhesive

**Table 1** Comparisons of the maximum adhesive stresses

t.2	Adherend model	Maximum peel stress	Maximum shear stress
t.3	Average stress model		$F/(2c)$
t.4	Shear lag model		$\beta_s F/2$
t.5	Linear adhesive-Euler-beam model	$\beta_\sigma^2 \left( M_k + \frac{V_k}{\beta_\sigma} \right)$	$\frac{(2\alpha_k M_k + Ft_1)\beta_{a1}c}{8\alpha_a t_1 c} + \frac{\alpha_k(Ft_1 - 2M_k)}{8\alpha_a t_1 c}$
t.6	Nonlinear adhesive-Timoshenko-beam model	$\beta_\sigma^2 \left[ M_k + \left( \frac{\beta_{a1}^-}{\beta_\sigma^2} \right) V_k \right] \quad \Delta < 0$	$\frac{[2\alpha_k M_k + Ft_1(1 - r_k)]\beta_{a1}c \coth \beta_{a1}c}{8\alpha_a t_1 c}$
t.7		$\beta_\sigma^2 \left[ M_k + \left( \frac{\beta_{a1}^+ + \beta_{a2}^+}{2\beta_\sigma^2} \right) V_k \right] \quad \Delta > 0$	$+\frac{\alpha_k(Ft_1 - 2M_k)\beta_{a2}c \coth \beta_{a2}c}{8\alpha_a t_1 c}$

stresses. When geometrical nonlinearity is considered, it is convenient to write the governing equations in terms of the adherend displacements.

### 24.3.2 Coupled Formulation for Load Update of Single-Lap Joints

One distinctive and challenging feature of a single-lap joint is its eccentric load path, which leads to the geometric nonlinearity that requires the load update. Goland and Reissner (1944) conducted uncoupled formulation for the load update and the adhesive stresses, respectively. In their formulation, the overlap was treated as a homogeneous beam for determining load update.

#### Coupled Formulation with Adhesive Shear Deformation Effect But No Overlap Nonlinearity

Hart-Smith (1973) showed that the uncoupled formulation of Goland and Reissner (1944) is inconsistent with the force conditions of an individual adherend at the overlap ends. To overcome this deficiency and consider the influence of the adhesive deformation, Hart-Smith (1973) modeled each adherend of the overlap as an individual beam and derived the coupled formulation for load update and the adhesive shear stress. By using continuity conditions at intersection  $I$ , Hart-Smith (1973) obtained the edge moment factor and then simplified it as:

$$k = \frac{1}{1 + \beta_k c \coth \beta_k l + (\beta_k c)^2 / 6} \quad \text{or} \quad k = \frac{1}{1 + \beta_k c + (\beta_k c)^2 / 6} \quad \text{when } \coth \beta_k l \approx 1 \quad (30)$$

In this formulation (Hart-Smith 1973), the force conditions at intersections  $I$  and  $II$  are consistent; the influence of the adhesive shear strain is included, and the large deflections of the outer adherends are also modeled. However, the equilibrium equations in Eq. 7 and  $w_1 \approx (w_1 + w_2)/2$  are used in this formulation. It is noted that Eq. 7 does not model the overlap geometric nonlinearity, and hence the large deflection effect of the overlap is ignored. Because  $w_1 \approx (w_1 + w_2)/2$  is used, the effect of the adhesive peel strain on the edge moment factor is also neglected.

### Coupled Formulation with the Shear and Nonlinear Effects But No Peel Effect

Oplinger (1994) treated the adherends as individual beams and considered the influence of the overlap deflection. The governing equations with the coupling of the adhesive shear strain and the overlap large deflection were derived, and then analytical solutions for SLJs were found. The edge moment factor was derived as:

$$k = \frac{R_3 \left(1 + \frac{t_a}{t_1} + R^2 C_2\right) + 8R_4 \frac{T_{h21}}{T_{h22}} R \left[C_1 \left(1 + \frac{t_a}{t_1}\right) - C_2\right]}{\left(1 + \frac{t_a}{t_1}\right) \left[R_3 + 8R_4 \frac{T_{h21}}{T_{h22}} R C_1 + \sqrt{8} (1 + R^2 C_1) \frac{T_{h21}}{T_{h1}}\right]} \quad (31)$$

The parameter definitions in the above equation can be found in Oplinger (1994) and are not given here due to complexity. In Eq. 31, the overlap geometric nonlinearity and the adhesive shear, but not peel strain, are considered. In Eqs. 30 and 31, the adherends are modeled as Euler beams, and thus the transverse shear stiffness is not modeled.

### Fully Coupled Nonlinear Formulation

Luo and Tong (2007, 2008) proposed fully coupled nonlinear formulation for isotropic SLJs based on the Euler beam theory and then extended to composite SLJs based on the Timoshenko beam theory. The displacements in Eqs. 24 and 26 are derived by taking into account geometric nonlinearity of the overlap and transverse shear stiffness of the adherends. The displacements of the left outer adherend of Fig. 5 can be derived as:

$$u_3 = \frac{F}{A_{d1}} x_3 + u_{o1}; w_3 = -\frac{M_k \sinh \beta_k x_3}{F \sinh \beta_k l} + \frac{t_1 + t_a}{2(l + c)} x_3 \quad (32)$$

By using the continuity conditions at intersection  $I$ , unknowns  $M_k$ ,  $u_{o1}$ , and  $B_{a6}$  can be determined. The adherend displacements, adhesive stresses, and the updating forces at the overlap ends can be obtained simultaneously. The simplified edge moment factor is given by:

$$k = \frac{1 + (\beta_k c)^2 \left[ \frac{\beta_{a1} c f(\beta_{a2} c) - 1}{8\alpha_a \beta_{a1} c (1 + t_a/t_1)} \right]}{1 + (\beta_k c) \coth \beta_k l + (\beta_k c)^2 \left[ \alpha_{sM} + \frac{\beta_{a1} c f(\beta_{a2} c) + \alpha_k}{8\alpha_a \beta_{a1} c} \right]} \quad (33)$$

where

$$f(\beta_{a2} c) = \frac{\beta_{a2} c \coth \beta_{a2} c - 1}{(\beta_{a2} c)^2}; \alpha_{sM} = \frac{\beta_{s1}^-}{2\beta_{\sigma c}^2} (\Delta < 0) \text{ or} \quad (34)$$

$$\alpha_{sM} = \frac{\beta_{s1}^+ + \beta_{s2}^+}{4\beta_{\sigma c}^2} (\Delta > 0)$$

For the isotropic adherends,  $\alpha_a = 1$ ,  $\alpha_k = 3$ , and  $\beta_{a1} \approx \beta_c = \beta_\tau$ , Eq. 33 degenerates to that given in Luo and Tong (2007) for the isotropic SLJ. When the peel effect is neglected, Eq. 33 becomes:

$$k = \frac{1 + (\beta_k c)^2 \left[ \frac{\beta_{a1} c f(\beta_{a2} c) - 1}{8\alpha_a \beta_{a1} c (1 + t_a/t_1)} \right]}{1 + (\beta_k c) \coth \beta_k l + (\beta_k c)^2 \left[ \frac{\beta_{a1} c f(\beta_{a2} c) + \alpha_k}{8\alpha_a \beta_{a1} c} \right]} \quad (34a)$$

In this case, the model is equivalent to that proposed by Oplinger (1994). In experiment, alignment tabs are often used to reduce peeling effects as shown in Fig. 5d (Adams et al. 1997; Tong and Steven 1999). In this case, the edge moment factor is (Luo and Tong 2016):

$$k = \frac{\frac{1 + (\beta_k c)}{\sinh \beta_k l} + (\beta_k c)^2 \left[ \frac{\beta_{a1} c f(\beta_{a2} c) - 1}{8\alpha_a \beta_{a1} c (1 + t_c/t)} \right]}{1 + (\beta_k c) \coth \beta_k l + (\beta_k c)^2 \left[ \alpha_{sM} + \frac{\beta_{a1} c f(\beta_{a2} c) + \alpha_k}{8\alpha_a \beta_{a1} c} \right]} \quad (34b)$$

When  $F$  is large,  $\sinh(\beta_k l) \gg \beta_k c$ ; in this case,  $k$  calculated by Eq. 34b is almost the same as that by Eq. 33.

Equation 33 includes all geometric parameters and material properties of composite single-lap joints except for the transverse normal stiffness. A good correlation with geometrically nonlinear FEA results has been illustrated in Luo and Tong (2007, 2008). In some cases, the following equations may also be used to predict the edge moment factor (Luo and Tong 2007):

$$k = \frac{1}{1 + \beta_k c \coth \beta_k l} \text{ or } k = \frac{1}{1 + \beta_k c} \text{ when } \coth \beta_k l \approx 1 \quad (35)$$

Equation 35 is simple and applicable for SLJs with a short overlap. Zhao et al. (2010) derived the second formula of Eq. 35 by considering overlap rotation and ignoring the overlap deformation. They showed that it was suitable for SLJs with a stiff overlap.

### 24.3.3 Numerical Comparisons

Two examples of single-lap joints are used to illustrate the above formulations. One is an isotropic SLJ and the other is a composite SLJ. The data of the isotropic SLJ are  $E_1 = 70$  (GPa),  $\nu_1 = 0.34$ ,  $t_1 = 1.6$  (mm);  $E_a/E_1 = 0.008$ ,  $\nu_a = 0.4$ ; and  $c/t_1 = 32$  and  $l/c = 5$ . For the composite SLJ,  $t_1 = 1.6$  (mm),  $t_a = 0.2$  mm,  $c/t_1 = 32$ ,  $l/c = 1.25$ ; and  $E_a = 2.4$  (GPa),  $\nu_a = 0.4$ . The ply thickness of composite adherends is 0.2 mm, and the ply material properties are  $E_L = 138$  (GPa),  $E_T = 9.4$  (GPa),  $\nu_{LT} = 0.32$ ,

$G_{LT} = 6.7$  (GPa); and  $\nu_{23} = 0.32$ ,  $G_{23} = 3.56$  (GPa); and the lay-up is  $[90/0/90/0]_s$ . The numerical results are presented for the SLJs in plane strain.

**Edge Moment Factor**

The edge moment factors ( $k$ ) of the isotropic SLJ predicted by various analytical solutions are illustrated in Fig. 7. It is noted that  $\Delta < 0$  when the Timoshenko beam is used to model isotropic adherends of this SLJ. It has been shown that edge moment factor predicted by Eq. 33 correlates very well with that predicted by the geometrically nonlinear FE analyses (Luo and Tong 2007, 2008).

Figure 7 indicates that the edge moment factor predicted by the formulation of Goland and Reissner (1944) is significantly larger than that predicted by Eq. 33 (Luo and Tong 2007, 2008) with an increase of the applied force due to ignoring influence of the adhesive deformation; the edge moment factor calculated by Oplinger’s formulation (1994) is obviously larger than that of Eq. 33 owing to neglecting the peel effect. The edge moment factor calculated using Eqs. 35 or 30 (Hart-Smith 1973) is considerably lower than that of Eq. 33. Equation 35 was given in Luo and Tong (2007), and the second formula in Eq. 35 was also derived by Zhao et al. (2010). This equation can be directly extended to composite SLJs.

Figure 8 shows the edge moment factors of the composite SLJ calculated by using the theoretical formulations. It is noted  $\Delta > 0$  for this composite SLJ. It has also been illustrated that  $k$  calculated by Eq. 33 correlates well with that of the geometrically nonlinear FE analyses (Luo and Tong 2008) for the composite SLJs.

Oplinger’s formulation (1994) is not easy to be extended to the laminated adherends, and thus its results are not given in this figure. Since  $k$  for Eq. 34a is equivalent to that of Oplinger’s model, the peel effect can be observed by comparing

**Fig. 7** Edge moment factor of the isotropic SLJ predicted by the beam-adhesive models

**Fig. 8** Edge moment factor of the composite SLJ predicted by the beam-adhesive models

$k$  for Eqs. 33 and 34a. It can be seen that the influence of adhesive peel strain on the edge moment factor is significant and should not be ignored.

### Adhesive Stresses

When the updating edge forces are determined, the relevant adhesive stresses can be calculated, and they are plotted in Figs. 9 and 10 for the composite SLJ.

Figures 9 and 10 illustrate distributions of the shear and peel stresses for the composite SLJ predicted by the linear adhesive-beam model based on the Euler beam theory and the nonlinear adhesive-beam model based on the Timoshenko beam theory, respectively.

In Figs. 9 and 10, the same edge moment factor at  $\beta_k c = 9$  calculated Eq. 33 is used for both models. Figure 9 shows that there are slight differences in values of shear stress predicted by the linear adhesive-beam model based on the Euler beam theory and the nonlinear adhesive-beam model based on the Timoshenko beam theory. However, there exist significant differences in the adhesive peel stress for the two models as shown in Fig. 10, including peak values and distribution patterns.

Harris and Adams (1984) investigated single-lap composite joints using a geometrically nonlinear finite element analysis (NFEA). They observed a small discrepancy in shear stress but large differences in the adhesive peel stress and the edge moment by comparing numerical results of Goland and Reissner (1944) with those of the NFEA. Figures 8, 9, and 10 confirm their observations through analytical solutions, as Luo and Tong (2008) illustrated that the edge moment factor, shear, and peel stresses predicted by the nonlinear adhesive-beam model based on the Timoshenko beam theory correlate well with those of the NFEA using commercial software NASTRAN.

**Fig. 9** Shear stress predicted by the linear adhesive-beam model based on the Euler beam theory and the nonlinear adhesive-beam model based on the Timoshenko beam theory

**Fig. 10** Peel stress predicted by the linear adhesive-beam model based on the Euler beam theory and the nonlinear adhesive-beam model based on the Timoshenko beam theory

**24.3.4 Analytical Approach for Adhesive Joints with Material Nonlinearity**

In design and strength analysis of adhesively bonded structures, nonlinear material properties need to be considered as soft or ductile adhesive materials can behave in

plastic regime. Owing to stress concentration and singular features, stresses near an edge of an adhesively bonded joint can reach beyond elastic limitation. Hence, material nonlinear analysis for adhesive joints is important. Analysis of material nonlinearity is usually required to be considered for all structural materials. However, due to low linear limitation of the ductile adhesive, stress–strain relationship of an adherend may still be within linear range when the adhesive is loaded beyond its linear limitation. Hence, only the adhesive material nonlinearity is considered here. For isotropic adherends that yield, Adams et al. (1997) have proposed a single design methodology (see ► Chap. 27, “Design Rules and Methods to Improve Joint Strength”).

Hart-Smith (1973) conducted material nonlinear analysis for SLJs using the linearly elastic and perfectly plastic model to describe the adhesive shear stress–strain relationship and the linear material property for the adhesive peel stress and adherends. In his analysis (Hart-Smith 1973), the adhesive layer is divided into elastic and plastic regions as shown in Fig. 11. Grant and Teig (1976) considered material nonlinearity of adhesive by dividing the adhesive into multiregions, in which the shear lag model was used. The obtained governing equations were then solved numerically.

Delale et al. (1981) used a strain energy function to define stress–strain relationships in conducting material nonlinear analysis for lap joints. Material nonlinear analysis of unbalanced lap joints subjected to general loadings was conducted by Bigwood and Crocombe (1990). In their analysis, the adherends were modeled as linearly elastic plates deforming in cylindrical bending, and plastic deformation theory was applied to the adhesive material. The stress–strain curve was described by using a continuous mathematical function. The adhesive yielding rule was assumed to obey the von Mises yield criterion. Bigwood and Crocombe (1990) derived a set of six simultaneous nonlinear differential equations in conjunction with the prescribed stress–strain function and then solved these nonlinear differential equations using finite difference method. The effect of the adhesive thickness on lap joint strength was also studied in Bigwood and Crocombe (1990).

Yang et al. (2004) developed an analytical model to predict the adhesive stress and strain distributions. In their analysis, the adherends were modeled as a laminated anisotropic plate, and the adhesive constitutive equation was described using the elastic–perfectly plastic constitutive relationship. The von Mises yield

**Fig. 11** Elastoplastic analysis of shear lag joints

criterion was also applied to the adhesive plastic deformation. They derived and numerically solved coupled differential equations of SLJs. In this analysis (Yang et al. 2004), the material nonlinear FEA was conducted for numerical comparison, and cohesive failure was studied. Lee and Kim (2007) presented a closed-form analytical model for material nonlinear analysis of symmetric SLJs, in which the elastoplastic perfect material property for adhesive was considered. The analysis was conducted for independent shear and peel stresses in the adhesive.

As discussed in the above brief review, material nonlinear analysis of adhesively bonded structures is very complicated, and analytical solutions are not admissible in general. Here, we only present analytical solutions of symmetric SLJs in tension with the elasto-perfectly plastic adhesive material using the shear lag model to explain the analytical approach for adhesively bonded joints with material nonlinearity.

As shown in Fig. 11, the governing equations for elastic and plastic parts can be written as (Hart-Smith 1973; Grant and Teig 1976; Lee and Kim 2007):

$$\begin{cases} \frac{d^2\tau}{dx^2} = \beta_v^2\tau & -c_s \leq x \leq c_s \\ \frac{d^2\gamma}{dx^2} = \frac{2\tau_s}{A_{d1}t_a} & c_s \leq |x| \leq c \end{cases} \quad (36)$$

where  $c = c_s + a_s$  and  $\gamma$  is the adhesive shear strain and  $\tau_s$  is the adhesive yield stress. The analytical solution of the shear stress in  $|x| \leq c_s$  can be readily obtained:

$$\tau = \frac{\beta_v(F - 2a_s\tau_s)\cosh \beta_v x}{2\sinh \beta_v c_s} \quad (37)$$

When the maximum value of Eq. 37 is equal to  $\tau_s$ , the plastic deformation will occur in the adhesive edge. The critical force  $F$  is equal to  $(2\tau_s/\beta_v)$ . With an increase of applied load  $F$ , the plastic deformation will develop along the adhesive. The following equation can be obtained from Eq. 37 to determine the plastic zone length  $a_s$ :

$$2\tau_s \sinh \beta_v(c - a_s) = \beta_v(F - 2a_s\tau_s)\cosh \beta_v(c - a_s) \quad (38)$$

When the plastic zone is small,  $\sinh \beta_v(c - a_s) \approx \cosh \beta_v(c - a_s)$ . In this case, the plastic zone length  $a_s$  is approximately given by:

$$a_s = \frac{\beta_v F - 2\tau_s}{2\beta_v\tau_s} \quad (39)$$

When  $a_s$  is determined, the stress distribution can be obtained: when  $|x| \leq (c - a_s)$ , it is given by Eq. 37 and it is equal to  $\tau_s$  in  $(c - a_s) < |x| \leq c$ .

## 24.4 Analytical Approach of Other Lap Joints

### 24.4.1 Analytical Solutions of Symmetric Lap Joints Subjected to General Loadings

In Sects. 2 and 3, analytical solutions for single-lap joints are derived from the governing equations of Eqs. 9, 20, and 21 for the linear and nonlinear overlaps. The governing equations are also applicable to the other symmetric lap joints such as single-strap joints and cracked lap shear specimens.

#### Linear Overlap Based on the Euler Beam Theory

The general solutions of Eq. 9 are (Goland and Reissner 1944):

$$\begin{cases} \tau = A_1 \sinh \beta_c x + A_2 \cosh \beta_c x + A_3 \\ \sigma = (B_1 \sinh \beta_\sigma x + B_2 \cosh \beta_\sigma x) \sin \beta_\sigma x + (B_3 \sinh \beta_\sigma x + B_4 \cosh \beta_\sigma x) \cos \beta_\sigma x \end{cases} \quad (40)$$

where  $A_i$  and  $B_i$  ( $i = 1, 2, 3; j = 1, 2, 3, 4$ ) are integration constants determined by relevant boundary conditions. When the forces at both overlap edges are prescribed, the boundary conditions can be derived as:

$$\begin{cases} \int_{-c}^c \tau(x) dx = N_{II} - N_{III}; & \frac{d\tau(\mp c)}{dx} = \frac{\beta_\tau^2}{8I_1} [t_1(N_2 - N_1) - 2\alpha_k(M_2 + M_1)]_{x=\mp c} \\ \frac{d^2\sigma(\mp c)}{dx^2} = -2\beta_\sigma^4(M_2 - M_1)|_{x=\mp c}; & \frac{d^3\sigma(\mp c)}{dx^3} = -2\beta_\sigma^4(V_2 - V_1)|_{x=\mp c} \end{cases} \quad (41)$$

By substituting Eqs. 40 into 41, the integration constants can be determined. Delale et al. (1981) presented analytical solutions of lap joints under tension, bending, and transverse shear, respectively.

#### Nonlinear Overlap Based on the Timoshenko Beam Theory

The general solutions of Eqs. 20 and 21 are (Luo and Tong 2008):

$$\begin{cases} u_a = A_{a1} \sinh \beta_{a1} x + A_{a2} \cosh \beta_{a1} x + A_{a3} \sinh \beta_{a2} x + A_{a4} \cosh \beta_{a2} x + A_{a5} x^2 + A_{a6} x + A_{a7} \\ w_a = B_{a1} \sinh \beta_{a1} x + B_{a2} \cosh \beta_{a1} x + B_{a3} \sinh \beta_{a2} x + B_{a4} \cosh \beta_{a2} x + B_{a5} x^2 + B_{a6} x + B_{a7} \end{cases} \quad (42)$$

When  $\Delta < 0$ , the analytical solutions are given by:

$$\begin{cases} u_s = A_{s1} x + A_{s2} \\ w_s = (B_{s1}^- \sinh \beta_{s1}^- x + B_{s2}^- \cosh \beta_{s1}^- x) \sin \beta_{s2}^- x + (B_{s3}^- \sinh \beta_{s1}^- x + B_{s4}^- \cosh \beta_{s1}^- x) \cos \beta_{s2}^- x \end{cases} \quad (43a)$$

When  $\Delta > 0$ , the solutions are:

$$\begin{cases} u_s = A_{s1}x + A_{s2} \\ w_s = B_{s1}^+ \sinh \beta_{s1}^+ x + B_{s2}^+ \cosh \beta_{s1}^+ x + B_{s3}^+ \sinh \beta_{s2}^+ x + B_{s4}^+ \cosh \beta_{s2}^+ x \end{cases} \quad (43b)$$

where the integration constants  $A_{ai}$  and  $B_{ai}$  ( $i = 1, 2, \dots, 7$ ),  $A_{si}$ , and  $B_{sj}^-$  or  $B_{sj}^+$  ( $i = 1, 2$ ;  $j = 1, 2, 3, 4$ ) can be determined by associated boundary conditions. When the forces at both overlap edges are given, the solutions can be found in Sect. 2 of Luo and Tong (2008). For the symmetric single-strap and lap shear joints, the analytical solutions can be obtained directly from the formulations of Luo and Tong (2008).

For double-lap and double-strap joints, analytical analyses are attributed to those for asymmetric joints by using the variable transformation discussed in Luo and Tong (2002) for the host beam with the piezoelectric patches bonded on the top and bottom surfaces. The analysis for asymmetric joints will be presented in the next section.

#### 24.4.2 Analytical Solutions of Asymmetric and Unbalanced Joints

Analytical analysis of balanced single-lap joints gives us insight into the essences of stress analysis for adhesively bonded joints. It has been widely used for adhesive characterization and benchmarking numerical methods and experimental testing. In general, adherends are asymmetric and adhesive joints are unbalanced.

Analytical approaches for unbalanced adhesive joints based on the Euler beam theory have been developed by a number of researchers (Hart-Smith 1973; Delale et al. 1981; Bigwood and Crocombe 1989; Luo and Tong 2002; Shahin et al. 2008). Luo and Tong (2009b, c) modeled the adherends as Timoshenko beams. Since the analytical procedure for the Euler beam is similar to that for the Timoshenko beam, the formulations are presented here for the Timoshenko beam only.

Fully coupled nonlinear analytical solutions for asymmetric and unbalanced adhesive joints are very complicated. Nevertheless, when the updated loadings are given, linear analysis based on the Timoshenko beam theory can predict sufficiently accurate adhesive stresses except for the case of very large deflection.

When the linear adhesive-beam model based on the Timoshenko beam theory is used, the distributions of adhesive shear and peel stresses are almost the same as those of the nonlinear model, and the values of the shear stress is slightly lower than that of the nonlinear analysis. Therefore, the linear adhesive-beam model based on the Timoshenko beam for stress analysis of asymmetric and unbalanced joints may be sufficiently accurate for engineering applications.

#### Governing Equations of Asymmetric and Unbalanced Linear Joints

In this model of adhesively bonded joints with asymmetric and unbalanced adherends, the geometric nonlinearity is not included; the adherends are described

as the Timoshenko beam and a two-parameter elastic medium is used to model the adhesive. Also, the adhesive stresses should be deemed as those in the adhesive's midplane. It should be noted that the predicted shear stress may be slightly lower due to ignoring the geometric nonlinearity.

The equilibrium equations and adhesive stresses are shown in Eqs. 7 and 8, respectively. The constitutive equations for laminated adherends with asymmetric lay-ups are:

$$\begin{aligned} N_i &= A_{di} \frac{du_i}{dx} - B_i \frac{d\phi_i}{dx}; Q_i = G_{ki} \left( \frac{dw_i}{dx} - \phi_i \right); \\ M_i &= B_i \frac{du_i}{dx} - D_i \frac{d\phi_i}{dx} \quad (i = 1, 2) \end{aligned} \quad (44)$$

where  $B_i$  ( $i = 1, 2$ ) are the extension-bending coupling stiffness of the adherends. By substituting Eqs. 7 and 44 into Eq. 8, the governing equations in terms of shear and peel stresses can be derived as (Luo and Tong 2009b, c):

$$\begin{cases} \frac{d^3\tau}{dx^3} - k_1 \frac{d\tau}{dx} - k_2\sigma = 0 \\ \frac{d^4\sigma}{dx^4} - k_5 \frac{d^2\sigma}{dx^2} + k_4\sigma + k_3 \frac{d\tau}{dx} = 0 \end{cases} \quad (45)$$

where

$$\begin{aligned} k_1 &= k_\tau k_{1d}; k_2 = k_\tau k_{2d}; k_3 = k_\sigma k_{2d}; k_4 = k_\sigma k_{4d}; k_5 = k_\sigma k_{5d}; k_\tau = G_a/t_a; \\ k_\sigma &= E_a/t_a \end{aligned} \quad (46)$$

$$\begin{cases} k_{1d} = \frac{D_1}{\Delta_1} \left( 4\alpha_{a1} + \frac{t_1 B_1}{D_1} \right) + \frac{D_2}{\Delta_2} \left( 4\alpha_{a2} - \frac{t_2 B_2}{D_2} \right); & k_{4d} = \frac{A_{d1}}{\Delta_1} + \frac{A_{d2}}{\Delta_2} \\ k_{2d} = \frac{t_1}{2\Delta_1} \left( A_{d1} - \frac{2B_1}{t_1} \right) - \frac{t_2}{2\Delta_2} \left( A_{d2} + \frac{2B_2}{t_2} \right); & k_{5d} = \frac{1}{G_{k1}} + \frac{1}{G_{k2}} \end{cases} \quad (47)$$

$$\Delta_i = A_{di} D_i - B_i^2; \alpha_{ai} = \frac{1 + \alpha_{ki}}{4}; \alpha_{ki} = \frac{A_{di} t_i^2}{4D_i} \quad (i = 1, 2) \quad (48)$$

Equation 45 is a set of differential equations with coupled shear and peel stresses. In the above equations,  $k_{1d}$  and  $k_{4d}$  reflect the extension, bending, and extension-bending coupling effects of the adherends;  $k_{2d}$  indicates the unbalanced condition of the substrates that couples the shear and peel stresses; and  $k_{5d}$  denote the shear stiffness. The shear and peel stresses become decoupled when  $k_{2d} = 0$ , which is seen in the case of balanced joints with identical substrates. If  $k_{5d} = 0$ , Eq. 45 becomes the governing equations based on the Euler beam theory. When the shear and peel stresses are solved analytically from Eq. 45, forces and displacements can be derived from Eqs. 7 and 44, respectively.

### Boundary Conditions

The governing equations shown in Eq. 45 can be analytically solved without introducing any other assumption for the prescribed boundary conditions. When the forces at the adhesive joint ends *I* and *II* are given, the boundary conditions can be expressed as:

$$\begin{cases} x = -c : \frac{d\tau}{dx} = k_\tau H_{nl}; & \frac{d^2\sigma}{dx^2} - k_5\sigma = k_\sigma H_{ml}; & \frac{d^3\sigma}{dx^3} - k_5\frac{d\sigma}{dx} + k_3\tau = k_\sigma H_{ql} \\ x = c : \frac{d\tau}{dx} = k_\tau H_{nl}; & \frac{d^2\sigma}{dx^2} - k_5\sigma = k_\sigma H_{ml}; & \frac{d^3\sigma}{dx^3} - k_5\frac{d\sigma}{dx} + k_3\tau = k_\sigma H_{ql} \end{cases} \quad (49)$$

where

$$\begin{cases} H_{nj} = \left[ \left( \frac{D_2}{\Delta_2} + \frac{B_2 t_2}{2\Delta_2} \right) N_{j2} - \left( \frac{D_1}{\Delta_1} - \frac{B_1 t_1}{2\Delta_1} \right) N_{j1} \right] - \left[ \left( \frac{A_{d2} t_2}{2\Delta_2} + \frac{B_2}{\Delta_2} \right) M_{j2} + \left( \frac{A_{d1} t_1}{2\Delta_1} - \frac{B_1}{\Delta_1} \right) M_{j1} \right] \\ H_{mj} = - \left[ \left( \frac{A_{d2}}{\Delta_2} M_{j2} - \frac{A_{d1}}{\Delta_1} M_{j1} \right) - \left( \frac{B_2}{\Delta_2} N_{j2} - \frac{B_1}{\Delta_1} N_{j1} \right) \right] \\ H_{qj} = - \left( \frac{A_{d2}}{\Delta_2} Q_{j2} - \frac{A_{d1}}{\Delta_1} Q_{j1} \right) \quad (j = I, II) \end{cases} \quad (50)$$

where  $N_{jk}$ ,  $M_{jk}$ , and  $Q_{jk}$  ( $j = I, II$ ;  $k = 1, 2$ ) are the force components in adherends 1 and 2 at the joint ends *I* and *II*.

### Analytical Approaches

Analytical solutions of the governing equations with coupled shear and peel stresses were discussed in detail in Luo and Tong (2002) for piezoelectric smart beams, in which the Euler beam theory was used. Stress analysis for adhesively bonded composite joints is to solve Eq. 45 with boundary conditions in Eq. 49.

One method to solve this boundary value problem of the ordinary differential equations is elimination; it attempts to obtain the uncoupled equations with higher-order differentiations by eliminating the coupled terms (Humi and Miller 1988). In this method, the boundary conditions with the higher-order differentiations should also be derived. This technique has been used to solve the governing equations with the coupled shear and peel stresses for adhesive joints based on the Euler beam theory by Hart-Smith (1973), Delale et al. (1981), Bigwood and Crocombe (1989), and Shahin et al. (2008). In these formulations, the Euler beam is used to model the adherends. In the adhesive joint model of Delale et al. (1981), the adhesive axial deformation is also considered.

Alternatively, the coupled equations can be directly solved (Humi and Miller 1988). The solutions are then substituted into the governing equations to find the relationships of the integration constants, and the boundary conditions can be directly used. To solve Eqs. 45 and 49, the general solutions of Eq. 45 can be obtained analytically, and then the relationships of the integration constants are

derived by substituting the general solutions into the first or second equation of Eq. 45. The integration constants can be determined by these relationships and the boundary conditions of Eq. 49. This approach is simpler than the elimination method in general. Luo and Tong (2009b, c) used this method for a semi-infinite long bonded composite joint. Here, analytical solutions for the adhesive joint with a length of  $(2c)$  are introduced as follows.

### General Solutions

Substituting  $\tau = Ae^{\sqrt{k_\sigma}\beta_t x}$  and  $\sigma = Be^{\sqrt{k_\sigma}\beta_t x}$  into Eq. 45 yields (Luo and Tong 2009b, c):

$$\lambda^3 + a_1\lambda^2 + a_2\lambda + a_3 = 0 \quad \text{or } \beta_t = 0 \quad (51)$$

where

$$\begin{aligned} \lambda &= \beta_t^2; a_1 = -\left(\frac{k_\tau k_{1d}}{k_\sigma} + k_{5d}\right); a_2 = \frac{k_{4d}}{k_\sigma} + \frac{k_\tau k_{1d} k_{5d}}{k_\sigma}; a_3 \\ &= -\frac{k_\tau(k_{1d} k_{4d} - k_{2d}^2)}{k_\sigma^2} \end{aligned} \quad (52)$$

There are two different sets of solutions for Eq. 51, depending on:

$$\Delta = Q^3 - R^2 \quad \text{where } Q = \frac{a_1^2 - 3a_2}{9} \quad \text{and } R = \frac{2a_1^3 - 9a_1a_2 + 27a_3}{54} \quad (53)$$

where  $\Delta$  is a function of  $t_a$ ; it may be larger than, equal to, or less than zero. It has been shown that  $\Delta \geq 0$  as  $t_a \rightarrow 0$  (Luo and Tong 2009b). That is, when the adhesive layer is sufficiently thin,  $\Delta \geq 0$ ; and  $\Delta < 0$  when the adhesive is relatively thick.

Relying on the characteristic roots of the associated polynomial equation shown in Eq. 51, analytical solutions of Eq. 45 are given by (Luo and Tong 2009b, c):

$$\begin{cases} \tau = A_1 \sinh \beta_1 x + A_2 \cosh \beta_1 x + (A_3 \sinh \beta_2 x + A_4 \cosh \beta_2 x) \sin \beta_3 x \\ \quad + (A_5 \sinh \beta_2 x + A_6 \cosh \beta_2 x) \cos \beta_3 x + A_7 \\ \sigma = B_1 \sinh \beta_1 x + B_2 \cosh \beta_1 x + (B_3 \sinh \beta_2 x + B_4 \cosh \beta_2 x) \sin \beta_3 x \\ \quad + (B_5 \sinh \beta_2 x + B_6 \cosh \beta_2 x) \cos \beta_3 x + B_7 \end{cases} \quad (\Delta < 0) \quad (54)$$

or

$$\begin{cases} \tau = A_1 \sinh \beta_1 x + A_2 \cosh \beta_1 x + A_3 \sinh \beta_2 x + A_4 \cosh \beta_2 x \\ \quad + A_5 \sinh \beta_3 x + A_6 \cosh \beta_3 x + A_7 \\ \sigma = B_1 \sinh \beta_1 x + B_2 \cosh \beta_1 x + B_3 \sinh \beta_2 x + B_4 \cosh \beta_2 x \\ \quad + B_5 \sinh \beta_3 x + B_6 \cosh \beta_3 x + B_7 \end{cases} \quad (\Delta \geq 0) \quad (55)$$

where calculation of  $\beta_i$  ( $i = 1, 2, 3$ ) for Eqs. 54 and 55 can be found in Luo and Tong (2009a, b);  $A_i$  and  $B_i$  ( $i = 1, 2, \dots, 7$ ) are the integration constants.

### Determination of the Integration Constants

There are 14 integration constants in Eqs. 54 or 55. By eliminating shear stress in Eq. 45, a 6 order differential equation with respect to peel stress can be obtained, and thus  $B_7 = 0$ . The axial equilibrium equation of adherend 1 of the overlap is shown in Eq. 41. By substituting Eqs. 54 or 55 into the first or second equation in Eq. 45, six simple relationships of the integration constants can be derived. There are six independent equations in Eq. 49. Therefore, 13 independent equations can be used to determine the 13 integration constants without introducing additional assumptions.

Directly solving the 13 simultaneous algebraic equations is too complicated in the context of obtaining the closed-form solutions. By using the method in Luo and Tong (2002), two sets of three simultaneous equations with three unknowns can be obtained, respectively. Therefore, explicit analytical solutions can be derived. The details can be found in Luo and Tong (2002) and are not discussed further here due to the space limitation.

### Geometrically Nonlinear Analysis for Unbalanced Single-Lap Joint

Fully coupled nonlinear analysis for unbalanced SLJs was conducted by Li et al. (2015) with flexible interfaces being considered. Free body diagrams for the unbalanced SLJ are the same as those in Fig. 6b except that adherends 1 and 2 are not identical. By using the Timoshenko beam theory and the free body diagrams, the governing equations for the unbalanced SLJ with geometrical nonlinearity can be derived. The nonlinear terms in the governing equations were linearized by using following transformation (Jiang et al. 2016):

$$N_1 = \frac{A_{d1}P}{A_{d1} + A_{d2}}; N_2 = \frac{A_{d2}P}{A_{d1} + A_{d2}} \quad (56)$$

where  $A_{d1}$  and  $A_{d2}$  are the extensional stiffness of adherends 1 and 2;  $P = N_1 + N_2$ . The linearized coupling differential equations are (Jiang et al. 2016):

$$\begin{aligned} \frac{d^6 w_1}{dx^6} + a_{11} \frac{d^5 u_1}{dx^5} + a_{12} \frac{d^4 w_1}{dx^4} + a_{13} \frac{d^3 u_1}{dx^3} + a_{14} \frac{d^2 w_1}{dx^2} + a_{15} \frac{du_1}{dx} + a_{16} w_1 &= f(x) \\ \frac{d^4 w_1}{dx^4} + b_{13} \frac{d^3 u_1}{dx^3} + b_{14} \frac{d^2 w_1}{dx^2} + b_{15} \frac{du_1}{dx} + b_{16} w_1 &= g(x) \end{aligned} \quad (57)$$

By eliminating  $w_1$  from Eq. 57 or using the approach in Sect. 3.1, a 9 order ordinary differential equation can be obtained (Eq. 23 in Jiang et al. 2016). By letting  $\lambda = \beta_t^2$ , a 4 order of polynomial equation is derived, and thus the analytical solutions for unbalanced geometrically nonlinear SLJs can be derived. Edge moment factors  $k_1$  and  $k_2$  are defined as:

$$k_1 = \frac{2M_1^*}{P(t_1 + t_a)}; k_2 = \frac{2M_2^*}{P(t_1 + t_a)} \quad (58)$$

where  $M_1^*$  and  $M_2^*$  are the undated bending moments at edges I and II. Other parameters in Eqs. 56–58 can be found in Jiang et al. (2016).

## 24.5 Failure Criteria Based on Continuum Mechanics

Failure of adhesively bonded structures can occur in adherends, adhesive, and interface. In this chapter, only failures in an adhesive and at interface between the adherend and adhesive are considered, referring to cohesive failure and debonding or delamination.

The adhesive shear and peel stresses peak at adhesive edges, and the peak stresses increase to infinity with the adhesive thickness decreasing to zero. Therefore, the failure of the adhesive joint will be initiated from the adhesive edge generally. There are two types of failure criteria to assess adhesive joint strength, based on continuum mechanics and fracture mechanics, respectively.

The failure criteria based on continuum mechanics can be summarized as (Huang et al. 2002):

$$\text{Maximum stress criterion : } \sigma_{\max} < [\sigma] \text{ and } \tau_{\max} < [\tau] \quad (59a)$$

$$\text{Von Mises criterion : } (\sigma_{\text{von}})_{\max} < [\sigma] \quad (59b)$$

$$\text{Tsai-Wu criterion : } \left[ \frac{\sigma_{\max}}{[\sigma]} \right]^2 + \left[ \frac{\tau_{\max}}{[\tau]} \right]^2 < 1 \quad (59c)$$

where  $[\sigma]$  and  $[\tau]$  are allowable shear and peel stresses of the adhesive material calibrated by experimental testing;  $\sigma_{\text{von}}$  is the von Mises stress.

When the above criteria are used to assess strength of adhesive joints, the maximum stresses need to be determined. The adhesive stresses in symmetric lap joints are given in Sects. 2 and 3 of this chapter. The analytical approaches for asymmetric and unbalanced adhesive joints are discussed in Sect. 4, and their closed-form solutions are normally complicated. If the adhesive is thin and the overlap is long enough, e.g.,  $c > 20(t_1 + t_a + t_2)$ , the joint length may be approximately treated to be semi-infinite. In this case, the adhesive stresses can be found, and the analytical solutions are given in Luo and Tong (2009c).

### 24.5.1 Shear and Peel Stresses of an Adhesive Joint with a Semi-infinite Length

When the length of an adhesively bonded composite joint is semi-infinite, the shear and peel stresses can be expressed as (Luo and Tong 2009b, c):

$$\begin{cases} \tau = A_2 e^{-\beta_1 x} + e^{-\beta_2 x} (A_5 \sin \beta_3 x + A_6 \cos \beta_3 x) \\ \sigma = B_2 e^{-\beta_1 x} + e^{-\beta_2 x} (B_5 \sin \beta_3 x + B_6 \cos \beta_3 x) \end{cases} \quad \Delta < 0 \quad (60a)$$

$$\begin{cases} \tau = A_2 e^{-\beta_1 x} + A_4 e^{-\beta_2 x} + A_6 e^{-\beta_3 x} \\ \sigma = B_2 e^{-\beta_1 x} + B_4 e^{-\beta_2 x} + B_6 e^{-\beta_3 x} \end{cases} \quad \Delta > 0 \quad (60b)$$

By substituting Eqs. 60a or 60b into the first or second equation in Eq. 45, three relationships of the integration constants are obtained. By eliminating three unknowns from the three relationships and the three boundary conditions, a set of three-order algebraic equations can be derived for the coupled shear and peel stresses, which can be solved analytically. An explicit form of shear and peel stresses can be found, and the details are given in Luo and Tong (2009b, c).

## 24.5.2 Failure Prediction Using the Criteria Based on Continuum Mechanics

When the maximum stresses are determined and the allowable stresses are calibrated, failure criteria based on continuum mechanics can be used to predict adhesive joint failure. When the failure criteria in Eqs. 59a and 59b are used to predict joint failure, it is found (Adams 1989; Gleich et al. 2001; da Silva et al. 2006) that the failure trend for different adhesive thickness predicted by the adhesive-beam models proposed by Goland and Reissner (1944) is different from that of the experimental results. In theory, the maximum stresses increase with decreasing adhesive thickness. However, failure load decreases with increasing the adhesive thickness when it is relatively thick, such as  $t_a > 0.1$  mm.

It is believed that the peak stresses in the thicker adhesive allow yielding to spread, and the global yielding may develop before the maximum stress reaches the allowable value (Hart-Smith 1973; da Silva et al. 2009). When the global yielding occurs, the adhesive thickness effect on the failure load may be predicted by the material nonlinear analysis (see details in da Silva et al. 2009). Gleich et al. (2001) showed the partial agreement with this trend when the fracture mechanics approach was used. Due to complex and singular feature of stresses in the vicinity of an adhesive edge, failure criteria based on the damage zone model and fracture mechanics have been used to predict joint failure.

## 24.6 Failure Criteria Based on Fracture Mechanics

As the adhesive is normally thin in bonded structures, stress concentration occurs near adhesive edges. The adhesive edge stresses increase with a decrease in adhesive thickness. As the adhesive thickness approaches zero, the edge shear and peel stresses defined by Eqs. 8 or 10 will reach infinite. That is, stress singularity appears near the adhesive edges. The singular stress fields in a free edge of laminates and at interface of dissimilar materials have been widely studied.

Here, failure criteria based on energy release rates for adhesive joints will be discussed.

### 24.6.1 Failure Prediction Using Energy Release Rates

Failure criteria based on fracture energy release rates can be written as (Fernlund et al. 1994):

$$G_T < G_{Tc} \text{ at } \varphi = A \tan \sqrt{\frac{G_{II}}{G_I}} \text{ or } \left( \frac{G_I}{G_{Ic}} \right)^2 + \left( \frac{G_{II}}{G_{IIc}} \right)^2 < 1 \quad (61)$$

where  $G_I$ ,  $G_{II}$ , and  $G_T$  are mode I, mode II, and total energy release rates and  $G_{Ic}$ ,  $G_{IIc}$ , and  $G_{Tc}$  are their critical values, respectively;  $\varphi$  is the phase angle. The critical energy release rates  $G_{Ic}$ ,  $G_{IIc}$ , and  $G_{Tc}$  are measured by testing.  $G_I$  and  $G_{II}$  or  $G_T$  and  $\varphi$  can be analytically or numerically determined. Here, only the analytical solutions are discussed.

### Energy Release Rate and J-Integral

An adhesive joint subjected to general loadings is illustrated in Fig. 12. When the J-integral is calculated along the adhesive joint boundary, the total energy release rate is given by (Fernlund and Spelt 1991; Fernlund et al. 1994):

$$G_T = \frac{1}{2} \left( \frac{N_1^2}{A_{d1}} + \frac{N_2^2}{A_{d2}} + \frac{M_1^2}{D_1} + \frac{M_2^2}{D_2} + \frac{Q_1^2}{G_{k1}} + \frac{Q_2^2}{G_{k2}} - \frac{N_o^2}{A_{d0}} - \frac{M_o^2}{D_o} - \frac{Q_o^2}{G_{ko}} \right) - Q_1 \phi_1 - Q_2 \phi_2 + Q_o \phi_o \quad (62)$$

where  $A_{do}$ ,  $D_o$ , and  $G_{ko}$  are extensional, bending, and shear stiffnesses of an entire beam in the uncracked part. It is noted that, unlike stress intensity factor, stress singularity is not required for calculating energy release rates.

**Fig. 12** The J-integral and energy release rate of an adhesively bonded joint

### Mode Partition Method

The total energy release rate is not sufficient to predict structural strength as the critical total energy release rate depends on the phase angle. That is, fracture modes must be separated. Four methods of mode partition may be used for fracture of adhesive joints: (1) the local method based on the stress singular field (Hutchinson and Suo 1992), (2) the global method based on the beam theory (Williams 1988), (3) the method using the adhesive edge stresses based on the adhesive-beam model (Fernlund and Spelt 1991), and (4) the global-local method (Luo and Tong 2012; Harvey et al. 2014; Li et al. 2015).

When the adhesive edge stresses are utilized to calculate energy release rates of the adhesive joint in Fig. 12, they can be written as (Fernlund and Spelt 1991):

$$G_I = \int_0^{\varepsilon(0)} t_a \sigma d\varepsilon = \frac{1}{2k_\sigma} [\sigma(0)]^2; G_{II} = \int_0^{\gamma(0)} t_a \tau d\gamma = \frac{1}{2k_\tau} [\tau(0)]^2 \quad (63)$$

### Singular Feature of the Adhesive Edge Stresses

As energy release rates  $G_I$  and  $G_{II}$  are finite values, we have:

$$\lim_{t_a \rightarrow 0} \sigma(0) = \lim_{t_a \rightarrow 0} \sqrt{\frac{2E_a G_I}{t_a}} \rightarrow \infty; \lim_{t_a \rightarrow 0} \tau(0) = \lim_{t_a \rightarrow 0} \sqrt{\frac{2G_a G_{II}}{t_a}} \rightarrow \infty \quad (64)$$

When the local and global methods are used for mode partition, only the force components shown in Fig. 12 are required as input. When Eq. 63 is utilized to separate fracture modes, the adhesive stresses need to be determined firstly, which is normally complicated. In this chapter, simple formulations of energy release rates for adhesively bonded joints will be discussed.

## 24.6.2 Analytical Solutions of Energy Release Rates for Cohesive Failure and Debonding

### Energy Release Rates for Cohesive Failure of Adhesive Joints

For an adhesively bonded joint with a semi-infinite length subjected to general loadings, the adhesive shear and peel stresses are given in Eqs. 60a or 60b when the adherends are modeled as Timoshenko beams. The explicit expressions of the adhesive stresses and their maximum values are given in Luo and Tong (2009b, c). By using Eq. 63, the energy release rates for cohesive failure can be obtained.

### Energy Release Rates for Debonding or Delamination of Adhesive Joints

The interface stresses for a sufficiently thin adhesive layer are given in Eq. 60b. As the adhesive thickness approaches zero, energy release rates can be derived as (Luo and Tong 2009b, c):

$$G_I = \frac{k_{1d}}{2(k_{1d}k_{4d} - k_{2d}^2)} \left[ \frac{k_{2d}H_{nl}}{k_{1d}} + \left( H_{ml} + k_f \sqrt{\frac{k_{5d}}{k_{4d}} \left( 1 - \frac{k_{2d}^2}{k_{1d}k_{4d}} \right)} H_{ql} \right) \right]^2; \quad (65)$$

$$G_{II} = \frac{H_{ld}^2}{2k_{1d}}$$

where  $H_{nl}$ ,  $H_{ml}$ , and  $H_{ql}$  are given in Eq. 50, which are used to define the boundary conditions at the joint end  $I$ . When adherends 1 and 2 are symmetrically laminated,  $B_1 = B_2 = 0$ ; in this case, Eq. 61 can be expressed as:

$$\begin{cases} G_I = \frac{k_{1d}}{2(k_{1d}k_{4d} - k_{2d}^2)} \times \left\{ \frac{k_{2d}}{k_{1d}} \left[ \left( \frac{N_2}{A_{d2}} - \frac{N_1}{A_{d1}} \right) - \frac{1}{2} \left( \frac{t_2 M_2}{D_2} + \frac{t_1 M_1}{D_1} \right) \right] \right. \\ \left. - \left( \frac{M_2}{D_2} - \frac{M_1}{D_1} \right) - k_f \sqrt{\frac{k_{5d}}{k_{4d}} \left( 1 - \frac{k_{2d}^2}{k_{1d}k_{4d}} \right)} \left( \frac{Q_2}{D_2} - \frac{Q_1}{D_1} \right) \right\}^2 \\ G_{II} = \frac{1}{2k_{1d}} \left[ \left( \frac{N_2}{A_{d2}} - \frac{N_1}{A_{d1}} \right) - \frac{1}{2} \left( \frac{t_2 M_2}{D_2} + \frac{t_1 M_1}{D_1} \right) \right]^2 \end{cases} \quad (66)$$

in which  $N_k$ ,  $M_k$  and  $Q_k$  ( $k = 1, 2$ ) are the force components in adherends 1 and 2 at the joint ends  $I$  where the fracture is initiated as shown in Fig. 12.

In Eq. 66,  $k_f$  ( $1 \leq k_f \leq \sqrt{2}$ ) reflects the influence of interface deformation near the crack-tip. As  $t_a \rightarrow 0$ ,  $k_f \rightarrow 1$ ; and when  $\Delta = 0$ ,  $k_f = \sqrt{2}$ . When the Euler beam theory is used to model the adherends,  $k_{5d} = 0$ . Equation 66 is reduced to the energy release rates for debonding or delamination derived based on the Euler beam theory (Luo and Tong 2009a).

If  $B_1 = -B_2$  and  $k_{2d} = 0$ , the energy release rates can be simplified as:

$$\begin{cases} G_I = \frac{A_{d1}}{4(A_{d1}D_1 - B_1^2)} \left[ -(M_2 - M_1) - \frac{B_1}{A_{d1}}(N_2 + N_1) - k_f \sqrt{\frac{A_{d1}D_1 - B_1^2}{A_{d1}G_{k1}}} (Q_2 - Q_1) \right]^2 \\ G_{II} = \frac{A_{d1}D_1 - B_1^2}{16(4\alpha_{d1}D_1 + t_1B_1)} \left[ \frac{2D_1 - B_1t_1}{(A_{d1}D_1 - B_1^2)}(N_2 - N_1) - \frac{A_{d1}t_1 - 2B_1}{(A_{d1}D_1 - B_1^2)}(M_2 + M_1) \right]^2 \end{cases} \quad (67)$$

The energy release rate  $G_I$  ( $G_{II} = 0$ ) for a double cantilever beam with crack length  $a$  subjected to a pair of load  $P$  is:

$$G_I = \frac{A_{d1}(Pa)^2}{4(A_{d1}D_1 - B_1^2)} \left[ 1 + \frac{k_f}{a} \sqrt{\frac{A_{d1}D_1 - B_1^2}{A_{d1}G_{k1}}} \right]^2 \text{ or} \quad (68)$$

$$G_I = \frac{(Pa)^2}{D_1} \left( 1 + \frac{k_f}{a} \sqrt{\frac{D_1}{G_{k1}}} \right)^2 \text{ when } B_1 = 0$$

Energy release rates in Eq. 65 are derived on the basis of adhesive edge stress by letting the edge adhesive thickness approach zero. Similar results are obtained in Bruno et al. (2003) and Wang and Harvey (2012) based on the beam theory. That is, these formulations are global ones.

For an interface crack or debonding of an adhesive joint, local details (stress, force, or deformation) near a crack-tip should be taken into account. By using the beam theory and considering the local details, analytical formulations of the mode mixity ratios can be derived (Luo and Tong 2012; Harvey et al. 2014; Li et al. 2015). For the isotropic adherends, two simple formulations are given in (Luo and Tong 2012):

$$\frac{G_{II}}{G_I} = \frac{3(1-r^2)^2}{(2+r+2r^2)^2} \text{ when } M_1 = -M_2; N_1 = N_2 = Q_1 = Q_2 = 0 \quad (69)$$

$$\frac{G_I}{G_{II}} = \frac{3(1-r^2)^2}{(2+r+2r^2)^2} \text{ when } N_1 = -N_2; M_1 = M_2 = Q_1 = Q_2 = 0 \quad (70)$$

where  $r (=t_1/t_2)$  is the thickness ratio. The numerical studies in Harvey et al. (2014) and Li et al. (2015) show that Eqs. 69 and 70 are quite accurate when  $0.1 \leq r \leq 10$ .

## Numerical Comparison of Energy Release Rates for the Cracked Lap Shear Specimen

An ASTM Round Robin for calculating energy release rates of cracked lap shear specimens (CLS) was reported by Johnson (1986). In this work, the energy release rates were calculated by nine groups for the two ASTM CLS specimens with four different debonded lengths ( $a = 53.54, 57.35, 76.4$  and  $152.6$ ), one with symmetrical substrates (CLS-A:  $t_1 = t_2$ ) and the other with asymmetrical substrates (CLS-B:  $t_1 = 2 t_2$ ). The CLS-B specimen configurations are shown in Fig. 13. The material properties are  $E_1 = E_2 = 72.45$  GPa,  $\nu_1 = \nu_2 = 0.33$ ,  $E_a = 1.932$ , and  $\nu_a = 0.4$ . It is indicated that the total energy release rate and mode ratio  $G_I/G_{II}$  predicted by the geometrically nonlinear finite element analysis (NFEA) were lab-to-lab consistent with the observed experimental behaviors (Johnson 1986).

Fernlund et al. (1994) calculated the total energy release rate and mode ratio  $G_I/G_{II}$  for the CLS-A and CLS-B specimens using both local and global methods. The mode ratios for the CLS-A specimen predicted by both methods are almost the same as those of the NFEA, while the mode ratios for the CLS-B specimen predicted by both methods are considerably different from those of the NFEA.

For the CLS-B specimen, the force components at the adhesive edge can be calculated using the formulations in Tong and Luo (2008). The adhesive edge stresses are then calculated using Eq. 57. The total energy release rate and mode ratio  $G_I/G_{II}$  are then obtained by using Eq. 60a or 60b. The total energy release rate for the CLS-B specimen predicted by Eqs. 57 and 60 is almost the same as that of the NFEA (Tong and Luo 2008). The mode ratios predicted by theoretical formulations and the NFEA are illustrated in Fig. 13. In Fig. 13, NFEA-1, NFEA-2, and NFEA-3

**Fig. 13** The mode ratios of the CLS-B specimen predicted by theoretical formulations and the geometrically-nonlinear finite element analyses

are referred to the NFEA results in Johnson (1986); the mode ratios predicted by using the local and global methods are taken from Fernlund et al. (1994); and the mode ratios calculated by the adhesive edge stresses are from Tong and Luo (2008).

It is noted that the coupling effect of interface shear and peel stresses are neglected in the global mode partition method in Williams (1988) and Fernlund et al. (1994). Since both local and global methods do not consider the adhesive layer, the mode ratios predicted by these methods are considerably different from that of the NFEA. The mode ratio predicted by the adhesive edge stresses based on the adhesive-beam model (Luo and Tong 2009b, c) correlates well with the NFEA given in Johnson (1986).

### 24.6.3 Failure Prediction Considering Plastic Deformation

Fracture mechanics-based criteria have shown promising agreement with the experimental results for brittle adhesives (Adams 1989; Fernlund et al. 1994; Tong 1996; Van Tooren 2004; Luo and Tong 2009c). The energy release rate criterion can be applied to cohesive failure and interface fracture. When it is used, energy release rate and its critical value for each mode should be calculated and measured. When fracture mechanics-based criteria are used, fracture envelopes are normally set up to assess crack initiation and propagation. For ductile adhesives, plastic deformation occurs before structural failure and the cohesive zone model has been widely used to

764 assess structural failure of adhesively bonded structures (Sheppard et al. 1998;  
765 Blackman et al. 2003; Liljedahl et al. 2006).

---

## 766 24.7 Summary

767 Analytical approaches for adhesively bonded structures are presented in this chapter.  
768 Stress analysis for adhesively bonded joints is conducted using the classical  
769 adhesive-beam model and the other adhesive-beam models. Closed-form solutions  
770 of symmetric joints are presented, and analytical procedures of asymmetric and  
771 unbalanced joints are discussed. Load update for single-lap joints is investigated in  
772 detail. Numerical results calculated using the classical and other formulations are  
773 illustrated and compared. It is shown that the nonlinear adhesive-beam model based  
774 on the Timoshenko beam theory provides enhanced results compared to the linear  
775 adhesive-beam model based on the Euler beam theory for adhesively bonded  
776 composite structures. Analytical solutions of energy release rates for cohesive failure  
777 and delamination are presented, and several failure criteria are reviewed and  
778 discussed.

**Abstract**

Finite element analysis (FEA) is a widely used computer-based method of numerically solving a range of boundary problems. In the method, a continuum is subdivided into a number of well-defined elements that are joined at nodes, a process known as discretization. A continuous field parameter, such as displacement or temperature, is now characterized by its value at the nodes, with the values between the nodes determined from polynomial interpolation. The nodal values are determined by the solution of an array of simultaneous equations using computational matrix methods, and the accuracy of the results is dependent on the discretization, the accuracy of the assumed interpolation form, and the accuracy of the computation solution methods. The current popularity of the method is based on its ability to model many classes of problem regardless of geometry, boundary conditions, and loading. Modeling the behavior of adhesive joints is complicated by a number of factors, including the complex geometry, the complex material behavior, and the environmental sensitivity. FEA is currently the only technique that can comprehensively address the challenges of modeling bonded joints under realistic operating conditions. However, a reliable and robust method of using FEA to model failure in bonded joints is still to be developed.

**25.1 Introduction**

In its 50-year life, the finite element method (FEM) has progressed from a specialist technique of the aerospace stress analyst to a ubiquitous tool of advanced engineering analysis, widely taught in undergraduate programs and the foundation of a billion-dollar industry. It is based on two basic concepts. The first is the representation of a continuum as a number of simple, well-defined sub-elements with a finite number of degrees of freedom. The second is the solution of differential equations by the weak (or generalized) method through the application of numerical integration techniques. This reduces a potentially unsolvable differential equation to a series of simple, linear simultaneous equations, which can be solved through the application of matrix methods. The methods at the core of the finite element method were proposed in the nineteenth century, but it was only with the development of microprocessor computers that the solution of the large number of simultaneous equations required to represent complex problems became practical. The power of the method is in its simplicity and generality, being unbounded by geometry, loads, boundary conditions, or class of problem. However, it should be remembered that both the discretization process and

the numerical solution methods used in the finite element method involve errors, and, hence, the FEM will always present an approximate solution to a problem. In most cases, these errors can be minimized and are usually more than compensated for by the reduction in errors associated with simplifying a problem to a level that enables an exact solution to be determined. The mathematical basis of the FEM is now well established and its role as a practical engineering tool widely recognized. Further development, application, and usage of the method are envisaged in the foreseeable future.

Although numerous analytical methods for determining stresses in bonded joints have been proposed, they generally require significant simplification of geometry, boundary conditions, and material behavior; even then, the more advanced analyses are exceedingly complex, sometimes requiring numerical methods of solution. The application of FEM to bonded joints, with its capability of handling complex geometry, material behavior, and boundary conditions, as well as nonlinearity and multi-physics modeling, is potentially very attractive. However, a number of cautions should be observed. Firstly, the thickness of the adhesive layer with respect to other dimensions is usually small, raising problems of creating a suitable mesh with a reasonable number of elements, while avoiding excessive element distortion. Secondly, adhesive material behavior can be exceedingly complex and will vary considerably with environment, presenting problems in adopting a suitable material constitutive law. Thirdly, the interface between the adhesive and adherend is difficult to model accurately, and at certain points, theoretical singularities exist at the bi-material junction, presenting difficulties in applying standard failure criteria. These issues can all be addressed to some degree to provide effective analyses of bonded joints, and it is envisaged that further advances in these areas will be made and that the application of FEA to bonded joints will continue to increase. However, despite all the advantages, it should still be remembered that the FEM is an approximate technique, and the integrity of results is highly dependent on the skills of the analyst.

This chapter is subdivided into a number of sections. This section provides a general background to the development and application of the FEM. Section 2 provides the fundamentals of the method, and Sect. 3 discusses some of the practical aspects of finite element modeling. Section 4 discusses application of the FEM to adhesively bonded joints, and Sect. 5 provides conclusions from the chapter and indicates potential future developments in the application of FEA to bonded joints.

### 25.1.1 Brief History of the Finite Element Method

The finite element method is a numerical analysis procedure that provides an approximate solution to problems in various fields of engineering. It is based on the matrix methods of structural analysis of the 1920s and 1930s. Advances in the aerospace industry and the development of computers in the 1950s and 1960s saw further development and computerization of these methods. Interest in delta wings leads to the requirement for a two-dimensional (2D) element of arbitrary shape. In 1956, the stiffness of a general 2D triangular element was derived (Turner et al. 1956), and in 1959, the direct stiffness method as a general, computer-based method

of structural analysis was proposed (Turner 1959). This was the direct precursor of nearly all current commercial finite element analysis (FEA) methods.

The term finite element was introduced by Clough (1960), and the first widely used finite element program was written by Wilson in the early 1960s (Fish and Belytschko 2007). The applicability of the method to general field applications was described by Zienkiewicz and Cheung (1967), and by the end of the 1960s, finite element analysis (FEA) was being applied to a wide variety of boundary problems, such as heat transfer, fluid flow, dynamics, free and forced vibration, and electrical and magnetic fields. The mathematical foundations of the finite element method were laid down in the 1970s (Champion and Ensminger 1988). In the 1980s, generalized software packages designed to run on powerful computers were developed, and improved techniques for analyzing nonlinear problems were established.

The personal computer (PC) was introduced in the late 1970s, and by the 1990s, the PC became sufficiently powerful to be practical for FEA. Commercial FEA software for PCs was developed and became widely used. FEA is now used in practically all fields of engineering analysis and is the clearly favored technique for many industries, including aerospace, automotive, nuclear, electronics, and defense. Several software vendors offer extremely powerful, general purpose, finite element software which can solve a wide range of problems.

### 25.1.2 Recent Developments

Finite element modeling was once the domain of a few high-technology industries and academic communities. An increase in the sophistication of the method and a widening of the user base has been accompanied by a shift from in-house software codes to powerful, user-friendly commercial software. The market is now dominated by a relatively small number of general commercial software packages and a number of more specific codes satisfying niche markets. Most of the commercial packages are capable of user modification, such as the introduction of user-written elements or material constitutive models.

A recent trend in the commercially available software is the availability of multi-physics simulations. The finite element method can be applied to many classes of problems such as structural, heat transfer, material transport (such as diffusion), fluid mechanics, and electromagnetic. Multi-physics analysis is concerned with the coupling of different analysis classes, such as thermo-structural, fluid-chemical, electro-thermal, fluid-structural, hygro-thermo-structural, etc. In multi-physics modeling, the nature of the coupling must be considered. For example, in a fully coupled thermo-mechanical analysis, both the effect of the thermal field on the structural response and the effect of the structural response on the thermal field are represented. This is implemented by partitioning the structural and field analyses using common time integration. The thermal and structural analyses are then performed either concurrently or sequentially, and communication is achieved via a common data transfer file. For strongly coupled systems, data transfer should be on the iterative level, but for weakly coupled systems, an incremental data transfer is usually sufficient. There may also be

situations that a single software or type of analysis is not able to solve for all the physics inherent in certain complex structures and systems. Such situations include problems involving fluid and structural domain interaction, system-level rigid body dynamics with inclusion of flexible parts, or inclusion of hydraulic/pneumatic control in a finite element-based simulation. In such cases, multiple solvers can be linked together by using software that acts as controller for all the involved solvers. The control software facilitates the transfer of information between the solvers during the simulation process and also provides mapping between field variables. The information exchange between solvers is generally linear, where one solver completes a job and the results are provided to the next solver. Such a linkage enables optimization and design space exploration studies involving various fields that fully interact with each other. However, the computational requirements of running these studies are generally high as multiple iterations are required to find an optimized solution. The limitations of computational requirements have been mostly met by the use of high performance computing clusters (HPCs). HPCs provide a multi-node, multicore configuration where a master node schedules the jobs received from multiple users. Installation and maintenance of HPCs is a costly business, and many companies are now moving toward cloud computing. In cloud computing, Internet-based services may be used to access remote compute clusters for the solution of large finite element-based problems. The access to cloud-based computing resources can be requirement based, which may help in reducing the cost of an analysis. The current issues with the use of cloud computing are related to the availability of high-speed Internet and data security.

In a drive to make the finite element method more accessible to users of various levels of experience, packaging of complex finite element analysis in the form of apps is becoming increasingly popular. A few commercial finite element software (such as COMSOL) are now providing this as a built-in capability and providing server applications for deploying the apps across the enterprise. The advantage of this approach is that complex finite element analysis models, which take a considerable time, effort, and level of expertise to setup, are developed and validated by experts in the field. These validated finite element models are then packaged as apps, allowing predetermined parameters to be changed in a controlled fashion, thus enabling users less experienced in finite element theory to carry out various types of studies.

Another area of current development is in damage and failure modeling. It is impossible for a linear finite element analysis to predict failure in a structure. However, in nonlinear analysis, it is possible to implement a failure model, and increasingly complex failure models are now supplied as standard features of commercial FEA software. It should be noted, however, that even though the failure model may look complex, the method of implementation within FEA is usually fairly straightforward. In most cases, this involves utilization of the results from the various increments of a nonlinear analysis. These are processed via some failure model to determine whether failure or damage has occurred in any of the elements. The properties of the failed or damaged elements are then modified, usually by control of the element stiffness matrix, removal of elements, or affecting nodal connectivity/element interaction.

One of the simplest failure models is that based on plastic yielding. In this case, progressive yielding of the structure is modeled until a “limit state” or state of “global

yielding” is reached. Fracture mechanics principles can also be used within an FEA. This can be based on either the stress intensity factor or energy approaches. An extension to this approach is cohesive zone modeling (CZM), which also allows for damage of a material ahead of a crack. The CZM technique allows the modeling of damage and failure in ductile (Dugdale 1960; Barenblatt 1962) and quasi brittle (Hillerborg et al. 1976) materials. The technique uses a layer of cohesive elements to represent a potential crack path or interface. The virtual crack closure technique (VCCT) for the determination of strain energy release rate was proposed by Rybicki and Kanninen on 1977 but has only recently been implemented in major commercially available finite element software. Another method for modeling cracks in materials is the extended finite element method (XFEM). The XFEM uses enriched shape functions to represent a discontinuous displacement field (Mohammadi 2008). The main advantage of XFEM is that the crack may initiate at any point in the material and propagate based on loading conditions. No remeshing is required as the crack can grow within an element and need not follow element boundaries. In order to overcome the individual drawbacks of CZM and XFEM methods, when applied to the adhesive joints, a combination of the two methods has been used (e.g., Mubashar et al. 2014; Stuparu et al. 2016). In such adhesive joint models, the XFEM is used to simulate cohesive damage and failure within the adhesive layer, whereas CZM is used to represent interfacial damage and crack growth. This enables crack initiation and propagation that can transfer from a cohesive crack to an interfacial crack and vice versa. However, such highly nonlinear models suffer from non-convergence problems, and some form of viscous stabilization is generally used to obtain a converged solution. Neumayer et al. (2016) attempted to develop a cohesive element that is able to predict cohesive as well as interfacial failure in the adhesive layer. The advantage of such a formulation is that a single layer of cohesive elements would be able to correctly predict the type of failure in an adhesive joint. The reduction in the finite element model size comes from using structural elements such as beams or shell elements for adherends. The proposed finite element formulation was used to determine the strength of single lap adhesive joints where it provided good prediction of failure strength of the joint under cohesive failure. However, for interfacial failure, the strength of the adhesive joints was underestimated by the proposed cohesive element.

Another methodology to alleviate problems associated with continuum meshes during large deformation simulations is to use meshless methods. One such method is smoothed particle hydrodynamics (SPH), which is generally used for highly nonlinear solid mechanics problems. In this method, a material continuum is approximated by discretization involving particles rather than elements, which allows for large deformations and crack propagation along arbitrary paths. The SPH method is a particle-based representation of the partial differential equations of a continuum. The particles are not directly connected to each other but are affected by neighboring particles. This means that the value of field variable at a point also includes contributions from the neighboring elements, where the number of neighboring elements contributing to a particle is based on a kernel function. The value of a field variable is determined by an interpolation scheme. Displacement is the field variable in the case of a structural analysis, as in the finite element method. A few attempts have been made to apply this method to adhesive joints (e.g., Tsai et al. 2014; Mubashar and Ashcroft 2015).

Continuum damage mechanics-based models are now available and implemented in commercial finite element software. Damage may be regarded as the growth of microvoids or microcracks in a material (Lemaitre and Desmorat 2005). Continuum damage mechanics was introduced in the late 1950s (Kachanov 1958) and is able to predict the reduced load bearing capacity of a material before failure. Damage is related to the growth of microcracks and microvoids in a material. Damage in a material is generally defined by a damage variable that has constitutive equations for evolution. The damage variable may be defined such that it is based on some physical characteristic of the material or is a representation of the effects of damage, e.g., reduction in stiffness. Damage may be isotropic or anisotropic and has also been defined for fatigue and creep loading conditions. The damage model combined with a failure criterion can be used in conjunction with plasticity models, providing a complete definition of material behavior.

### 25.1.3 Applications of Finite Element Analysis

Owing to the general nature of the finite element method, it can be used to solve boundary value problems in many fields. The initial applications of the finite element method were in aircraft structures, but it is now widely applied to the solution of many other engineering problems. These include the stress and thermal analysis of components, crash analysis of vehicles and aircraft, seismic analysis of civil engineering structures, nuclear engineering, fluid flow analysis, soil structure interaction, steady-state and transient behavior of electronic devices, and electromagnetics. The use of composites is increasing in modern structures, such as aircrafts and automobiles, and FEA provides a convenient method to determine the performance and durability of composites. The fabrication of different types of composite lay-up can be explored at design stage to avoid problems during manufacturing. FEA can also be used in the optimization of structural components where automatic mesh generation makes the process highly automated. Full vehicle body noise and vibration analysis are performed to improve the performance of modern automobiles. Virtual crash testing of aircraft and drop testing of electronic devices such as mobile phones and laptops may now be conducted using commercially available FEA software. Applications in offshore structures include ship design and reliability studies of oil and gas equipment. Manufacturing industry is also taking advantage of the capabilities of finite element method where finite element method-based simulation models are used to develop better cutting tools, estimate the best machining conditions, predict residual stresses, and determine the shape of a part after forming processes.

A recent area of application is in biomedical engineering where FEA is used to determine the performance of implants such as heart valves and the expansion of stents during angioplasty. Prosthesis designs may be analyzed using FEA so they can be adapted to a particular patient. Other biomedical applications involve modeling of bone, biological soft tissues, blood flow, and blood vessels (Kojić et al. 2008). Some examples of finite element models, including a heart stent, chassis for multi-axle

vehicle, an adhesively bonded composite T-Joint, and two-dimensional orthogonal machining, are shown in Fig. 1.

**25.1.4 Comparison with Other Methods**

Other analysis methods that use discretization include the finite difference method, the boundary element method, and the finite volume method. However, FEA is by far the most commonly used method in structural mechanics. The finite difference method approximates differential equations using difference equations. The method works well for two-dimensional problems but becomes cumbersome for regions with irregular boundaries (Segerlind 1984). Another difference between the finite element and finite difference methods is that in the finite difference method, the field variable is only computed at specific points, while in the finite element method, the variation of a field variable within a finite element is available from the assumed interpolation function (Hutton 2003). Thus the derivatives of a field variable can be directly determined in finite element method as opposed to the finite difference method where only data concerning the field variable is available. The boundary element method is also not general in terms of structural shapes (MacNeal 1994).

**25.2 The Finite Element Method**

This section provides a condensed view of the fundamentals of the finite element method, in which an attempt has been made to summarize the underlying theory behind the main classes of analysis that may usefully be used in analyzing

**Fig. 1** Examples of finite element models: (a) a heart stent, (b) chassis of a multi-axle vehicle, (c) composite T-joint, and (d) machining of material

adhesively bonded joints. One of the many textbooks on finite element analysis, such as Cook (1995) or Zienkiewicz and Taylor (2000), should be referred to for a more complete treatment of the subject.

### 25.2.1 Fundamentals of the Finite Element Method

In the finite element method (FEM), a continuous structure is considered as a number of smaller elements joined at nodes. Each node has a limited number of degrees of freedom (dof). Hence, the continuum is now represented by a finite number of dof and determined by the number of elements, the number of nodes per element, and the number of dof per node. Over each element, a field quantity, such as displacement in structural analysis, is interpolated, usually adopting a polynomial form, from values of the field quantity at the nodes. By joining the elements, the field quantity is interpolated over the whole structure by an array of polynomial expressions. A set of simultaneous equations is formulated in which the primary unknowns are the values of the field quantity at the nodes.

There are a number of variants of the finite element method depending on the formulation and solution of the problem. The most common variant is the stiffness method in which the displacement compatibility conditions are satisfied and the equations of equilibrium are solved to yield the unknown nodal displacements. The governing equation using matrix symbolism is of the following form:

$$[F] = [K][u] \quad (1)$$

where  $[u]$  is a vector of unknown values of the field quantity at the nodes,  $[K]$  is a matrix of known constants, and  $[F]$  is a vector of known loads. In stress analysis,  $[u]$  is the displacement vector,  $[F]$  is the vector of applied loads, and  $[K]$  is the stiffness matrix.

The most widely used methods in finite element formulation are the variational method and the method of weighted residuals. The variational approach involves the solution of a governing partial differentiation equation, such as the equilibrium equation in an elasticity problem, by determining the conditions that make some quantity (or functional) stationary (i.e., either maximum or minimum). In elasticity problems, the functional used is the total potential energy of the structure. First, an approximate form for the solution is assumed. This must be admissible, that is it must satisfy internal compatibility and essential boundary conditions. The stationary potential energy theorem is then used to determine the optimum value for the constants. This theorem states that for all admissible configurations of a conservative system, those that satisfy the equations of equilibrium make the potential energy stationary with respect to small admissible variations of displacement, i.e., equilibrium configurations are defined when

$$\frac{\partial \Pi_p}{\partial a_i} = 0 \quad (2)$$

339 where  $\Pi_p$  is potential and  $a_i$  is the  $i$ th dof.

$$\Pi_p = U + \Omega \quad (3)$$

340 where  $U$  is the strain energy and  $\Omega$  is the potential of the load system. The strain  
341 energy in a stressed body is given by

$$U = \frac{1}{2} \int \{\varepsilon\}^T [E] \{\varepsilon\} dV \quad (4)$$

342 where  $[E]$  is the elastic constant matrix, which defines the relationship between stress  
343  $\{\sigma\}$  and strain  $\{\varepsilon\}$ , i.e.,

$$\{\sigma\} = [E] \{\varepsilon\} \quad (5)$$

344 The potential of the load system is

$$\Omega = -\{u^e\}^T \{F^e\} \quad (6)$$

345 The total potential of the system is therefore

$$\Pi_p = U + \Omega = \frac{1}{2} \int \{\varepsilon\}^T [E] \{\varepsilon\} dV - \{u^e\}^T \{F^e\} \quad (7)$$

346 A shape function,  $[N]$ , is used to relate the vector of displacements in the element,  
347  $\{u\}$ , to the vector of nodal displacements,  $\{u^e\}$ .

$$\{u\} = [N] \{u^e\} \quad (8)$$

348 The strain vector can then be determined by partial differentiation of the dis-  
349 placement vector, giving

$$\{\varepsilon\} = \left\{ \frac{du}{dx} \right\} = \left[ \frac{dN}{dx} \right] \{u^e\} = [B] \{u^e\} \quad (9)$$

350 where  $[B]$  is the strain-displacement matrix. Substituting (9) into (7),

$$\Pi_p = \frac{\{u^e\}^T}{2} \int [B]^T [E] [B] dV \{u^e\} - \{u^e\}^T \{F^e\} \quad (10)$$

351 Applying the stationary potential energy theorem,

$$\frac{\partial \Pi_p}{\partial \{u^e\}} = 0 = \int [B]^T [E] [B] dV \{u^e\} - \{F^e\} \quad (11)$$

$$\{F^e\} = \int [B]^T [E] [B] dV \{u^e\} \quad (12)$$

and as  $\{F^e\} = [K^e]\{u^e\}$ :

$$[K^e] = \int [B]^T [E] [B] dV \quad (13)$$

Equation 13 can be solved by numerical integration for each element.

### 25.2.2 Natural Coordinates

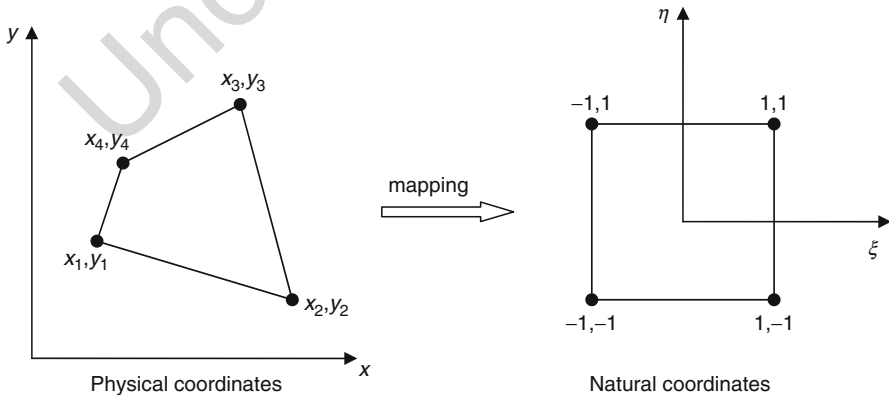

It can be seen that integration of the  $[B]$  matrix is necessary for element formulation via the variational approach. A numerical integration method, such as Gauss quadrature, is used in which the real element shape is mapped onto an idealized element shape with well-defined boundaries and hence integration limits. This is achieved by transforming from the physical coordinate system (e.g.,  $xy$ ) to a natural coordinate system (e.g.,  $\xi\eta$ ) as shown in Fig. 2.

The shape functions can now be derived in terms of the natural coordinates. However, it is necessary to transform the variables to the physical coordinates in order to determine  $[B]$ . This can be achieved using the chain rule. For the 2D case in Fig. 2,

$$\frac{\partial N}{\partial \xi} = \left( \frac{\partial N}{\partial x} \right) \left( \frac{\partial x}{\partial \xi} \right) + \left( \frac{\partial N}{\partial y} \right) \left( \frac{\partial y}{\partial \xi} \right) \quad (14)$$

$$\frac{\partial N}{\partial \eta} = \left( \frac{\partial N}{\partial x} \right) \left( \frac{\partial x}{\partial \eta} \right) + \left( \frac{\partial N}{\partial y} \right) \left( \frac{\partial y}{\partial \eta} \right) \quad (15)$$

In matrix form, this can be rewritten as

**Fig. 2** Transformation from physical to natural coordinates

$$\begin{bmatrix} \frac{\partial N}{\partial x} \\ \frac{\partial N}{\partial y} \end{bmatrix} = [J]^{-1} \begin{bmatrix} \frac{\partial N}{\partial \xi} \\ \frac{\partial N}{\partial \eta} \end{bmatrix} \quad (16)$$

where the Jacobian matrix  $[J]$  is given by

$$[J] = \begin{bmatrix} \frac{\partial x}{\partial \xi} & \frac{\partial y}{\partial \xi} \\ \frac{\partial x}{\partial \eta} & \frac{\partial y}{\partial \eta} \end{bmatrix} \quad (17)$$

The Jacobian can be regarded as the scale factor that relates the physical length with the reference length. Element distortion affects the Jacobian determinant and introduces errors into the numerical integration. Thus element distortion needs to be controlled to obtain acceptable integration results.

### 25.2.3 Isoparametric Elements and Numerical Integration

In isoparametric elements, the same interpolation functions are used to define the variation of the primary variable across the element and the shape of the element. In other words,  $[N]$  is used to determine the element shape from the nodal coordinates  $[x^e]$  (hence the term shape function, which takes on added significance for isoparametric elements) and to determine element displacement from nodal displacements.

$$x = [N][x^e]^T \quad (18)$$

$$u = [N][u^e]^T \quad (19)$$

In the case of quadratic or higher interpolations, this has the advantage that the distribution of the primary variable is represented more closely and also that the element sides can be curved. The element stiffness matrix requires the strain-displacement relationship to be known, e.g., for the one-dimensional case:

$$\varepsilon_x = \frac{du}{dx} = \left( \frac{d}{dx} [N] \right) \{u^e\} \quad (20)$$

where

$$\frac{d}{dx} = \frac{d\xi}{dx} \frac{d}{d\xi} \quad (21)$$

384 As  $[N]$  is expressed in terms of natural coordinates, the chain rule for differenti-  
 385 ation must be used. First, the Jacobian is calculated as

$$J = \frac{dx}{d\xi} = \frac{d}{d\xi}[N]\{x^e\} \quad (22)$$

386 And hence the  $[B]$  matrix is calculated as

$$[B] = \frac{1}{J} \frac{d}{d\xi}[N] \quad (23)$$

387 The stiffness matrix  $[k]$  is now obtained using

$$[k] = \int [B]^T [E] [B] dx = \int [B]^T [E] [B] J d\xi \quad (24)$$

388 The only issue left is that Eq. 24 cannot generally be solved algebraically. Instead  
 389 a numerical integration scheme (such as *Gauss Quadrature*) has to be used to  
 390 determine the stiffness matrix. An integral having arbitrary limits can be transformed  
 391 so that its limits are from  $-1$  to  $1$ , e.g.,

$$I = \int_{x_1}^{x_2} f(x) dx \quad (25)$$

392 can also be expressed as

$$I = \int_{-1}^1 \varphi(\xi) d\xi \quad (26)$$

393 and therefore, as in all isoparametric formulations in FEA, the integral can be  
 394 evaluated between the same limits  $-1$  and  $1$ . In general, the integral can be  
 395 computed by sampling from a number of points and multiplying by an appropriate  
 396 value or *weighting factor*  $W$ . This leads to the following generalization for *Gauss*  
 397 *quadrature*:

$$I = \int_{-1}^1 \varphi(\xi) d\xi \approx W_1 \varphi_1 + W_2 \varphi_2 + \dots + W_n \varphi_n \quad (27)$$

398 where  $n$  is the number of sampling (Gauss) points. As the number of gauss points  
 399 increases, more accurate integration results are obtained in general. On the other  
 400 hand, using too many Gauss points would require more computational resources,  
 401 and the results may not improve.

The element stiffness matrices are summed to form the global stiffness matrix, as given in Eq. 1, which will be a symmetrical square matrix with the order of the numbers of dof in the finite element model. Sophisticated computational techniques have been developed that enable the solution of these equations for large assemblages of elements, thereby, allowing complex structures to be modeled to a high degree of accuracy. Once all the nodal degrees of freedom have been determined, it is a relatively simple procedure to determine strains in the elements from Eq. 9 and then to calculate stresses using Eq. 5.

---

## 25.3 Nonlinear Finite Element Analysis

### 25.3.1 Sources of Nonlinearity

In a linear analysis, response is directly proportional to load. This is applicable if displacements and rotations are small, stress is directly proportional to strain, and loads maintain their original directions as the structure deforms. In a linear analysis, equilibrium reactions are written in terms of the original configuration, and displacements are obtained by solving a single set of equilibrium equations.

Nonlinearity typically arises because of material or geometric nonlinearities. Nonlinearity makes the problem more difficult because the geometry, support conditions, and material properties required for the equilibrium equations are not known until the solution is known. The solution cannot be obtained in a single step, and some sort of iterative solution must be used, together with a relevant convergence test. In a nonlinear analysis, the principle of superposition cannot be applied, and a separate analysis is required for each load case.

Geometric nonlinearity arises when deformations are large enough to significantly alter the way load is applied or resisted by the structure. Examples include follower loads, membrane stiffening, and snap-through effects. Finite element analysis of large deflection problems is carried out using the same elements as used in small deflection analysis, but extra attention must be paid to errors due to excessive element distortion. Nonlinear solution algorithms update the stiffness matrix in the solution process, ensuring equilibrium equations based on the deformed configuration are generated.

Contact nonlinearity may also be considered a form of geometric nonlinearity. Most real problems involve contacting bodies; however, in many cases, this is circumvented in FEA by the use of simplifying boundary conditions. However, in cases where the interaction of two or more bodies is of interest, a contact analysis must be set up. It should be noted that if contact is not set up, the two contacting bodies will simply pass through each other. Numerous methods of incorporating contact in FEA are available but most involve two main steps. The first is the detection of contact, and the second is the imposition of forces to prevent interpenetration of the contacting bodies. In order to detect penetration, it is usual to first identify the surfaces that are likely to make contact. As a nonlinear analysis

proceeds, checks are then made to assess contact. Once contact has been made, the penetration distance is calculated and appropriate forces applied to prevent interpenetration. From this analysis, the point of contact, contact force, deformed shape of contacting bodies, and contact stresses can all be calculated. The results may be influenced by the mesh in the contact region, the nonlinear controls, and the contact algorithms used.

Material nonlinearity may be hyperelastic or elastoplastic. The difference between the behavior of an elastic and elastoplastic material is seen on unloading as in the former case, the unloading path coincides with the loading path, whereas in the latter case, a different unloading path results in permanent deformation when the load has been removed. Elastoplastic behavior is characterized by a linear region up to the yield point, after which softening behavior is seen. Hyperelastic materials such as elastomers exhibit nonlinear elastic response for even large strains.

### 25.3.2 Solution Algorithms

Numerical methods are incapable of solving nonlinear equations explicitly, and the actual behavior must be approximated by a sequence of linear steps. Incremental and iterative methods are available to solve a system of nonlinear equations. In the incremental method, the response is approximated by dividing the solution into a number of linear increments and updating the stiffness at each increment. The incremental method may underestimate the nonlinear behavior, and a progressive divergence from the actual response may be observed. A better approximation would be obtained by decreasing the size of the increments, but for a controlled reduction in error, an iterative method is required.

Iterative methods utilize the secant stiffness, which is defined as  $F/u$ . One of the commonly used iterative techniques is the Newton-Raphson method. The first stage in this method is the same as the first increment in the incremental method. After the increment, as the stiffness as a function of displacement is known, the internal forces can be calculated from:

$$r = ku \quad (28)$$

where  $k$  is the secant stiffness at the end of increment. The difference between the applied force and the resisting force can then be calculated from:

$$e = F - r \quad (29)$$

This force imbalance can then be used to drive the displacement toward the correct value by using an equilibrium iteration method at constant load. The process can be repeated until a suitably small imbalance is attained.

The Newton-Raphson method may be computationally expensive in a multi-dof problem because a new global stiffness matrix is used in each iterative step.

In the modified Newton-Raphson method, the same global stiffness matrix is used in all the iterative steps within an increment. This method requires more iterations to achieve convergence, but each iteration is computed far more quickly.

Appropriate selection of convergence criteria is essential to obtain sufficient accuracy in a reasonable time. Convergence is also based on the solution algorithm. Convergence failure is usually defined when the convergence tolerance is not reached in a specified number of iterations. In this case, it is common to reduce the incremental load step.

## 25.4 Thermal Analysis

### 25.4.1 Introduction

Thermal analysis is primarily concerned with the calculation of temperature distribution in a body and the magnitude and direction of heat flow. There are many similarities between the formulation and solution of thermal and structural problems in FEA. The global FE equation for a steady-state thermal problem is

$$[K_T][T] = [Q] \quad (30)$$

where  $[K_T]$  is a matrix of material constants including thermal conductivity,  $[T]$  is a column matrix of nodal temperatures, and  $[Q]$  is a column matrix of thermal loads. Thermal finite elements are assembled in a similar way as structural finite elements. In contrast to stress analysis, however, thermal analysis is a scalar problem as temperature is nondirectional. Also, a thermal finite element node has only one degree of freedom, namely, temperature. In a thermal analysis, the temperature field (like the displacement field in structural analysis) is continuous, but the temperature gradients (like strains in structural analysis) are not continuous between elements, and higher mesh refinement is required in regions where temperature gradient changes rapidly.

### 25.4.2 Heat Conduction

Fourier heat conduction equation for an isotropic material:

$$f_x = -k \frac{\partial T}{\partial x} \quad \text{or} \quad q_x = -kA \frac{\partial T}{\partial x} \quad (31)$$

where  $f_x$  is heat flux per unit area ( $\text{Wm}^{-2}$ ),  $k$  is the thermal conductivity ( $\text{Wm}^{-1} \text{K}^{-1}$ ),  $q_x$  is the rate of heat flow (W), and  $A$  is the cross-sectional area ( $\text{m}^2$ ). The negative sign indicates that heat flows in the opposite direction to the increase in temperature. This can be extended to a general anisotropic case:

$$\begin{Bmatrix} f_x \\ f_y \\ f_z \end{Bmatrix} = - \begin{bmatrix} k_x & 0 & 0 \\ 0 & k_y & 0 \\ 0 & 0 & k_z \end{bmatrix} \begin{Bmatrix} \partial T / \partial x \\ \partial T / \partial y \\ \partial T / \partial z \end{Bmatrix} \quad \text{or} \quad \{f\} = -[D]\{T_{\partial}\} \quad (32)$$

If the energy balance in a differential element is considered,

$$- \left[ \frac{\partial}{\partial x} \quad \frac{\partial}{\partial y} \quad \frac{\partial}{\partial z} \right] \begin{Bmatrix} f_x \\ f_y \\ f_z \end{Bmatrix} + Q = c\rho \frac{\partial T}{\partial t} \quad (33)$$

where  $Q$  is the rate of internal heat generation per unit volume,  $c$  is the specific heat ( $\text{J kg}^{-1} \text{K}^{-1}$ ),  $\rho$  is the mass density ( $\text{kg m}^{-3}$ ), and  $t$  is time. From Eqs. 32 and 33, the common form of the governing partial differential equation for heat transfer can be obtained.

$$\frac{\partial}{\partial x} \left( k_x \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial y} \left( k_y \frac{\partial T}{\partial y} \right) + \frac{\partial}{\partial z} \left( k_z \frac{\partial T}{\partial z} \right) + Q = \rho c \frac{\partial T}{\partial t} \quad (34)$$

In a steady-state problem,  $\partial T / \partial t = 0$ . Therefore, for an isotropic material (where  $k_x = k_y = k_z$ ) under steady-state conditions, Eq. 34 reduces to

$$k \left( \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \right) + q_v = 0 \quad (35)$$

Many other problems are governed by an equation of the same form as Eq. 34, which is known as the quasi-harmonic equation. Table 1 lists different classes of problems governed by the quasi-harmonic equation.

When a steady-state condition does not exist, the temperature changes as a function of time. This is resisted by the thermal mass, which is dependent on the mass density and the specific heat of the material. In a transient thermal analysis, Eq. 30 is reformulated as

**Table 1** Classes of problem governed by the quasi-harmonic equation

Field problem	Unknown (T) (potential)	Material constant ( $K_T$ )	Load (Q)
Heat conduction	Temperature	Thermal conductivity	Internal heat generation
Diffusion	Moisture concentration	Diffusion coefficient	Moisture source
Seepage flow	Hydraulic head	Permeability	Storage
Electric conduction	Voltage	Electric conductivity	Internal current source
Electrostatics	Voltage	Permittivity	Charge density
Magnetostatics	Magnetic potential	Reluctivity	Current density
Elastic torsion	Stress function	1/shear modulus	Twice the rate of twist

$$[K_T]\{T\} + [C]\left\{\frac{dT}{dt}\right\} = \{Q(t)\} \quad (36)$$

[C] is the heat capacity matrix and is assembled from element heat capacity matrices.

$$[C] = \sum [C^e] \quad \text{where} \quad [C^e] = \int [N]^T [N] \rho c dV \quad (37)$$

In a transient analysis,  $\{T\}$  is required as a function of time when the initial temperatures are prescribed and  $\{Q(t)\}$  is a known function of time. This calculation is usually performed as a direct integration in time. At the  $n$ th instant of time, Eq. 36 is written in the form:

$$[K_T]\{T\}_n + [C]\left\{\frac{dT}{dt}\right\}_n = \{Q\}_n \quad (38)$$

Direct integration is then based on the formula:

$$[T]_{n+1} = [T]_n + \Delta t \left( (1 - \gamma) \left\{\frac{dT}{dt}\right\}_n + \gamma \left\{\frac{dT}{dt}\right\}_{n+1} \right) \quad (39)$$

where the time integration constant,  $\gamma$ , is chosen by the analyst.

## 25.5 Dynamic Analysis

### 25.5.1 Introduction

In dynamics problems, frequencies and modes of vibration and/or response to time-dependent forces are determined. This section provides an introduction to the way that a number of dynamic and vibration problems can be solved in a finite element package. These aspects are further developed in ► Chaps. 29, “Design for Impact Loads,” and ► 30, “Vibration Damping of Adhesively Bonded Joints.” The governing equation for structural dynamics in FEA is

$$[K][u] + [C][\dot{u}] + [M][\ddot{u}] = [F(t)] \quad (40)$$

where  $[K]$  is the stiffness matrix,  $[C]$  is the damping matrix, and  $[M]$  is the mass matrix.  $u$  is displacement and the load,  $F$ , is a function of time. It can be seen from this equation that the externally applied forces are resisted by the sum of three resisting forces. These are stiffness forces given by  $[K][u]$ , damping forces given by  $[C][\dot{u}]$ , and inertia forces given by  $[M][\ddot{u}]$ .

If there are no nonlinearities,  $[K]$ ,  $[C]$ , and  $[M]$  contain only constants, i.e., they are not functions of time or displacement. In general, a dynamic FEA analysis seeks to determine displacements, velocities, and accelerations as a function of time, given the load and material properties. In many cases, however, a dynamic analysis has the simpler goal of determining the frequencies and modes of vibration, and this is discussed in the next section.

## 25.5.2 Free Vibration

In free vibration, loads are either zero or constant. Constant massless loads affect natural frequencies only if they modify the stiffness of the structure. Loads associated with mass are included in  $[M]$ . All dof move in phase with each other at the same frequency. Motion can be described as displacements varying sinusoidally with time relative to a mean configuration  $[u_m]$  associated with any constant loads  $[F_c]$ . The mean configuration can be computed from a standard static analysis:

$$[u_m] = [K]^{-1}[F_c] \quad (41)$$

If  $[F_c]$  is zero, then the mean configuration is the unstressed shape. The displacement as a function of time can then be described by the following equation:

$$\{u\} = \{u_m\} + \{\bar{u}\} \sin \omega t \quad (42)$$

where  $\{\bar{u}\}$  is the vector of nodal displacement amplitudes in vibration. The governing equation for undamped free vibration can thus be derived:

$$\{\bar{u}\}([K] - \lambda[M]) = 0 \quad \text{where} \quad \lambda = \omega^2 \quad (43)$$

This is an eigenvalue problem and has the trivial solution  $\{\bar{u}\} = 0$  and nontrivial solutions equal to the number of dof. Each solution consists of an eigenvalue (in this case the square of the natural frequency of vibration,  $\omega_i^2$ ) and an associated eigenvector (in this case the mode of vibration  $\{\bar{u}\}_i$ ). The smallest nonzero value of  $\omega_i$  is the fundamental frequency of vibration. The physical interpretation of Eq. 43 is that the various vibration modes are different displacement configurations in which elastic loads are in balance with inertia loads. Unlike a static problem, no support is required to obtain a solution for an eigenvalue problem. An unsupported structure will undergo rigid body modes in which all strains and the natural frequency are zero.

Unless there is shock loading, only the lowest frequency modes are usually important in structural response, and only a selected number of solutions are generally specified by the user, regardless of the number of dof in the model. It should also be noted that lower modes will have more elements per wave and hence the discretization error will be less.

### 25.5.3 Dynamic Response Analysis

Dynamic response analysis is concerned with the response of a structure to an arbitrary time-dependent loading. For dynamic response analysis, Eq. 40 is written as

$$[K][u_n] + [C][\dot{u}_n] + [M][\ddot{u}_n] = [F(t)_n] \quad (44)$$

where  $[F_n]$  is the known time-dependent forcing function at the  $n$ th instant and the equation is solved for displacements, velocities, and accelerations corresponding to  $[F_n]$ .  $n = 1, 2, 3$ , etc. corresponds to times of  $t = 0$ ,  $t = \Delta t$ ,  $t = 2\Delta t$ , etc., where  $\Delta t$  is a time increment. After the response is calculated at instant  $n$ , the time is incremented by  $\Delta t$  and the response calculated at instant  $n + 1$ . Hence a plot of displacement, velocity, or acceleration as a function of time can be constructed.

Dynamic response analysis can be undertaken in FEA by using a modal method or by a direct integration method. The latter is so called because no transformation to a special form is required and the governing equation is solved by a step-by-step procedure in the time domain. Hence direct integration advances the solution from a known condition at time  $t$  to an unknown condition at time  $t + \Delta t$ . Two forms of direct integration are commonly encountered. In an explicit integration scheme, the solution at time  $t + \Delta t$  is obtained from a consideration of equilibrium at time  $t$ . This is most suitable for high-frequency response and shock loading in which many time increments are considered. In an implicit integration scheme, the solution at time  $t + \Delta t$  is obtained by considering equilibrium at time  $t + \Delta t$ . This is more computationally expensive as a stiffness matrix conversion is required at each time increment and is more suitable to low frequency and inertial problems.

## 25.6 Application of the Finite Element Method

The finite element modeling process has three main stages, which are termed preprocessing, processing, and post-processing.

### 25.6.1 Preprocessing

In the preprocessing stage, the geometric model is created, and material parameters, loads, boundary conditions, and analysis controls are defined. The geometric model is discretized by meshing with elements. This process results in a data file containing all the necessary information in a format required for the finite element processor. The preprocessing is increasingly being carried out by sophisticated graphical interfaces; however, the ability to create or modify the data files using text editors is usually retained. Many of the commercial graphical preprocessors are capable of preparing data files in a format suitable for a number of different processors.

A number of questions must be asked before modeling commences. The most important of these are probably: Is finite element modeling necessary? What information is required from the analysis and to what degree of accuracy? Finite element modeling can be an expensive activity, and if an effective analytical solution has already been derived for the problem, then this will almost inevitably be a cheaper option. Analytical models for adhesively bonded joints are discussed in ► [Chap. 24, “Analytical Approach.”](#) Experimental methods should also be considered. A clear understanding of what is required from the analysis, and to what degree of accuracy, is needed before the model can be properly planned. The finite element method is always an approximation, and one of the most important skills of the modeler is determining how to create the simplest model that provides the required answer to the required degree of accuracy. A good principle is to start with an oversimple model and to gradually refine this model until sufficient accuracy has been achieved. Some analytical or experimental validation of the simple model provides confidence in the modeling approach and can be used to justify further extension of the analysis. Once the nature of the problem has been understood and simplified to a form suitable for finite element analysis, the finite element model can be planned. Key decisions to be made at this stage are the type of analysis, the selection of element type(s), the meshing strategy, and the load and boundary condition simulation.

Most finite element packages have an element library of hundreds of different element types. These can be divided into three geometric types, namely, structural elements (e.g., bar, beam, shell elements), planar elements (e.g., plane stress, plane strain, and axisymmetric elements), and solid elements (e.g., brick, wedge, tetrahedron). A further subdivision is by the order of the element. Linear elements are only capable of modeling straight boundaries. Higher order elements (e.g., quadratic and cubic) are characterized by mid-element nodes and can provide a more accurate interpolation of field variation within the element. These elements are more computationally expensive, and a compromise between the number and order of elements should be considered. Isoparametric elements use the same parameters to define geometry and field variation and are capable of representing curved sides and surfaces, as discussed in Sect. 26.2.3.

Models can be constructed using a number of different types of elements as long as there is acceptable element connectivity. Particular attention must be paid to the dof at common nodes and interpolation functions along common edges and surfaces. The network of elements and nodes that discretize the model is called the mesh. Mesh density refers to the number of elements in a given region and is increased to give greater accuracy in critical locations. In noncritical regions and where there are low stress gradients, it is more efficient to use a low mesh density. Transition zones are used to provide a smooth transition from regions of high and low mesh density. Sharp changes in mesh density may result in excessive element distortion and should be avoided in critical areas. A careful choice of geometric entities will greatly simplify the mesh generation process.

The process of modifying the mesh to improve the accuracy of the solution is termed mesh refinement. Ideally, the results should converge to an exact solution as the mesh is refined. Mesh generation is often the most time-consuming activity for

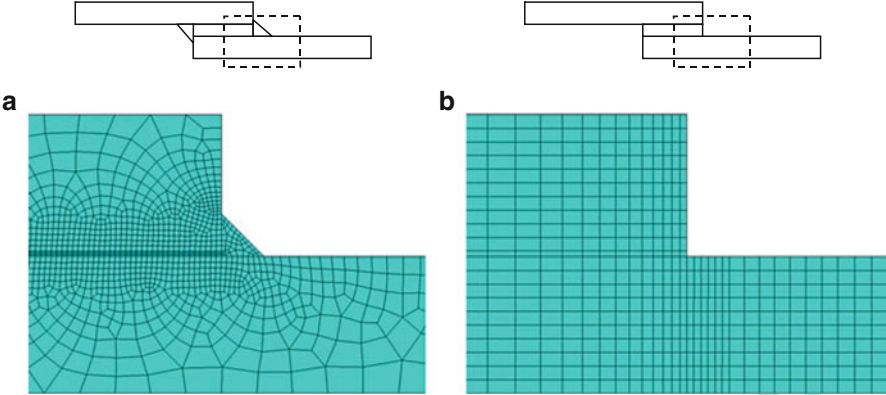

the modeler, and care must be taken to ensure that the mesh contains enough elements to produce results of sufficient accuracy while avoiding an excessive number of elements that will result in large files and long process times. Efficient meshes become increasingly important in three-dimensional (3D) modeling and nonlinear analysis. In the early days, finite element meshes were created by manually editing an input text file, which was labor intensive and required detailed planning. Nowadays, meshes are usually created using semiautomatic methods via graphical interfaces. In semiautomatic methods, the user defines the boundary discretization, and computer algorithms are used to generate the mesh. Fully automatic methods are also available that can be used for self-adaptive mesh refinement. Examples of meshing a 3D bracket using different elements are shown in Fig. 3. Before applying the finite element mesh, the desired position for nodes at the boundaries of the bracket were specified, a process sometimes called seeding. The element type was then specified and an automatic meshing algorithm used to create the final mesh. Hexahedral meshes can generally be generated for regular shapes using automatic mesher, while tetrahedral meshes may have to be used for more complex shapes. Examples of meshes for single lap joints are shown in Fig. 4. The free mesh was generated using a medial axis mesher, and the structured mesh was generated by an advancing front mesher. It can be seen that the former is useful for meshing the complex geometry involved in modeling the adhesive spew fillet; however, the latter results in a more controlled mesh when the geometry is simpler.

In most structural applications, maximum stresses occur at a boundary. It is important, therefore, to ensure that the mesh conforms closely to the boundaries of the model. Finite element models are generally stiffer than the continuous structure. This can be minimized by ensuring that elements remain close to being square. In general, the performance of elements will deteriorate as they become distorted or reach high aspect ratios. Commercial software vendors generally provide indicators regarding the limits of operation of their element formulations and the means of checking for excessive distortion or element aspect ratios in the model.

An element will have both geometric and material properties. Spatially, an element is defined by its nodes; however, additional geometric input is usually

**Fig. 3** An example of the application of different elements to a problem. (a) Hexahedral element mesh, (b) tetrahedral element mesh

**Fig. 4** Examples of finite element meshes for a single lap joint based using different meshing algorithms. **(a)** a free mesh created using a medial axis mesher, **(b)** a structured mesh created using an advancing front mesher

required for line and surface elements. For structural analysis, the minimum material property is the modulus of elasticity. In most cases, Poisson’s ratio or shear modulus must also be specified. If an orthotropic material is used, then the orientation of the material must be specified as well as the elastic constants relative to each principal axis. If post-yield behavior is to be modeled, then an elastoplastic material model must be applied and the yield and hardening behavior defined. Constitutive adhesive and sealant models are discussed in more detail in ► [Chap. 23, “Constitutive Adhesive and Sealant Models.”](#) Additional material properties will also be required for dynamic or thermal analysis.

Various forms of symmetry are often present in a structure that can be used to reduce the size of the FEA model, thereby reducing modeling and processing time. Total reflective symmetry exists when a plane exists in the structure such that half the structure and loading on one side of the plane is the mirror image of the structure and loading on the other side of the plane. As each half of the model will behave in an identical manner, only half of the structure needs to be analyzed. The condition of symmetry is represented in the model by the application of boundary conditions along the plane of symmetry. Some structures may have more than one plane of symmetry in which case the size of the model can be further reduced. In the case of axisymmetrical structures, all planes intersecting a single axis are planes of symmetry, and in this case, a 3D structure can be accurately modeled with a 2D model. Other conditions such as geometric and/or loading antisymmetry can also be used to reduce the model size in some cases. A careful consideration of the mechanics of the problem should be used to apply the correct boundary conditions in these cases.

The simulation of boundary conditions and other forms of restraint requires an understanding of the mechanics of the problem. As with other elements of the modeling procedure, the selection of boundary conditions will involve some simplification of the problem, which must be justifiable. The choice of boundary conditions defines the extent of the model. In some cases, more than one

constraining condition should be analyzed to provide upper and lower boundary values for the analysis. An important consideration when applying constraints is to ensure that rigid body motion is prevented. If not, the system stiffness matrix will be singular, and a fatal error will occur in the processing stage. Constraint equations can be used to further define the boundary conditions. For example, constraint equations can be used to ensure that a certain plane remains plane under deformation, while it can otherwise translate or rotate in space. Similarly, a line can be constrained to remain straight under load.

In most software packages, loads can be applied to nodes, elements, or geometric features. However, in all cases, the loads will be converted into equivalent nodal loads for the analysis. If stresses close to the point of loading are not critical, then the high stress concentrations under a point load can be ignored, as according to Saint-Venant's Principle, this will not affect the stress distribution in other parts of the structure. If the area of loading is important, then attention must be paid to the method of load application to ensure that the nodal loading is representative of the actual loading. One method to reduce stress concentrations close to the loading point is to use additional elements to transfer the loads. However, if the actual point of contact is important, a contact analysis may be required. Another way to apply a load is by the specification of a prescribed displacement.

Once a finite element model is set up in the preprocessing stage, it is sent to a finite element processor, generally referred to as solver, for solution.

## 25.6.2 Processing

In the processing stage, the solver solves the problem and creates output files with the results of the analysis process such as nodal deflections, element stresses, etc. This normally involves the solution of many thousands of equations and can involve the creation of large temporary files. Processing is generally controlled by the software package. With most packages, the progress of the analysis can be monitored. This is particularly useful in nonlinear analysis as the analysis time tends to be longer and the user can observe progress toward convergence of the solution against a selected convergence criterion. Both implicit and explicit finite element schemes are available in commercial finite element solvers. Explicit methods are used for the solution of large deformations and short duration events such as crash, blast, or impact. Explicit methods are conditionally stable, while the implicit methods are unconditionally stable.

With the advent of multicore processors and HPCs, a solution can be solved using multiple processor cores. This decreases the time required to solve a problem by dividing the problem domain into several smaller domains and sending each smaller domain to a single processor core. However, in terms of solution time, all problems do not scale linearly when solved using multiple processor cores. The communication overhead due to data transfer between the solution domains may in fact increase the solution time in some cases. Extra software licenses are generally required for employing multiple cores for solution of a problem.

25.6.3 Post-processing

The output from the processor enables the user to analyze the results from the analysis in text and/or graphical form. This is termed post-processing. The user can view an analysis log giving details of the analysis process and search for status messages created by the software to indicate possible errors in the analysis. With the tendency toward larger models, sifting through large text files can be laborious, and it is now more common to view results in graphical mode. However, some output in text format is often required, and this can usually be controlled via the graphical interface.

Graphic postprocessors are capable of presenting results in many different formats. One of the most useful plots to look at initially is the deformed mesh. Any major errors should be obvious from the deformed shape. If the scale of the deformation is being assessed from this plot, the magnification factor must be set to 1. Contour plots can then be used to show the distribution of stresses, strains, displacements, or other parameters through the structure. The deformation of a single lap joint with aluminum adherends after application of a 6 kN load is shown in Fig. 5. Joint displacement is illustrated on the deformed shape in the form of a displacement contour plot. Results in various directions can usually be viewed as well as a number of calculated parameters such as principal and von Mises equivalent stresses and strain energy density. These should be viewed “unsmoothed” in the first instance in order to identify areas where further mesh refinement is required.

**Fig. 5** Displacement contours and deformation of a single lap joint with aluminum adherends after application of a 6 kN tensile load

The post-processing software may also be used to check the integrity of the model, e.g., by showing information on element distortion or negative pivot errors. Text output files should be searched for warnings and errors. Problems with memory allocation may also be identified here. Another useful check that can be made is to compare applied loads with reactions to ensure that equilibrium is maintained in the principal directions.

## 25.7 Application of FEA to Adhesive Joints

### 25.7.1 General Considerations

A number of analytical methods for the analysis of adhesive joints are available (Volkersen 1938; Goland and Reissner 1944; Demarkles 1955; Adams and Peppiatt 1973), but these methods are limited in their applicability by joint geometry and stress conditions. The analytical methods may provide a good overall measure of joint stress levels but are not able to provide detailed information in the regions of high stresses where failure initiation occurs. Analytical models are described in detail in ► Chap. 24, “Analytical Approach.” Finite element modeling has been successfully used to model adhesive joints of various configurations and enables a detailed analysis of the stress state developing in a joint under complex loading conditions. However, the nature and geometry of adhesive joints presents some unique challenges to finite element modeling. Theoretical stress singularities are present in many adhesive joint configurations, especially in joints with square or sharp edge adherends, as illustrated in Fig. 6.

Stress concentrations tend to exist at the ends of overlaps, and refined meshes are required in regions of high stress gradient. The thickness of the adhesive layer is usually small compared to the overall geometry of the joint; thus, a small element size is required in the adhesive layer as compared to the adherends. If the same element size is used throughout the joint, the problem becomes too cumbersome computationally, and a suitable mesh that transitions in size from the adhesive layer to the adherends is required. An example of mesh transition in a plate is shown in Fig. 7. The size of elements gradually increases from the region of fine mesh to the region of coarse mesh in the transition region. Such transitions enable accuracy to be retained in critical regions while reducing the overall number of elements in the model. However, it should be noted that there is usually element distortion in the transition regions that may affect accuracy.

**Fig. 6** Points of theoretical stress singularity in adhesive joints

**Fig. 7** Transition mesh in a 2D plate

**Fig. 8** Rotation of overlap after application of load in a single lap joint

Adhesive and adherend may exhibit considerable plasticity before failure and thus require nonlinear material models. In single lap joints, rotation of adherends occurs during loading, as illustrated in Fig. 8, and geometrically nonlinear analysis is required to determine the correct stress state.

Adhesive fillets are formed at the ends of overlaps and need to be included in the analysis. Other factors that may need to be considered in the FEA include anisotropic behavior of adhesives and adherends and the synergetic effects of various factors such as temperature, moisture, stress, etc., which may lead to complex, non-intuitive behavior. Informed decisions regarding these factors are needed, while developing a finite element model and necessary modifications needs to be made to finite element models based on the required results, available time, and available computational resources. Adhesive joints are generally analyzed to determine stresses resulting from different types of loadings or to determine the residual strength of joints by carrying out a failure analysis.

### 25.7.2 Stress Analysis

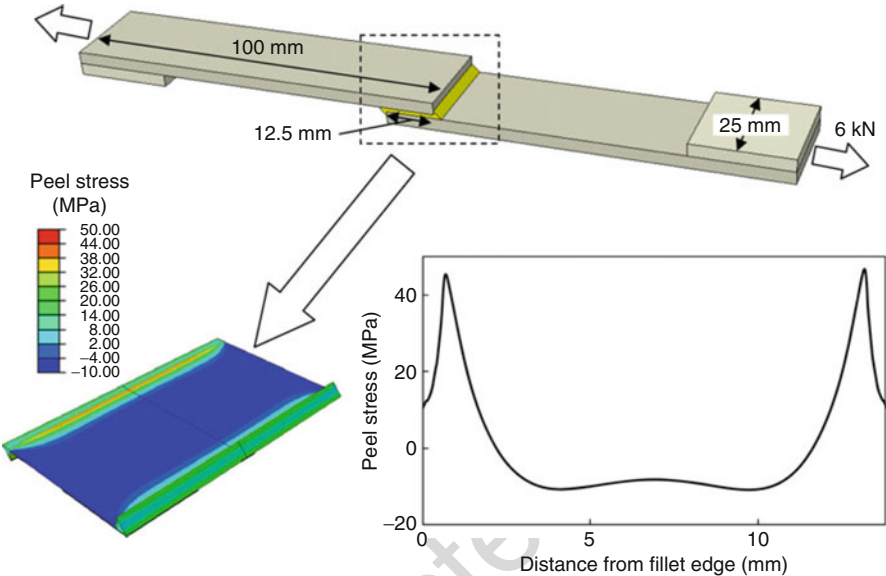

This type of analysis is based on the study of stresses and strains in adhesive joints. By considering the stress state in single lap joints, which are commonly used in industry and have a simple geometry, it can be seen that a complex state of stress is present in adhesive joints. When loaded in tension, the shear stresses in the adhesive layer in single lap joints have a nonuniform distribution owing to the differential straining of the adherends. This shear lag effect, as shown in Fig. 9, causes maximum stresses at the ends of the overlap.

The second factor influencing the stress state in a single lap joint is the rotation of the adherends due to unsymmetric loading. Peel stresses are generated in the adhesive layer, which are maximum at the overlap edges. Thus, when the combined state of stress is considered for a single lap joint, the highest stresses occur at the

**Fig. 9** Shear lag effect in adhesive joint

**Fig. 10** Contour plot of peel stresses in adhesive layer and plot of peel stress variation along the overlap length in the middle of the adhesive layer for an aluminum-epoxy single lap joint

overlap end regions. An example of the FEA-determined stress distribution in the adhesive layer of a single lap joint is shown in Fig. 10. The maximum peel stresses may be seen to occur at the overlap ends. Stress states in other types of joints may be more complex depending on joint geometry and loading.

Bulk tensile testing has shown that adhesives generally exhibit plasticity, and, hence, nonlinear material properties are required to model their behavior over the full load range. Nonlinear properties may also be required for adherends. Thus, a combination of elastoplastic material models may be used to predict the behavior of adhesive joints under load. The definition of the yield surface is important when using elastoplastic material models. The von Mises yield surface is commonly used for the analysis of metals, which assumes that the yield behavior is independent of hydrostatic stress. As a result, the yield surface is identical in tension and compression. However, the yield behavior of polymers has been shown to exhibit hydrostatic stress dependence (Ward and Sweeney 2004) as the yielding starts earlier in tension than in compression. Thus, a yield criterion which includes hydrostatic stress effects should be used to determine the yield surface. Various yield criteria with hydrostatic stress dependence such as Drucker-Prager, Mohr-Coulomb, and modified Drucker-Prager/cap plasticity model have been implemented in commercially available finite element software.

As most adhesives are polymeric materials, they may exhibit a time-dependent response to loading. Hence under certain conditions, a viscoelastic or viscoelastic-plastic material model may be required to determine the time-dependent response of the adhesive to loading. Constitutive models for adhesives are discussed in more detail in ► Chap. 23, “Constitutive Adhesive and Sealant Models.”

An analyst may use a suitable failure criterion with stress analysis to determine if the stresses or strains obtained from the finite element model are within permissible limits. Various failure criteria have been used, in combination with elastoplastic material models, to predict adhesive joint strength. These include maximum stress, maximum strain, plastic yielding, maximum principal stress or strain, and plastic energy density. An example of plastic strains developing in an adhesive joint can be seen in Fig. 11. The zone of plastic deformation initially appears in the middle of the adhesive layer and expands toward the edges of the joint as load increases, as indicated in the figure, before growing toward the overlap center.

Maximum stress- and strain-based failure criteria were used by Harris and Adams (1984) to predict the failure of single lap joints. A nonlinear finite element analysis with an elastoplastic material model for the adhesive and adherends was carried out. The selection of stress- or strain-based failure criterion was based on the results of uniaxial tensile test results. For an un-toughened adhesive, a brittle failure was observed and a maximum stress criterion was used, while for a toughened adhesive, failure was ductile and a maximum strain-based criterion was used. However, these

**Fig. 11** Equivalent plastic strain in adhesive layer of a single lap joint subjected to tensile loading using an elastoplastic material model

criteria are difficult to implement when highly localized stress concentrations or stress singularities exist in an adhesive joint.

In order to avoid the problems of localized stress effects in adhesive joint strength prediction, Crocombe (1989) used a global yielding criterion. Failure of the joint was defined when a path of adhesive along the overlap region started deforming plastically and no further increase in applied load was observed. This criterion was used to study failure in single lap, double lap, and shear test joints, and a good correlation between experimental and numerical results was reported. Failure in the adhesive layer was defined when the overall region of the adhesive layer became plastic and was not able to support any load. However, this type of failure criterion may not be applicable in joints where localized failure may occur. Dorn and Liu (1993) used an accumulative plastic strain-based criterion for single lap joint strength prediction. A critical region was identified, and the maximum accumulative effective plastic strain in the critical region was used as a parameter for strength prediction. Another approach is to use a hybrid method, for example, a global finite element model was used with a localized analytical solution for a circular crack which was proposed by Wahab et al. (2004).

The strength-based failure methods are relatively simple to use; however, they are sensitive to mesh refinement, and an overall mesh convergence study should be carried out to obtain reliable results. In the case of stress singularities, the selection of failure criteria, based on localized values, becomes difficult. Although the concept of selection of a failure parameter at a characteristic length from the singularity may be used; the selection of an appropriate characteristic length becomes important in this case. Alternatives are to average over an area or to define failure when a value is exceeded in all elements in a defined area. Wahab et al. (2001a) compared a wide range of strength of materials-based failure criteria using both the characteristic length and averaging methods.

### 25.7.3 Failure Analysis

Failure in an adhesive joint may occur in the adhesive layer, in the adherends, or at the interface of adhesive and adherend. Failure in the adhesive layer is generally referred to as cohesive failure, while failure in the region of the adherend-adhesive interface (or interphase) is known as interfacial failure. Both types of failures may be incorporated in a finite element model. Failure analysis differs from the stress analysis approach described above in that a suitable failure criterion is provided as part of the material definition in the finite element model. Both failure initiation and crack propagation may be included in a finite element model. In failure initiation models, a state variable is used to indicate if a material has failed; however, no change in material stiffness is considered. In models with crack propagation criteria, the elements satisfying the failure criteria are considered to have no stiffness and may be removed from the analysis. This is in contrast to stress analysis where the elements surpassing a failure criterion remain part of the analysis and continue to contribute to the overall stiffness of the material. Failure criteria may be based on stress or strain, fracture mechanics, or continuum damage models. Stress- and strain-

based failure criteria were discussed in the previous section, and continuum damage models are discussed in the next section.

Fracture mechanics methods assume there is an existing flaw or crack in the material, and that crack growth will occur when a selected fracture criterion is satisfied. Fracture mechanics considers that a crack may be loaded in three different ways: (i) Mode I where the load is applied normal to the crack plane, (ii) Mode II where the load acts to produce in-plan shear, and (iii) Mode III where load generates an out-of-plane shear. The fracture criterion may be energy based, such as the critical strain energy release rate,  $G_c$ , proposed by Griffith (1920), or stress based, such as the critical stress intensity factor,  $K_{Ic}$ , given by Irwin (1957). In recent years, the J-integral approach has been used to determine the strain energy release rate through the use of a path-independent integral around the crack tip. In linear elastic materials, J is equal to  $G$ ; in nonlinear elastic materials, J represents the nonlinear strain energy release rate. The energy-based fracture mechanics failure criteria dictate that failure will occur when the strain energy release rate equals a critical value, the fracture energy, which is ideally independent of the size and geometry of the structure. In the stress-based approach, the stress intensity factor can be computed at the crack tip and compared to the critical value of stress intensity factor, the fracture toughness. Most of the commercially available finite element software are able to determine strain energy release rate and stress intensity factors. For nonlinear materials, the J-integral may be used.

Wahab et al. (2001a) compared  $G$  and  $J$  as failure criteria for predicting fatigue threshold in bonded composite joints with various strength-based criteria. A principal stress-based criterion provided good threshold predictions for small plastic deformations. From the elastic and elastoplastic fracture parameters, the J-integral was shown to correlate well with the threshold load of different joints. In this work, the virtual crack closure technique (VCCT) was used to determine  $G$ . This is based on Irwin's crack closure integral method, which assumes that the energy absorbed upon crack growth is equal to the work required to close the crack. In an attempt to overcome the limitations of linear elastic fracture mechanics, Stein et al. (2015) presented a material model for brittle failure in adhesive lap joints, which is based on the concepts of finite fracture mechanics. The proposed material model is based on tensile strength and fracture toughness of adhesive in Mode I. A number of adhesive lap joint configurations were used for the validation of the proposed material model. The stress predictions of the proposed material model, when compared to a cohesive zone element-based finite element adhesive joint model, were promising. The cohesive zone elements are discussed in the next section.

One of the limitations of the fracture mechanics methods is that they require the existence of a pre-crack to determine the strain energy release rate (or other fracture mechanics parameter). Fracture mechanics approaches may require several finite element analyses to determine fracture energies at different crack lengths. Design of the mesh for fracture mechanics problems also requires special consideration. A "spider web" mesh configuration is generally favored in fracture mechanics problems. This consists of concentric circles, which are focused at the crack tip. At the crack tip, special elements may be used that are capable of representing the

theoretical singularity. These are generally known as crack tip or singularity elements. An example finite element mesh for fracture mechanics-based failure models is shown in Fig. 12.

**25.7.4 Advanced Analysis Methods**

Advanced analysis techniques include methods that cannot only predict failure but can also predict damage evolution in a material. A specimen is said to be damaged when a large number of microcracks are randomly scattered over a large part of the volume such that the volume partially loses the ability to transfer load and the fracture strength is reduced. A typical stress-strain diagram with damage is shown in Fig. 13. A material model with elastic and plastic material definitions would follow the “abcd” curve, while a damage- and failure-based model would follow the “abcd” curve where material stiffness starts to degrade after point “c” and complete failure occurs at point “d.”

A method of predicting failure based on the concepts of stress and fracture mechanics is the cohesive zone method. The cohesive zone model has been used increasingly in recent years to simulate crack initiation, propagation, and failure. The cohesive zone model allows multiple cracks to be modeled, and the direction of crack propagation need not be known in advance; however, cohesive zone elements need to be present at all possible crack paths. Cohesive zone models follow a traction-separation constitutive law to predict failure initiation, damage, and failure. Several shapes for the traction-separation law have been presented in the literature, with the bilinear, exponential, and trapezoidal shapes, as shown in Fig. 14, being the most commonly used for strength prediction.

**Fig. 12** Finite element mesh for a fracture mechanics-based failure model

**Fig. 13** Typical uniaxial stress-strain response of a ductile material

**Fig. 14** Different types of cohesive zone damage model

The shape of the traction-separation law is difficult to determine from experimental methods and is often assumed or simplified. The effect of the shape of traction-separation law is dependent on the nature of the problem including specimen geometry and material behavior. The shape of the traction-separation law also influences the numerical performance of the solution, and more convergence difficulties have been observed when using trapezoidal than bilinear traction-separation laws in a finite element analysis. Thus, the selection of cohesive zone law should be based on all the mentioned factors. Generally, a trapezoidal traction-separation curve is considered more suitable for ductile materials, while a bilinear cohesive zone law is commonly used for brittle and composite materials. In a bilinear traction-separation law, the initial response of the cohesive zone is elastic until reaching a critical traction. Once the critical traction is reached, stiffness degradation starts and continues until it reaches zero and failure occurs. The area under the traction-separation curve is equal to the fracture toughness of the material and is known as the cohesive energy,  $G_{coh}$ .

Several methods have been suggested for calibration of the traction-separation laws; however, a generally accepted method is still required. The method used by

Liljedahl et al. (2007) was to obtain the cohesive zone model parameters using a combination of experimental and numerical methods. A mixed mode flexure (MMF) specimen was tested to failure under three-point bending conditions. The experimental results, along with a fracture mechanics-based finite element model, were used to determine the fracture energy of the adhesive. The experimentally determined fracture energy was then used in a cohesive zone model and the optimum value of tripping traction determined by fitting to the MMF data. The cohesive zone model parameters obtained in this manner were then used to predict the damage and failure in single lap joints. The methodology provides a set of cohesive zone model parameters that are independent of joint geometry. Desai et al. (2016) used a J-integral-based approach where J-integral was determined from the experimental load-displacement curve of a DCB adhesive specimen and the parameters of the cohesive law were determined. The experiments were conducted at two loading rates and for different thicknesses of the adhesive layer. It was shown that the cohesive zone law parameters determined by this method were not unique for a particular type of adhesive and were sensitive to the loading rate and thickness of the adhesive layer. A few researchers have successfully used inverse methods to determine a unique set of cohesive law parameters (Azevedo et al. 2015; Desai et al. 2016). In this approach, the experimentally determined load-displacement curve and the load-displacement curve obtained from a cohesive zone-based finite element model are compared and the difference between the two curves is minimized by changing the values of the cohesive law parameters. Although this method can provide a unique set of parameters for the cohesive law, it is computationally expensive, as many simulation runs are needed to find the best fit of the experimental load-displacement curve.

One of the main limitations of the cohesive zone model is that cohesive elements should be present on the crack path. Although several layers of cohesive elements may be introduced in a structure, it is not feasible to introduce cohesive elements between every field element, even in a moderate size mesh. The method is suitable for interfacial failure or crack representation when the bulk material failure, based on micro-mechanics, does not affect fracture. An example of the use of cohesive zone elements in a single lap joint is shown in Fig. 15. A layer of cohesive elements is embedded at the experimentally observed crack path. After the application of a tensile load, the cohesive zone elements started to show damage, which is represented by a damage variable. The damage variable can have values between zero and one where zero indicates no damage and one represents fully damaged material.

Continuum damage models are able to predict damage and failure in a ductile material. A damage variable is used in continuum damage models to determine the degradation in material stiffness. The damage variables used are of two types; the first type can predict the value of damage but does not characterize the damage itself, such as damage equivalent stress. The second type of damage variable is linked to some physical definition of damage such as porosity or relative area of micro-cavities (Voyiadajis and Kattan 2005). This type of variable is based on macroscopic material properties, and its evolution is governed by a state equation. If several

**Fig. 15** Adhesive layer of a single lap joint, modeled using cohesive zone elements, after application of tensile load. A damage variable with values between zero and one represents the amount of damage: zero meaning no damage and one meaning fully damaged

damage mechanisms occur in a material, each of them may be represented by an independent damage variable.

A general framework for damage models was provided by Lemaitre and Desmorat (2005). It consists of the definition of variables that define the state of corresponding material mechanisms, known as state variables. The damage model framework also includes the definition of state laws and definition of the laws of evolution of the state variables. The Gurson model is one of the models based upon a continuum damage framework that has been used to determine the strength of polymers. A comparison of continuum damage and fracture mechanics models for fatigue threshold prediction, when applied to composite double lap and lap strap joints, showed slightly better results with the continuum damage model (Abdel Wahab et al. 2001c).

Adhesively bonded joints are subjected to several environmental factors including temperature, moisture, and ultraviolet light, which affect their long-term performance. A finite element-based multi-physics analysis provides a convenient method for analyzing the effects of not only individual factors but also their combined effects on joints. Moisture is known to degrade the performance of adhesive joints over time, and the diffusion of moisture in adhesive joints has been determined using the finite element method (Abdel Wahab et al. 2001b). Coupled diffusion-stress FEA combined with the cohesive zone method has been used to predict the failure of bonded joints subjected to environmental aging (Loh et al. 2003; Liljedahl et al. 2007). The distribution of normalized moisture concentration in the adhesive layer of a single lap joint after moisture conditioning in water at 50 °C for 6 months is shown in Fig. 16. The joint has non-absorbing adherends, and moisture is only diffusing through the exposed adhesive surfaces. It can be seen that the center of the adhesive layer has very low moisture concentration. Recent advances in multi-

**Fig. 16** Normalized moisture concentration in the adhesive layer of a single lap joint when conditioned in water at 50 °C for 6 months

physics hygro-mechanical analysis are focused on developing methodologies that can predict the moisture distribution in an adhesive joint under varying humidity conditions (Mubashar et al. 2009) and thus enable the development of joint durability tools that can be used at the design stage to predict performance under realistic in-service conditions. This subject is further developed in ► [Chap. 31, “Effect of Water and Mechanical Stress on Durability.”](#)

Another important characteristic of adhesives is their time-dependent response to loads. Adhesives may exhibit viscoelastic or visco-plastic material behavior, such as creep and relaxation, resulting in time-dependent stresses and strains. In adhesives with a high glass transition temperature relative to the operating temperature, it may be acceptable to model the adhesive with a time-independent material model. However, as temperature, absorbed moisture, stress level, and time under load increase, there is an increased likelihood of errors in using such a model. Selection of a time-dependent material model will depend on a number of factors including the polymer type and the stress state. Adhesives generally show linear viscoelastic behavior at low stress conditions and a nonlinear viscoelastic or visco-plastic response at higher stresses. A number of commercially available FEA products have some form of standard linear solid viscoelasticity model implemented in the form of Prony series. Nonlinear viscoelastic material models are becoming available in commercial finite element software and can now be used without writing a user material subroutine. Adhesive models that include viscoelastic effects are discussed in ► [Chap. 24, “Analytical Approach.”](#) Constitutive adhesive and sealant models and creep are detailed in ► [Chap. 36, “Storage of Adhesives.”](#)

Finite element analysis may also be used to determine the response of adhesive joints under impact loading. Adhesives generally exhibit strain rate dependent

material properties under impact conditions. The solution of impact problems is difficult to obtain from closed form solutions, and the FEM is an excellent tool to solve such problems. Explicit finite element solvers can easily solve large deformation problems and dynamic events where inertia of the structure is of significant importance. ► Chap. 29, “Design for Impact Loads.” treats this subject.

---

## 25.8 Summary and Conclusions

The finite element method provides a powerful tool for solving problems that are difficult to solve using closed form solutions. Recent developments in the computer industry and the commercially available finite element codes have made it possible to apply the method to a vast number of application areas. Multi-physics problems can be solved to determine the effects of different physics. Another important development is the application of finite element analysis to damage and failure modeling. The method is general in nature and may be applied to complex geometries and loading conditions. The method is based on discretizing a domain then solving a set of equations to determine the response of the continuum. The method can be used to solve nonlinear problems which may involve material, geometric, or contact nonlinearity. In case of nonlinear problems, iterative methods are commonly used to solve the system equations. The finite element method has been developed for application in field problems such as thermal analysis where heat conduction, convection, and radiation problems may be solved. Another application of finite element method is in dynamic analysis. Dynamic problems such as free vibrations or full dynamic response of a system may be solved using commercially available finite element software.

Due to the complex behavior of adhesive joints and the effects of environmental factors on their performance, finite element analysis has been proven to be one of the best tools for adhesive joint design and analysis. The geometry and loading of adhesive joints may require special considerations in terms of model development and meshing. Nonlinear stress analysis methods have been successfully used to analyze the behavior of various types of adhesive joints under loading, and a number of stress- or strain-based criteria have been proposed to determine the residual strength of an adhesive joint. Failure analysis methods based on fracture mechanics concepts have also been applied to adhesive joints with varying degrees of success, and, more recently, the cohesive zone method has been successfully applied to predict damage and failure in adhesive joints of different types. Continuum damage models, which are capable of predicting damage as well as failure, have also seen some degree of success when applied to adhesive joints. The effects of environmental degradation, mainly those of moisture and temperature, may be included in multi-physics FEA to determine the durability of adhesive joints. The time-dependent viscoelastic behavior of adhesives may also be included in durability studies to determine the time-dependent response of adhesives to applied loads. Finally, the response of adhesive joints under impact loading may be studied using explicit finite element codes.

The rapid development in computing power and FEA codes, together with increased automation of the technique, will see the finite element method become more mainstream, becoming an important part of the design and analysis procedure. Highly complex problems can now be solved easily using high performance computing clusters, and as these high performance clusters become available for desktop systems, the complexity of problems being solved will continue to increase. At present, the specific complexities of analyzing adhesively bonded joints using FEA means that it is still mainly the domain of specialists. However, in the future, it is envisaged that routines enabling the nonspecialist to use the finite element method to accurately solve defined adhesive joint problems will become more widely available.

## Abstract

The aim of this chapter is to introduce special numerical techniques. The first part covers special finite element techniques which reduce the size of the computational models. In the case of the substructuring technique, internal nodes as parts of a finite element mesh can be condensed out so that they do not contribute to the size of the global stiffness matrix. A postcomputational step allows to determine the unknowns of the condensed nodes. In the case of the submodel technique, the

e-mail: [andreas.oechsner@gmail.com](mailto:andreas.oechsner@gmail.com)

results of a finite element computation based on a coarse mesh are used as input, i.e., boundary conditions, for a refined submodel. The second part of this chapter introduces alternative approximation methods to solve the partial differential equations which describe the problem. The boundary element method is characterized by the fact that the problem is shifted to the boundary of the domain and as a result, the dimensionality of the problem is reduced by one. In the case of the finite difference method, the differential equation and the boundary conditions are represented by finite difference equations. Both methods are introduced based on a simple one-dimensional problem in order to demonstrate the major idea of each method. Furthermore, advantages and disadvantages of each alternative approximation methods are given in the light of the classical finite element simulation. Whenever possible, examples of application of the techniques in the context of adhesive joints are given.

---

## 26.1 Introduction

The most spread engineering tool to simulate structural problems is the finite element method (FEM). This approximation method has attracted the attention of analysts largely due to its property of discretizing a continuous system into a series of finite elements, which can be associated with physical parts. The single elements are then assembled to obtain the complete system solution using given initial and boundary conditions. The assembly process uses appropriate balance equations at the nodes which are used to define the elements and serve also as connection points between the elements.

The existing literature on finite elements is by now very extensive and encompasses all types of common field problems such as structural mechanics, heat and mass transfer, fluid flow and acoustics, see the reviews (Mackerle 1995a, b), or the classical textbooks (Reddy 2006; Öchsner and Merkel 2013; Öchsner 2016).

As in the case of existing literature, there is a huge number of finite element codes ranging from simple academic programs such as FEAP (Robert L. Taylor) to commercially available general purpose programs. Some of the common commercial codes used in industry as well as in academia are NASTRAN (Richard H. MacNeal, Robert Schwendler), ANSYS (John Swanson), MARC (Pedro Marcal), ABAQUS (David Hibbitt), and ADINA (Klaus-Jürgen Bathe).

Nowadays, commercial finite element programs are quite powerful and user friendly codes which are available for all platforms of operating systems. Some commercial packages, such as ABAQUS or MARC (Javanbakht and Öchsner 2017), even allow to extend the functionality via user subroutines.

However, reliable results can only be obtained when the user of such commercial packages understands the problem, how to model it, the behavior of finite elements, the assumptions and limitations of the code, and when the analyst is able to check for errors at all stages. It is not necessary that the end-user understands in detail all procedures and routines, but incorrect results, which may cause serious damage such as production delay, redesign, or even collapse, can be avoided only by those who

understand the basic ideas and single steps of the FEM (cf. ► [Chap. 25, “Numerical Approach: Finite Element Analysis”](#)).

A practical limit of the finite element method can be reached if the system of equations contains so many unknowns that the used computer hardware (working memory) is no more able to handle the size of the matrix system. To overcome this problem, special finite element techniques, i.e., substructuring and sub-modelling, can be applied (Cook et al. 2002). These techniques are introduced in the first part of this chapter. Newer approaches to overcome the problem of limited computer hardware can be summarized under the expression of parallel computing where a computational task is partitioned and parallel processed on several computers.

On the other hand, the finite element method is only one of the classical approximations methods in engineering. The boundary element method (BEM) (Banerjee 1994) and the finite difference method (FDM) (Mitchell and Griffiths 1980) are alternative numerical approaches to solve problems described by partial differential equations. Despite the fact that the finite element method is the major engineering tool, each of the classical methods has its own advantages and disadvantages and may be depending on the specific problem more or less appropriate than the finite element method. A brief introduction of these classical approximation methods in the context of adhesion technology can be found in (da Silva and Campilho 2012).

A common feature from the theoretical foundation is that all these classical approximation methods can be derived based on the weighted residual method (Brebbia et al. 1984). The second part of this chapter introduces both alternative methods based on a one-dimensional problem in order to describe the main idea of the approach. Each subsection closes with some general comments on advantages and disadvantages of the alternative method and examples of applications in the context of adhesive joints. All the presented techniques and methods in this chapter are not very common in standard engineering practice. Thus, the major idea is to introduce the main concept of each technique based on simple examples and to bring the reader in a position where he can decide if it makes sense for him to look deeper in one of the mentioned techniques.

---

## 26.2 Substructures

### 26.2.1 Introductory Example

The idea of substructuring a large finite element model will be introduced in the following based on one-dimensional bar elements. This focus on one-dimensional elements reveals the advantage that the entire notation remains rather simple compared to the general three-dimensional approach whereas the steps are the same as in the general case. A tapered bar element (it should be noted here that in the case of a bar with constant axial stiffness  $EA$ , the finite element solution at the nodes is equal to the analytical solution) of length  $L$  with linearly changing cross sections from  $A_1$

to  $A_2$  between the two boundary nodes is considered in the following. In addition, the displacement field between the nodes should be linearly interpolated, i.e., the element is based on linear interpolation functions. For such an element, the elemental stiffness matrix is given by:

$$\mathbf{K}^e = \frac{E}{L} \times \frac{A_1 + A_2}{2} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}. \quad (1)$$

This finite element is used to compose a simple substructure as shown in Fig. 1 where two elements are used to model a part of a tapered bar.

The stiffness matrix given in Eq. (1) can be applied to these two elements to formulate the principal finite element equation for both elements as:

$$\frac{E_I}{L_I} \times \frac{A_1 + A_2}{2} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} \begin{bmatrix} F_1 \\ F_2 \end{bmatrix} \quad (\text{element I}), \quad (2)$$

$$\frac{E_{II}}{L_{II}} \times \frac{A_2 + A_3}{2} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \begin{bmatrix} u_2 \\ u_3 \end{bmatrix} \begin{bmatrix} F_2 \\ F_3 \end{bmatrix} \quad (\text{element II}). \quad (3)$$

Assembling of these individual finite element equations gives the global finite element formulation in the general form  $\mathbf{Ku} = \mathbf{F}$  as:

$$\frac{E}{2L} \begin{bmatrix} (A_1 + A_2) & -(A_1 + A_2) & 0 \\ -(A_1 + A_2) & (A_1 + 2A_2 + A_3) & -(A_2 + A_3) \\ 0 & -(A_2 + A_3) & (A_2 + A_3) \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = \begin{bmatrix} F_1 \\ F_2 \\ F_3 \end{bmatrix}. \quad (4)$$

The last equation (4) constitutes a system of three linear independent equations for the three unknown nodal displacements  $u_1, \dots, u_3$ . The second equation of (4) can be rearranged to express the internal unknown  $u_2$  as a function of the boundary values  $u_1$  and  $u_3$  as:

$$u_2 = \frac{2L}{E} \frac{F_2}{A_1 + 2A_2 + A_3} + \frac{(A_1 + A_2)u_1}{A_1 + 2A_2 + A_3} + \frac{(A_2 + A_3)u_3}{A_1 + 2A_2 + A_3}. \quad (5)$$

**Fig. 1** Simple substructure consisting of two linear bar elements with linearly changing cross sections. Finite element nodes are numbered by Arabic numbers (1, 2, 3) and are symbolized by black circles (•). The finite elements themselves are numbered by Roman numbers (I, II)

This relationship in the form  $u_2 = u_2(u_1, u_3)$  can be substituted back into the first and third equation of (4). After rearranging and collecting common expressions, the following  $2 \times 2$  system of equations remains for the nodal boundary values of the element shown in Fig. 2:

$$\frac{E}{2L} \frac{(A_1 + A_2)(A_2 + A_3)}{A_1 + 2A_2 + A_3} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} F_1 + \frac{A_1 + A_2}{A_1 + 2A_2 + A_3} F_2 \\ F_3 + \frac{A_2 + A_3}{A_1 + 2A_2 + A_3} F_2 \end{bmatrix}. \quad (6)$$

The described process of partially solving a system of equations of a given substructure in such a way that only interconnecting or boundary nodes remain in the system is known in literature as *static condensation*. In the general approach, only such nodes are often condensed out where no boundary conditions are prescribed. As a consequence, the external force  $F_2$  in Eq. (6) can be set to zero in the following derivations. From a practical point of view, static condensation changes the order of which nodal unknowns are calculated. For the given example shown in Figs. 1 and 2, the nodal displacements  $u_1$  and  $u_3$  would be first calculated and then by substituting these results into Eq. (5), the internal nodal value  $u_2$  would be obtained. It should be noted here that static condensation does *not* introduce any further approximation into the finite element analysis. The attribute “static” is used to distinguish from a similar process in structural dynamics where the stiffness and mass matrix are reduced. However, the condensation introduced in the case of dynamics further approximates in the mass matrix. The effect of creating substructures and assembling them to solve a global system of equations will be illustrated in the following simple example shown in Fig. 3.

The shown tapered bar is discretized by four linear elements of linearly changing cross sections. The bar is fixed at the left-hand side and the right-hand end is subjected to a force boundary condition  $F$ . The two left- and right-hand elements, i.e., elements (I + II) and elements (III + IV), should be grouped to substructures and used to solve the problem. The classical solution procedure without substructures would consist of assembling the global stiffness matrix of all four elements which would result in the following  $5 \times 5$  stiffness matrix:

**Fig. 2** Superelement obtained from the substructure shown in Fig. 1

**Fig. 3** Tapered bar, discretized by four linear elements with linearly changing cross sections. Each element has the same length  $L$  and the same Young's modulus  $E$ . Finite element nodes are symbolized by black circles (•)

$$\frac{E}{2L} \begin{bmatrix} (A_1 + A_2) & -(A_1 + A_2) & 0 & 0 & 0 \\ -(A_1 + A_2) & (A_1 + 2A_2 + A_3) & -(A_2 + A_3) & 0 & 0 \\ 0 & -(A_2 + A_3) & (A_2 + 2A_3 + A_4) & -(A_3 + A_4) & 0 \\ 0 & 0 & -(A_3 + A_4) & (A_3 + 2A_4 + A_5) & -(A_4 + A_5) \\ 0 & 0 & 0 & -(A_4 + A_5) & (A_4 + A_5) \end{bmatrix} \quad (7)$$

Thus, the classical approach results in a  $5 \times 5$  global system of equations or after considering the boundary condition at the left-hand end, i.e., deleting the first row and column of the global system of equations, in a reduced  $4 \times 4$  system which must be solved. Using the approach based on substructures as indicated in Fig. 3, the following two superelements based on Eq. (6)

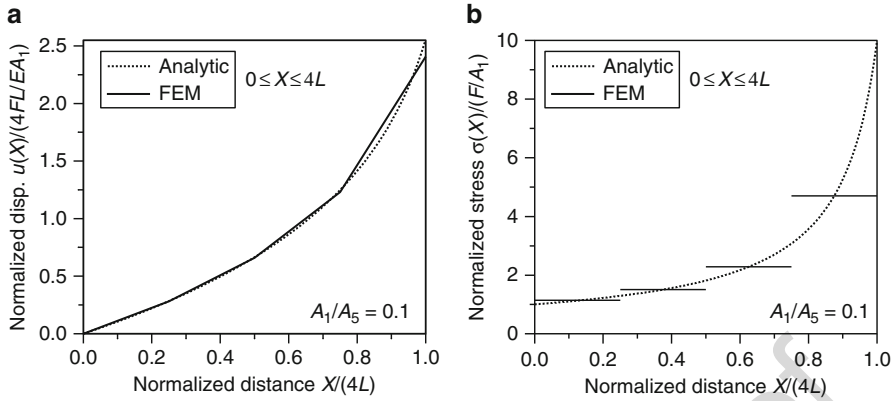

$$\underbrace{\frac{E}{2L} \frac{(A_1 + A_2)(A_2 + A_3)}{A_1 + 2A_2 + A_3}}_{\alpha_1} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} \dots \\ 0 \end{bmatrix}, \quad (8)$$

$$\underbrace{\frac{E}{2L} \frac{(A_3 + A_4)(A_4 + A_5)}{A_3 + 2A_4 + A_5}}_{\alpha_2} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \begin{bmatrix} u_3 \\ u_5 \end{bmatrix} = \begin{bmatrix} 0 \\ F \end{bmatrix}, \quad (9)$$

need to be assembled to the following global system of equations:

$$\frac{E}{2L} \begin{bmatrix} \alpha_1 & -\alpha_1 & 0 \\ -\alpha_1 & \alpha_1 + \alpha_2 & -\alpha_2 \\ 0 & -\alpha_2 & \alpha_2 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = \begin{bmatrix} \dots \\ 0 \\ F \end{bmatrix}. \quad (10)$$

After introducing the boundary condition at the left-hand end, i.e.,  $u_1 = 0$ , only a  $2 \times 2$  system remains to be solved. Compared to the global system of equations in the classical approach, introduction of substructures reduces the demand on the computer storage space by 50% in the elaborated example. The final results for nodal displacements and stresses are shown in Fig. 4. Due to the linear interpolation

**Fig. 4** Comparison between finite element and analytical solution for the problem shown in Fig. 3: (a) normalized displacements; (b) normalized stresses

functions, the finite element solution gives a piecewise linear approximation of the deformation. Nevertheless, four elements give a quite good overall representation of the deformed shape for the given input data. Due to the linear shape functions of the applied elements, the strains and stresses are constant in each element and the finite element solution approximates the analytical solution only in an average sense. If higher accuracy for the stresses or strains is required, more elements or elements with higher order interpolation functions must be introduced.

## 26.2.2 General Case of Static Condensation

A more formal procedure for the static condensation introduced in the previous sections can be described as follows (Cook et al. 2002). Let equation  $\mathbf{K}^s \mathbf{u}^s = \mathbf{F}^s$  be the global system of equations for a given substructure. Then, this equation can be rearranged in the following manner:

$$\begin{bmatrix} \mathbf{K}_{bb} & \mathbf{K}_{bc} \\ \mathbf{K}_{cb} & \mathbf{K}_{cc} \end{bmatrix}^s \begin{bmatrix} \mathbf{u}_b \\ \mathbf{u}_c \end{bmatrix}^s = \begin{bmatrix} \mathbf{F}_b \\ \mathbf{F}_c \end{bmatrix}^s, \quad (11)$$

where  $\mathbf{u}_b$  are the unknowns to be retained and  $\mathbf{u}_c$  are the internal values which should be condensed. The unknowns to be retained are sometimes called super or master nodes while the internal nodes are sometimes denoted as slaves. The external loads  $\mathbf{F}$  are in the same way separated. Equation (11) can be solved by blockwise inversion of the stiffness matrix, i.e., inversion of a  $2 \times 2$  block matrix

$$\begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix}^{-1} = \begin{bmatrix} (\mathbf{A} - \mathbf{B}\mathbf{D}^{-1}\mathbf{C})^{-1} & -(\mathbf{A} - \mathbf{B}\mathbf{D}^{-1}\mathbf{C})^{-1}\mathbf{B}\mathbf{D}^{-1} \\ -\mathbf{D}^{-1}\mathbf{C}(\mathbf{A} - \mathbf{B}\mathbf{D}^{-1}\mathbf{C})^{-1} & \mathbf{D}^{-1} + \mathbf{D}^{-1}\mathbf{C}(\mathbf{A} - \mathbf{B}\mathbf{D}^{-1}\mathbf{C})^{-1}\mathbf{B}\mathbf{D}^{-1} \end{bmatrix} \quad (12)$$

182 to obtain

$$F_b = \frac{u_b}{(K_{bb} - K_{bc}K_{cc}^{-1}K_{cb})^{-1}} + K_{bc}K_{cc}^{-1}F_c \quad (13)$$

183 and by introducing this expression in the second matrix equation of the solution of (11):

$$u_c = K_{cc}^{-1}(F_c - K_{cb}u_b). \quad (14)$$

184 This expression can be used for the calculation of  $u_c$ , when  $u_b$  is known.  
 185 Considering (14) in the first equation of (11) and rearranging, the following expres-  
 186 sion can be obtained

$$\underbrace{(K_{bb} - K_{bc}K_{cc}^{-1}K_{cb})}_{\text{condensed stiffness matrix}} u_b = \underbrace{F_b - K_{bc}K_{cc}^{-1}F_c}_{\text{condensed load vector}}, \quad (15)$$

187 or in compact form:

$$K_{\text{cond}}^s u_b = K_{\text{cond}}^s. \quad (16)$$

188

### 189 26.2.3 Static Condensation Applied to Substructures

190 In the following, a finite element mesh as shown in Fig. 5 which is subdivided in two  
 191 substructures A and B is considered, adapted from (Raghu 2009). The nodes at the  
 192 interface where substructure A is connected to B are collected in a group “i”. The  
 193 remaining nodes of substructures A are named “a” and the respective nodes remaining  
 194 for substructure B are called “b”. All external forces acting on nodes “a” are collected in  
 195 a vector  $F_a$ , the same for external forces acting on the group of nodes “i” or “b”.

196 The principal finite element equations  $K^s u^s = F^s$  for each substructure ( $s = A$   
 197  $\vee B$ ) can be arranged in the following way according to the distinction a-i and i-b:

$$\begin{bmatrix} K_{aa} & K_{ai} \\ K_{ia} & K_{ii}^A \end{bmatrix} \begin{bmatrix} u_a \\ u_i \end{bmatrix} = \begin{bmatrix} F_a \\ F_i \end{bmatrix}, \quad (17)$$

$$\begin{bmatrix} K_{ii}^B & K_{ib} \\ K_{bi} & K_{bb} \end{bmatrix} \begin{bmatrix} u_i \\ u_b \end{bmatrix} = \begin{bmatrix} F_i \\ F_b \end{bmatrix}. \quad (18)$$

198 These two equations can be assembled to the global finite element equation  
 199  $Ku = F$  to obtain

$$\left[ \begin{array}{cc|c} K_{aa} & K_{ai} & 0 \\ K_{ia} & K_{ii} & K_{ib} \\ \hline 0 & K_{bi} & K_{bb} \end{array} \right] \begin{bmatrix} u_a \\ u_i \\ u_b \end{bmatrix} = \begin{bmatrix} F_a \\ F_i \\ F_b \end{bmatrix}, \quad (19)$$

**Fig. 5** Finite element model subdivided into two substructures A and B. Nodes at the interface of both structures are collected in group “i,” the remaining nodes of substructure A are denoted by “a”, while the remaining nodes of substructure B are denoted by “b”. Finite element nodes are symbolized by *black circles* (•)

where  $\mathbf{K}_{ii} = \mathbf{K}_{ii}^A + \mathbf{K}_{ii}^B$ . Equation (19) can be now treated as Eq. (11) to calculate the condensed stiffness matrix and the condensed load vector as given in Eq. (15):

$$\mathbf{K}_{\text{cond}} = \begin{bmatrix} \mathbf{K}_{aa} & \mathbf{K}_{ai} \\ \mathbf{K}_{ia} & \mathbf{K}_{ii} \end{bmatrix} - \begin{bmatrix} \mathbf{0} \\ \mathbf{K}_{ib} \end{bmatrix} \mathbf{K}_{bb}^{-1} \begin{bmatrix} \mathbf{0} & \mathbf{K}_{bi} \end{bmatrix} \quad (20)$$

$$= \mathbf{K}^A + \mathbf{K}_{\text{cond}}^B. \quad (21)$$

$$\begin{aligned} \mathbf{F}_{\text{cond}} &= \begin{bmatrix} \mathbf{F}_a \\ \mathbf{F}_i \end{bmatrix} - \begin{bmatrix} \mathbf{0} \\ \mathbf{K}_{ib} \end{bmatrix} \mathbf{K}_{bb}^{-1} \mathbf{F}_b, \\ &= \begin{bmatrix} \mathbf{F}_a \\ \mathbf{0} \end{bmatrix} + \begin{bmatrix} \mathbf{0} \\ \mathbf{F}_i - \mathbf{K}_{ib} \mathbf{K}_{bb}^{-1} \mathbf{F}_b \end{bmatrix}, \end{aligned} \quad (22)$$

$$= \begin{bmatrix} \mathbf{F}_a \\ \mathbf{0} \end{bmatrix} + \mathbf{F}_{\text{cond}}^B. \quad (23)$$

Thus, the condensed global system of equations  $\mathbf{K}_{\text{cond}} \mathbf{u}_{\text{cond}} = \mathbf{F}_{\text{cond}}$  can be written in the following manner:

$$(\mathbf{K}^A + \mathbf{K}_{\text{cond}}^B) \begin{bmatrix} \mathbf{u}_a \\ \mathbf{u}_i \end{bmatrix} = \begin{bmatrix} \mathbf{F}_a \\ \mathbf{0} \end{bmatrix} + \mathbf{F}_{\text{cond}}^B. \quad (24)$$

A graphical representation of the condensed finite element model is shown in Fig. 6 where the nodes of group “b” are completely vanished. In addition, the equations for the condensed stiffness matrix and load vector of substructure B are

**Fig. 6** Finite element model after static condensation. Finite element nodes are symbolized by black circles (•)

**Fig. 7** Single-step lap joint with adherends considered as substructures. Only the mesh of the adhesive layer is required at the first step of the computation. Finite element nodes are symbolized by black circles (•)

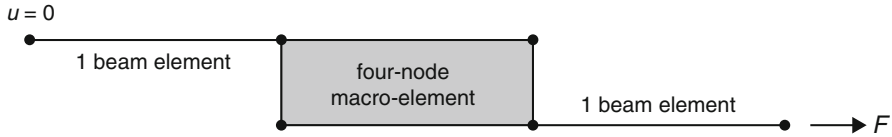

given which are required to calculate the condensed global system according to Eq. (24). Looking at these two equations, the important conclusion can be drawn that the condensed model of substructure B is independent of the stiffness of substructure A. Thus, any changes in substructure A will be considered correctly and the same result as calculated from the entire structure will be obtained.

The described procedure for connecting different substructures implies that the finite element mesh at the interface of the substructures is identical. However, there are more advanced techniques which allow the connection of substructures even when neither mesh pattern nor element types match along the interface (Knight et al. 1991; Zhao et al. 1999; Dohrmann et al. 2000; Gmür and Kauten 1993).

A typical example for the substructuring technique from the context of adhesive technology is shown in Fig. 7 (Groth 1986) where a single-stepped lap joint is modeled.

Both adherends were treated as substructures with the lower and upper adhesive interface nodes considered as the supernodes. Substructure A was condensed to the lower row of nodes while substructure B was condensed to the upper row of nodes. The only assumption in Groth (1986) was that the adherends behave linearly, i.e., that no material or geometrical nonlinearities are considered.

A more sophisticated approach to model a single-lap joint was introduced by Paroissien et al. (2013) who modeled the entire adhesive layer as a single four-node

**Fig. 8** Modeling approach of a single-lap joint where the adhesive layer is represented by a single macro-element while the adherends are single beam elements. Finite element nodes are symbolized by black circles (•) (Adapted from Paroissien et al. 2013)

macroelement with elasto-plastic material behavior, see Fig. 8. The advantage of this simplified approach was seen in the extremely small finite element model, i.e., only based on six nodes, which allows the conduction of extensive parametric studies.

## 26.3 Submodels

### 26.3.1 Introductory Example

The same simple example as in Sect. 2.1 should be considered in the following. It is now assumed that the area of interest is near the left-hand boundary, i.e.,  $X \rightarrow 0$ , and that the coarse mesh shown in Fig. 9 does not provide the required accuracy in regards to the stresses.

To increase the accuracy without increasing the degrees of freedom in the global mesh, a first simulation can be based on the coarse mesh as shown in Fig. 9. The obtained results, i.e., the nodal displacement at node 2 can be used in a second step as displacement boundary condition for the submodel shown in Fig. 10. This submodel comprises the same domain as element I in the coarse mesh but is discretized by five finite elements of constant length  $L/5$ . A second simulation based on the submodel and the boundary condition resulting from the coarse mesh simulation gives a much better approximation of the stresses in the domain  $0 \leq X \leq L$ . For the given data set, the analytical solution for the normalized stress at the fixed support is equal to 1 while the result from the submodel gives only a deviation of 1.8%. However, the result based on the coarse mesh deviates by 14.3% in this area near the left-hand boundary (Fig. 11).

### 26.3.2 Submodeling Based on Internal Forces

To generalize the introductory example of Sect. 3.1, the finite element structure shown in Fig. 5 is again considered. However, only the isolated substructure A should be now considered and be subjected to the internal loads from substructure B to A which are acting on the interface nodes of group “i” (Raghu 2009). To this end, Eq. (24) can be rearranged to the following form:

**Fig. 9** Tapered bar, discretized by four linear elements with linear changing cross sections. Each element has the same length  $L$  and the same Young's modulus  $E$ . High accuracy for the stresses is required near the left boundary. Finite element nodes are symbolized by *black circles* (•)

**Fig. 10** Submodel composed of five finite elements. Finite element nodes are symbolized by *black circles* (•)

$$\begin{bmatrix} K_{aa} & K_{ai} \\ K_{ia} & K_{ii}^A \end{bmatrix} \begin{bmatrix} u_a \\ u_i \end{bmatrix} = \begin{bmatrix} F_a \\ f_i \end{bmatrix} + \underbrace{\begin{bmatrix} -(K_{ii}^B - K_{ib}K_{bb}^{-1}K_{bi}^0)u_i - K_{ib}K_{bb}^{-1}F_b \end{bmatrix}}_{F_{BA}}, \quad (25)$$

255 where  $F_{BA}$  is the internal load vector from substructure B to A. It can be shown that  
 256 this force is composed of two parts. To this end, the principal finite element equation

**Fig. 11** Stress results for the submodel structure and comparison with the analytical solution and the stress obtained from the coarse mesh

for substructure B according to (18) must be solved for a given  $\mathbf{F}_B$  and the condition  $\mathbf{u}_i = \mathbf{0}$ . One way to solve this  $2 \times 2$  system of equations is to calculate the inverse  $(\mathbf{K}^B)^{-1}$  and to solve for the remaining unknowns, i.e.,  $\mathbf{F}_i$  and  $\mathbf{u}_b$ :

$$\mathbf{F}_i = \mathbf{K}_{bb}^{-1} \mathbf{K}_{ib} \mathbf{F}_b, \quad (26)$$

$$\mathbf{u}_b = \mathbf{K}_{bb}^{-1} \mathbf{F}_b. \quad (27)$$

It can be seen from the last equations that a part of the force  $\mathbf{F}_{BA}$  is the force over the interface when substructure B is constrained to zero at the interface ( $\mathbf{u}_i = \mathbf{0}$ ) and loaded with the external force vector  $\mathbf{F}_B$ . The second part of  $\mathbf{F}_{BA}$  can be obtained by considering Eq. (18) under a given prescribed displacement at the interface ( $\mathbf{u}_i \neq \mathbf{0}$ ) and the condition that no external force is acting on the nodes of group “b” ( $\mathbf{F}_b = \mathbf{0}$ ). Solving of the  $2 \times 2$  system for the remaining unknowns, i.e.,  $\mathbf{F}_i$  and  $\mathbf{u}_b$ , gives:

$$\mathbf{F}_i = (\mathbf{K}_{ii}^B - \mathbf{K}_{ib} \mathbf{K}_{bb}^{-1} \mathbf{K}_{bi}) \mathbf{u}_i, \quad (28)$$

$$\mathbf{u}_b = -\mathbf{K}_{bb}^{-1} \mathbf{K}_{bi} \mathbf{u}_i. \quad (29)$$

Thus, the second part of the force  $\mathbf{F}_{BA}$  is the force over the interface when substructure B is constrained with an enforced displacement at the interface ( $\mathbf{u}_i \neq \mathbf{0}$ ) and the condition no external force is acting on nodes “b”. This second part of the force  $\mathbf{F}_{BA}$  is indirectly dependent on stiffness changes of submodel A. As a result, a stiffness modification in structure A will change the displacement  $\mathbf{u}_i$  and this will change the internal force. Consequently, any stiffness changes in submodel A will lead to an inherent inaccuracy in the local analysis of submodel A if the internal force method is used. A graphical representation of the submodel A is given in Fig. 12 where in addition the internal force  $\mathbf{F}_{BA}$  is indicated.

**Fig. 12** Internal force submodeling method for submodel A. Finite element nodes are symbolized by black circles (•)

### 26.3.3 Submodeling Based on Enforced Displacement

An alternative way of submodeling consists of analyzing submodel A alone by imposing a displacement at the interphase nodes “i”. This enforced displacement is normally obtained from a global analysis as shown in the introductory example of Sect. 3.1. Evaluating the principal finite element equation of substructure A according to Eq. (17) for a given displacement  $u$  gives the remaining primary unknown as:

$$u_a = K_{aa}^{-1} (F_a - K_{ai} u_i). \quad (30)$$

As can be seen from the last equation, the same conclusion as in the case of internal force submodeling method holds: Any stiffness change in submodel A will lead to an inherent inaccuracy in the local analysis of submodel A if the enforced displacement method is used. A graphical representation of the submodel A is given in Fig. 13 where in addition the external displacement  $u_i$  is indicated.

Because submodels normally consist of a refined mesh, it is required to interpolate the nodal displacements from the global mesh along the cut boundaries to all the nodes of the finer mesh along the cut boundaries.

A typical example of the submodeling technique is given in (Wang et al. 2009) where single-lap joints were experimentally and numerically investigated. A schematic sketch is shown in Fig. 14 where the global model and the submodel are shown. For the coarse mesh, the arc segment of the spew fillet was even omitted and only a rectangular shape was considered, cf. the dotted line in Fig. 14a. To give some idea on the mesh density, the coarse mesh in this investigation contained 13,000 elements while the submodel, which comprises a much smaller part of the entire structure, could be discretized with 12,000 elements in order to achieve high accuracy in this area.

An typical alternative example for the submodeling technique is given in (Wahab et al. 2004) where an adhesively bonded composite beam was investigated. There, a fine submodel was used which contains the details of a semicircular crack in the center of the adhesive layer.

**Fig. 13** Enforced displacement submodeling method for submodel A. Finite element nodes are symbolized by black circles (•)

## 26.4 Boundary Element Method

### 26.4.1 Introductory Example

The mathematics involved in the derivation of the boundary element method is much more demanding than in the case of the finite element method. Thus, the major idea of the boundary method is introduced based on the loaded bar as shown in Fig. 15. The general approach can be found in the common textbooks (Banerjee 1994; Raamachandran 2000; Gaul et al. 2003; Beer et al. 2008).

The problem is described by the following partial differential equation

$$EA \frac{d^2 u}{dX^2} = -p(X) \tag{31}$$

and the boundary conditions

**Fig. 15** Bar loaded with a distributed load  $p(X)$  and an end load  $F$

$$u(X=0) = 0 \text{ and } \frac{du}{dX}(X=L) = \frac{F}{EA}. \quad (32)$$

In a more formal way, Eq. (31) can be written as

$$EA\mathcal{L}\{u\} = -p(X), \quad (33)$$

where the second-order differential operator is given by  $\mathcal{L} = \frac{d^2}{dX^2}$ . The partial differential equation describes the problem in each point of the domain and is therefore called the strong formulation or the initial statement. However, this partial differential equation can be only fulfilled in each point by the exact solution. Replacing the exact solution by an approximate solution results in a so-called residual  $R$ :

$$R = \frac{d^2u}{dX^2} + \frac{p(X)}{EA} \neq 0. \quad (34)$$

The principal idea of the weighted residual method is to multiply the residual with a so-called weighting function  $w$  and to request that the error vanishes over a certain region of the domain. This leads to the so-called inner product:

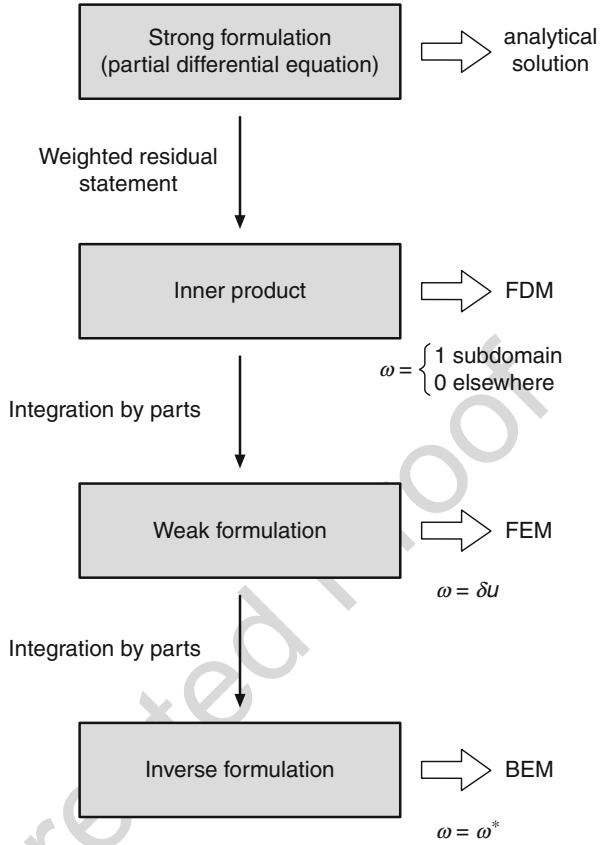

$$\int_0^L \left( \frac{d^2u}{dX^2} + \frac{p(X)}{EA} \right) w dX \stackrel{!}{=} 0. \quad (35)$$

Equation (35) can be integrated by parts in order to shift the differential operator from the field variable  $u$  to the weight function  $w$ . Depending on the order of integration and the choice of the weight function  $w$ , it is possible to derive based on the weighted residual method all the classical approximation methods, cf. Fig. 16 and (Brebbia et al. 1984; Zienkiewicz and Taylor 2000).

The first integration by parts of the derivative term in Eq. (35) yields

$$\int_0^L \frac{d^2u}{dX^2} dX = \left[ \frac{du}{dX} w \right]_0^L - \int_0^L \frac{du}{dX} \frac{dw}{dX} dX, \quad (36)$$

**Fig. 16** Classical approximation methods in the context of the weighted residual method

and the so-called weak form is obtained:

$$\int_0^L \frac{du}{dX} \frac{dw}{dX} dX = \int_0^L \frac{p(X)}{EA} w dX + \left[ \frac{du}{dX} w \right]_0^L. \quad (37)$$

The weak form is characterized by the fact that the order of derivative in the field variable and the weight function is the same. This statement is normally used to derive finite element formulations. Integration by parts of the first integral in the weak form according to Eq. (37) gives

$$\int_0^L \frac{du}{dX} \frac{dw}{dX} dX = \left[ u \frac{dw}{dX} \right]_0^L - \int_0^L u \frac{d^2 w}{dX^2} dX, \quad (38)$$

and the so-called inverse formulation is derived as:

$$\int_0^L u \frac{d^2 w}{dX^2} dX = - \int_0^L \frac{p(X)}{EA} w dX - \left[ \frac{du}{dX} w \right]_0^L + \left[ u \frac{dw}{dX} \right]_0^L. \quad (39)$$

The characteristic of the inverse formulation is that the differential operator  $\mathcal{L}$  is completely shifted to the weight function  $w$ . The next step is to choose a weight function  $w$ . In the scope of the boundary element method, the weight function is chosen to be a fundamental solution:  $w = w^*$  (Love 1944; Sokolnikoff 1956). This fundamental or Kelvin solution  $w^*$  is in the considered case the deformation which is observed at some point  $X$  of an infinite bar due to a unit force at some distant point  $\xi$  in the bar. Alternatively, it is that function which satisfies the differential equation with right-hand side zero at every point of an infinite bar except the force point at which the right-hand side is infinite. Applied to our problem, the fundamental solution is defined by:

$$\frac{d^2 w^*}{dX^2} = \delta(X - \xi), \quad (40)$$

where the Dirac delta function  $\delta(x, \xi)$  is defined in a simple manner as:

$$\delta(X - \xi) = \begin{cases} \infty & \text{for } X = \xi \\ 0 & \text{for } X \neq \xi \end{cases} \quad (41)$$

In the scope of the boundary element method, the selection or sifting property, i.e.,

$$\int_{x_1}^{x_2} f(X) \delta(X - \xi) dX = f(\xi), \quad (42)$$

is the main property which is used for the theoretical derivations. Equation (40) can be multiplied with the field variable  $u$  and integrated to obtain, under consideration of the selection property, the following statement:

$$\int_0^L \frac{d^2 w^*}{dX^2} u(X) dX = \int_0^L \delta(X, \xi) u(X) dX = u(\xi), \quad (43)$$

which leads with Eq. (39) to the so-called representation formula

$$u(\xi) = - \int_0^L \frac{p(X)}{EA} w^* dX - \left[ \frac{du}{dX} w^* \right]_0^L + \left[ u \frac{dw^*}{dX} \right]_0^L. \quad (44)$$

Last equation yields the value  $u(\xi)$  inside the domain, i.e., the bar, if the boundary solution is known.

In order to continue the derivation, the fundamental solution must be known. For the condition given in Eq. (40), the fundamental solution is given by:

$$w^* = \frac{1}{2} |X - \xi|. \quad (45)$$

However, it must be noted here that no fundamental solution can be obtained for some differential operators. The graphical representation of Eq. (45) is shown in Fig. 17 where it can be seen that the function has a kink at  $X = \xi$ . As a result, the first-order derivative shows a jump of magnitude 1, which corresponds to the introduced unit load  $F(\xi) = 1$ . The second-order derivative is everywhere zero except for the load point where the value converges infinity.

Furthermore, it can be seen from Eq. (45) that the displacement of the infinite bar is constraint to zero at the load point:  $w^*(X = \xi) = 0$ . The first-order derivative of Eq. (45) is given for  $X \neq \xi$  as (cf. Fig. 17b)

$$\frac{dw^*}{dX} = \frac{1}{2} \times \text{sgn}(X - \xi), \quad (46)$$

where “sgn” is the signum function defined as:

$$\text{sgn}(X - \xi) = \begin{cases} +1 & \text{for } X > \xi \\ 0 & \text{for } X = \xi \\ -1 & \text{for } X < \xi \end{cases} \quad (47)$$

As can be seen from Fig. 17, the second-order derivative of Eq. (45) is given by the Dirac delta function.

Inserting the fundamental solution (45) and boundary conditions into the representation formula (44) gives

$$u(\xi) = - \int_0^L \frac{p}{EA} w^* dX - \underbrace{\frac{du}{dX}}_{F_o/(EA)} w^* \Big|_L + \frac{du}{dX} w^* \Big|_0 + u \frac{dw^*}{dX} \Big|_L - \underbrace{u \frac{dw^*}{dX}}_0 \Big|_0 \quad (48)$$

or

$$u(\xi) = - \int_0^L \frac{p(X)}{EA} \frac{1}{2} |X - \xi| dX - \frac{F}{EA} \frac{1}{2} |L - \xi| + \left( \frac{du}{dX} \right)_0 \frac{1}{2} |\xi| + u_L \frac{1}{2}. \quad (49)$$

Last equation gives the displacement at any point  $\xi$  in the domain only in terms of boundary variables. The domain integral  $\left( \int_0^L \dots \right)$  does not contain any unknown and can therefore be regarded as a constant term. To obtain two equations for the unknown boundary values  $\left( \frac{du}{dX} \right)_0 = \left( \frac{du}{dX} \right)_{(X=0)}$  and  $u_L = u(X = L)$ , the load point

**Fig. 17** Fundamental solution for a bar subjected to a unit concentrated load at location  $X = \xi$ : (a) schematic sketch of  $w^*$ ; (b) first-order derivative; (c) second-order derivative

371 can be placed on the boundaries. With  $\xi = 0$  and  $\xi = L$ , the following two equations  
 372 are obtained:

$$\underbrace{u(\xi = 0)}_0 = - \int_0^L \frac{p(X)}{2EA} |X| dX - \frac{F_0 L}{2EA} + \frac{u_L}{2}, \quad (50)$$

$$u(\xi = L) = - \int_0^L \frac{p(X)}{2EA} |X - L| dX + \left( \frac{du}{dX} \right)_0 \frac{1}{2} |-L| + \frac{u_L}{2}. \quad (51)$$

373 This system of two equations can be solved to obtain the two unknowns. It is  
 374 assumed for simplicity that the distributed load is constant, i.e.,  $p(X) \rightarrow p_0$ , to obtain  
 375 the unknowns as:

$$u(X = L) = \frac{F_0 L}{EA} + \frac{p_0 L^2}{2EA}, \quad (52)$$

$$\left( \frac{du}{dX} \right) \Big|_{(X=0)} = \frac{F_0}{EA} + \frac{p_0 L}{EA}. \quad (53)$$

376 The last step is the calculation of the value  $u(\xi)$  inside the domain based on the  
 377 boundary values. Inserting the two calculated boundary values in Eq. (49) gives the  
 378 distribution of the displacement as:

$$u(\xi) = \frac{p_0}{EA} \left( L\xi - \frac{\xi^2}{2} \right) + \frac{F_0 \xi}{EA}, \quad (54)$$

379 which is equal to the analytical solution. However, this holds only for this simple  
 380 case and is not true in general since only approximate solutions are obtained.

### 26.4.2 General Comments

381 The major difference between the modeling of a problem with the finite element  
 382 method and the boundary element method is related to the discretization, cf. Fig. 18.  
 383 In the case of the finite element method, the entire domain must be discretized,  
 384 whereas the boundary element method requires only the discretization of the bound-  
 385 ary. In addition, a symmetry plane does not require a discretization. As a direct result,  
 386 the size of the obtained system of equations can be much lower than in finite element  
 387 approaches.

**Fig. 18** Comparison between the general FEM and BEM approach: (a) structural model; (b) finite element mesh; (c) boundary element mesh

Furthermore, changes in the geometry are much easier to incorporate if only the boundary must be subdivided by a mesh. Further advantages of the boundary element method are in the case of stress concentrations where the stresses are evaluated, for example, on the crack boundary and not at the integration points inside the element as in the case of the finite element method. Apart from this, the treatment of infinite and semi-infinite boundaries is much easier in the case of the boundary method. As in the case of the finite element method, there are practically no limitations concerning the geometry which can be modeled. However, there are several disadvantages which must be mentioned. First of all, the derivation of the method is highly mathematical and the theoretical foundation is still not incorporated in many engineering degree courses. The stiffness matrix in the case of the boundary element method might be much smaller compared to the finite element approach but the matrix is fully populated and many highly efficient equation solvers which take advantage of the band structure obtained with finite element approaches cannot be used. Domain integrals must be considered in the case of nonlinearities which requires at least some kind of coarse mesh inside the domain and the dimensionality is no longer reduced.

Typical applications of the boundary element method in the context of adhesion technology are commonly found for the modeling of cracks (fracture mechanics) and other types of stress singularities (Lee 1998), cf. the bibliography of Mackerle (1995a). The article by Vable and Maddi (2006) addresses the specific problems (i.e., numerical modeling considerations which limited the application of BEM in the past) related to bonded joints and boundary element simulation. In addition, numerical results of lap joints, cf. Fig. 19, with several spew angles were presented which demonstrate the potential of the boundary element method in analysis of bonded joints. In a similar way, (Gonçalves et al. 2014) analyzed single-lap joints by the BEM code BEASY to evaluate peak shear and peel stress distributions. In addition, the BEM results were compared to analytical and finite element solutions.

Another typical application of the boundary element method in the context of adhesion technology is the simulation of reinforcement or repair of damaged (e.g., cracked) panels by adhesively bonded patches. This repair technique is quite common in aerospace industry and several references cover this practical topic, see (Young and Rooke 1992; Wen et al. 2002, 2003; Lourenço et al. 2003; Pisa and Aliabadi 2015).

## 26.5 Finite Difference Method

The first widely known approximation method for partial differential equations is the finite difference method (Southwell 1946; de G Allen 1955) which approximates the governing equations of a field problem using local expansions for the variables, generally truncated Taylor series. Comprehensive descriptions of the method can be found for example in (Forsythe and Wasow 1960; Collatz 1966; Mitchell and Griffiths 1980).

### 26.5.1 Introductory Example

To illustrate the major idea of the finite difference method, the solution of an end-loaded bar as shown in Fig. 20 will be considered. A good introduction to the application of the finite difference method to Bernoulli beams can be found, for example, in Bathe (1996).

The problem in Fig. 20 is described by the ordinary differential equation

$$EA \frac{d^2 u}{dX^2} = -p(X) \quad (55)$$

which is to be solved in the domain  $X \in [0, L]$  under the given boundary conditions

$$u(X=0) = 0, \quad (56)$$

$$F(X=L) = F. \quad (57)$$

The problem shown in Fig. 20 implies that the distributed load is zero ( $p(X) = 0$ ) in Eq. (55). As a first step to solve the differential equation, it is assumed that the numerical solution is to be determined only at a set of  $n$  points within the domain including the end, cf. Fig. 21.

These  $n$  nodes or grid points will be used to derive approximations to the derivatives of the function  $u(X)$ . To simplify the approach, these  $n$  nodes are equally spaced, at a distance equal to  $\Delta X$ . As in the case of the finite element method, high gradients would require a smaller node spacing in order to meet the requirements on the

**Fig. 20** Bar with constant axial stiffness  $EA$ , loaded at its tip with a single force  $F_0$

**Fig. 21** Finite difference model of a one-dimensional problem

accuracy of the approximate solution. However, the general idea of the finite difference method will be here introduced based on an equi-spaced division of the domain. A typical inner node of the domain is denoted in the following by  $i$  and the two neighboring nodes are called  $i - 1$  on the left-hand and  $i + 1$  on the right-hand side. For sufficient smooth functions  $u(X)$ , a Taylor's series expansion around node  $i$  gives:

$$u_{i+1} = u_i + \left(\frac{du}{dX}\right)_i \Delta X + \left(\frac{d^2u}{dX^2}\right)_i \frac{\Delta X^2}{2} + \cdots + \left(\frac{d^k u}{dX^k}\right)_i \frac{\Delta X^k}{k!}, \quad (58)$$

$$u_{i-1} = u_i - \left(\frac{du}{dX}\right)_i \Delta X + \left(\frac{d^2u}{dX^2}\right)_i \frac{\Delta X^2}{2} - \cdots + \left(\frac{d^k u}{dX^k}\right)_i \frac{\Delta X^k}{k!}. \quad (59)$$

The infinite series of Eqs. (58) and (59) are truncated for practical use after a certain number of terms. As a result of this approximation, the so-called truncation errors occurs. Summing up the expression of Eqs. (58) and (59) gives

$$u_{i+1} + u_{i-1} = 2u_i + \left(\frac{d^2u}{dX^2}\right)_i \Delta X^2 + \frac{1}{12} \left(\frac{d^4u}{dX^4}\right)_i \Delta X^4 + \cdots, \quad (60)$$

or rearranged for the second-order derivative:

$$\left(\frac{d^2u}{dX^2}\right)_i = \frac{u_{i+1} - 2u_i + u_{i-1}}{\Delta X^2} - \underbrace{\frac{1}{12} \left(\frac{d^4u}{dX^4}\right)_i \Delta X^2}_{O(\Delta X^2)} - \cdots. \quad (61)$$

The  $O$  in Eq. (61) reads “order of” and states if the second-order derivative of  $u(X)$  is approximated by the first expression on the right-hand side of Eq. (61), the truncation error is of order of  $\Delta X^2$ . This approximation is a second-order accurate approximation because of the truncated terms. In a similar way, other derivatives can be derived from Eqs. (58) and (59). Subtracting of Eqs. (58) from (59) gives

$$u_{i+1} - u_{i-1} = 2 \left(\frac{du}{dX}\right)_i \Delta X + \frac{1}{3} \left(\frac{d^3u}{dX^3}\right)_i \Delta X^3 + \cdots \quad (62)$$

459 or rearranged for the first-order derivative

$$\left(\frac{du}{dX}\right)_i = \frac{u_{i+1} - u_{i-1}}{2\Delta X} - \underbrace{\frac{1}{6} \left(\frac{d^3u}{dX^3}\right)_i \Delta X^2}_{o(\Delta X^2)} - \dots \quad (63)$$

460 This last approximation of the first-order derivative is called centered difference  
461 or centered Euler and the truncation error is of order  $\Delta X^2$ . Rearranging Eq. (58), i.e.,

$$u_{i+1} - u_i = \left(\frac{du}{dX}\right)_i \Delta X + \left(\frac{d^2u}{dX^2}\right)_i \frac{\Delta X^2}{2} + \dots, \quad (64)$$

462 or

$$\left(\frac{du}{dX}\right)_i = \frac{u_{i+1} - u_i}{\Delta X} - \underbrace{\left(\frac{d^2u}{dX^2}\right)_i \Delta X}_{o(\Delta X)} - \dots, \quad (65)$$

463 gives an expression for the forward difference or forward Euler approximation of the  
464 first-order derivative. In a similar way, Eq. (59) can be rearranged to obtain the  
465 backward difference or backward Euler approximation of the first-order derivative as:

$$\left(\frac{du}{dX}\right)_i = \frac{u_i - u_{i-1}}{\Delta X} + \underbrace{\left(\frac{+d^2u}{dX^2}\right)_i \Delta X}_{o(\Delta X)} - \dots \quad (66)$$

466 Further derivatives of  $u(X)$  can be obtained if  $u$  is evaluated at nodes  
467  $i + 2$ ,  $i - 2$ , etc. through a Taylor's series about the node  $i$ . Some common expres-  
468 sions for derivatives of different order are summarized in Table 1.

469 Returning to the problem shown in Fig. (20) and described by Eq. (55), a finite  
470 difference approximation of second-order accuracy for node  $i$  can be written as:

$$EA \left( \frac{u_{i+1} - 2u_i + u_{i-1}}{\Delta X^2} \right) = -p_i, \quad (67)$$

471 or as

$$\frac{EA}{\Delta X} (-u_{i-1} + 2u_i - u_{i+1}) = R_i, \quad (68)$$

472 where the equivalent nodal force  $R_i$  resulting from a distributed load  $p(X)$  is in  
473 general given for an *inner* node  $i$  as:  $R_i = \int_{-\Delta X/2}^{\Delta X/2} p(\tilde{x}) d\tilde{x}$ . In this integral, the local

t.1 **Table 1** Finite difference  
t.2 approximations for various  
t.3 differentiations, (Bathe  
t.4 1996)

Derivative	Finite difference approximation	Error
$\left(\frac{du}{dX}\right)_i$	$\frac{u_{i+1}-u_i}{\Delta X}$	$O(\Delta X)$
	$\frac{u_i-u_{i-1}}{\Delta X}$	$O(\Delta X)$
	$\frac{u_{i+1}-u_{i-1}}{2\Delta X}$	$O(\Delta X^2)$
$\left(\frac{d^2u}{dX^2}\right)_i$	$\frac{u_{i+1}-2u_i+u_{i-1}}{\Delta X^2}$	$O(\Delta X^2)$
$\left(\frac{d^3u}{dX^3}\right)_i$	$\frac{u_{i+2}-2u_{i+1}+2u_{i-1}-u_{i-2}}{2\Delta X^3}$	$O(\Delta X^2)$
$\left(\frac{d^4u}{dX^4}\right)_i$	$\frac{u_{i+2}-4u_{i+1}+6u_i-4u_{i-1}+u_{i-2}}{\Delta X^4}$	$O(\Delta X^2)$

474 coordinate  $x$  has its origin at the location of node  $i$ . In the case of the boundary nodes,  
475 the equivalent nodal loads must be calculated as  $R_1 = \int_0^{\Delta x/2} p(\tilde{x})d\tilde{x}$  in  $R_n = \int_{-\Delta x/2}^0$   
476  $p(\tilde{x})d\tilde{x}$  order to completely distribute the entire load  $p(X)$  to the nodes.

477 Returning to the example shown in Fig. 20 and assuming  $n = 5$  nodes, i.e., two  
478 boundary nodes and three inner nodes, the evaluation of the finite difference  
479 approximation at the inner nodes [2,4] gives:

node 2 :  $\frac{EA}{\Delta X}(-u_3 + 2u_2 - u_1) = 0,$  (69)

node 3 :  $\frac{EA}{\Delta X}(-u_4 + 2u_3 - u_2) = 0,$  (70)

node 4 :  $\frac{EA}{\Delta X}(-u_5 + 2u_4 - u_3) = 0.$  (71)

480 These three equations still contain five unknowns  $u_1, \dots, u_5$ , and it is required to  
481 introduce the boundary conditions in order to solve this system of equations. The given  
482 displacement  $u_1 = 0$  (Dirichlet or first-type boundary condition) can be easily intro-  
483 duced in Eq. (69) but the consideration of the force boundary condition (Neumann or  
484 second-type boundary condition) at the right-hand boundary requires more efforts.  
485 Considering the equilibrium condition (Fish and Belytschko 2007), i.e.,  $\frac{dN}{dX} = -p(X)$   
486 together with the integrated form of the differential equation (55) gives the following  
487 expression for the internal normal force  $N$  as a function of the derivative of  $u(X)$ :

$$EA\left(\frac{du(X)}{dX}\right)_i = N(X). \tag{72}$$

488 To evaluate the gradient in Eq. (72), the different formulations given in Table 1  
489 can be used. If the higher accurate centered difference scheme should be used, it is  
490 necessary to introduce a fictitious node outside the bar as shown in Fig. 22.

491 Then, the finite difference approximation for the boundary node 5 can be  
492 written as:

**Fig. 22** Fictitious finite difference node  $n + 1$  outside the bar

$$\text{node 5 : } \frac{EA}{\Delta X} (-u_6 + 2u_5 - u_4) = 0, \quad (73)$$

and the gradient at the boundary node together with the force equilibrium, i.e.,  
 $N_5 = F$ , reads as

$$\left( \frac{du(X)}{dX} \right)_5 = \frac{u_6 - u_4}{2\Delta X} = \frac{F}{EA}, \quad (74)$$

from which the expression for  $u_6$  can be obtained as:

$$u_6 = u_4 + \frac{2F\Delta X}{EA}. \quad (75)$$

This result can be introduced in Eq. (73) to receive the required expression to  
 substitute  $u_5$  in Eq. (71) by given values:

$$u_5 = u_4 + \frac{F\Delta X}{EA}. \quad (76)$$

Thus, the final system of equations under consideration of the boundary conditions is given as:

$$\frac{EA}{\Delta X} \begin{bmatrix} 2 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 1 \end{bmatrix} \begin{bmatrix} u_2 \\ u_3 \\ u_4 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ F \end{bmatrix}. \quad (77)$$

It should be mentioned here that the same result can be obtained in this case based  
 on the finite element method. Simplifying Eq. (7) for constant cross-sectional area, i.e.,

$$\frac{EA}{\Delta X} \begin{bmatrix} 1 & -1 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & 0 \\ 0 & -1 & 2 & -1 & 0 \\ 0 & 0 & -1 & 2 & -1 \\ 0 & 0 & 0 & -1 & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \\ u_5 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ F \end{bmatrix}, \quad (78)$$

and consideration of the boundary condition, i.e.,  $u_1 = 0$ , and elimination of  $u_5$   
 gives the same expression as in Eq. (77).

## 26.5.2 General Comments

The difference between the modeling of a problem with the finite element and the finite difference method is related to the discretization, cf. Fig. 23. In the case of the finite element method, the domain must be discretized with elements (which are composed of nodes and boundaries and which may have a bad shape), whereas the finite difference method requires only the discretization based of grid points which are not joined to elements. As a direct consequence, results are in the case of the finite difference method only obtained at the grid points and not interpolated as in the case of the finite element method. If required, such an interpolation between the grid points must be additionally implemented.

The advantage of the finite difference method is the simple computer implementation of the procedures and thus, it is easy to write own codes and to implement or consider new features. The drawback can be the consideration of the boundary conditions for complex shaped geometries and the consideration of the symmetry of the stiffness matrix might be difficult. Thus, many applications of the finite difference method are restricted to simple geometries. To overcome these problems, the so-called finite difference energy method was developed (Bushnell et al. 1971) where the displacement derivatives in the total potential energy of a system are approximated by finite differences and the minimum condition of the potential energy is used to calculate the unknown displacements.

In engineering practice, the finite difference method is nowadays not widely used and only quite a few publications are available since commercial finite element packages offer a huge range of features and possibilities to incorporate arbitrary geometries and nonlinearities. Typical examples of the application of the finite difference method in the context of adhesive technology are shown in Fig. 24. Crocombe and Bigwood (1992) derived a new sandwich model which considers the nonlinear stress-strain response of both the adherends and the adhesive layer under arbitrary loads imposed on the ends of the sandwich element. This new sandwich model can be easily incorporated into a wide variety of common adhesive geometries, cf. Fig. 24a. To model the adhesive layer, a series of nonlinear shear and tensile springs was assumed under consideration of the von Mises yield criterion.

**Fig. 23** Comparison between the general FEM and FDM approach: (a) finite element mesh; (b) finite difference grid points. The structural model is shown in Fig. 18a

**Fig. 24** Examples of simple geometries for finite difference approach: (a) Sandwich model; (b) beam with strengthening plate; (c) pipe joint

The analytical derivations resulted in a set of six nonlinear first-order differential equations which were solved numerically using a finite-difference scheme. The model shown in Fig. 24a was extended by Wang et al. (2003) to include shear deformation of the adherends and then coupled to an existing analytical model for the detached adherend in a peel specimen. The major goal was to develop a reliable model of predicting adhesive failure in arbitrary joints to large-scale adherend yielding. As in the case of Crocombe and Bigwood (1992), a system of six nonlinear first-order differential equations was obtained and solved by the DBVPFD solver (*Double (Precision) Boundary Value Problem Finite Difference*) from the IMSL (*International Mathematical and Statistical Library*) Fortran library (IMSL Math/Library Manual 1997). A method for determining the elastic shear and peel stresses in an adhesive joint between a strengthening plate and a beam, cf. Fig. 24b, was developed by (Stratford and Cadei 2006) where the governing equations for shear and peel stresses were solved using a finite difference scheme with constant node spacing. The stresses in adhesively bonded composite tubular joints, cf. Fig. 24c, subjected to torsion were investigated by (Xu and Li 2010). Their analytical derivations resulted in a system of 18 second-order partial differential equations and 6 linear equations with 24 unknowns which were solved by a mathematical model based on the finite difference method.

In order to use a more realistic cohesive zone model which added the effects of normal stresses to a classical pure shear model, Carrara and Ferretti (2013) applied

**Table 2** Suggested applications of different approximation methods.

Method	Suggested application
Finite element method (FEM)	Any standard engineering problem; nonlinearities
Boundary element method (BEM)	Cracks; stress singularities; large stress gradients
Finite difference method (FDM)	Own code development and solution of new analytical derivations for simpler geometries

the finite difference method to solve a system of first-order nonlinear ordinary differential equations. The problem itself was related to fibre-reinforced polymer plates which were bonded on a concrete structure.

## 26.6 Conclusion

In the scope of this chapter, special numerical techniques were covered. First of all, techniques to reduce the size of a model in a computational finite element approach were presented. Substructuring and submodeling allow a significant reduction of the model size. However, it seems that the permanent increase of the performance of computer hardware pushes these techniques a bit to the background. Nevertheless, the presented methods are highly efficient and can dramatically reduce computational times and save resources. The second part of the chapter focused on alternative approximation methods. The boundary element and the finite difference method were introduced and advantages and disadvantages highlighted. The boundary method shows its advantages in the context of stress singularities while the finite difference method is easy to implement for simple geometries. Suggestions for the application of the different approximation methods are summarized in Table 2.

### Abstract

One of the main reasons for the increasing use of adhesive bonding is the fact that the stress distribution is more uniform than with other conventional methods of joining which enables to reduce weight. However, even in adhesive joints the stress distribution is not perfectly uniform and this leaves room for improvements. The major enemy of adhesive joints is peel or cleavage stresses. These should be reduced if strong joints are to be designed. In this chapter, the main factors influencing the joint strength are first discussed. The focus is on lap joints because these are the most common. Methods are then proposed to improve the joint strength by using fillets, adherend profiling, and other geometric solutions. Hybrid joining is also a possibility to improve the strength of adhesive joints, and adhesives may be used in conjunction with rivet or bolts, for example. Joints may be damaged in some way and it is important to discuss also methods to guarantee an efficient repair design. Finally, configurations are recommended for several types of joints such as butt joints, strap joints, cylindrical joints, and T joints. The main rule for all cases is to spread the load over a large area and reduce the peel stresses.

## 27.1 Introduction

Knowledge of the state of stresses inside the adhesive layer of an adhesively bonded joint is essential for joint strength prediction and joint design. There are two methods for the stress analysis of lap joints, namely analytical and numerical methods. Analytical methods using closed-form algebra employ classical linear theories in which some simplifications are used. The finite element (FE) method, on the other hand, is a well-established numerical technique which can handle complex structures and nonlinear material properties where classical methods generally fail to work. Although the closed-form solutions have their limitations, they are easy to use, especially for parametric studies. The FE method needs large computer power, especially if high accuracy is required, and experienced personnel. Consequently, the former is widely used for joint design and the latter for research or for complex geometries. There are many analytical models in the literature for obtaining stress and strain distributions. Many closed-form models are based on modified shear-lag

equations, as proposed originally by Volkersen (1938). Reviews of these closed-form theories and their assumptions can be found in da Silva et al. (2009a, b) and in ► Chap. 24, “Analytical Approach.” As the analytical equations become more complex (including factors such as stress variation through the adhesive thickness, plasticity, thermal effects, etc.), there is a greater requirement to use computing power to solve for the stresses. Hart-Smith (1973) had a great influence on the methods used for stress analysis of adhesive joints. Versions of this method have been prepared as Fortran programs and have been used extensively in the aerospace industry. Other analyses have been implemented in spreadsheets or as a program for personal computers (PCs). The software packages are there to assist in the design of efficient joints. A brief overview of commercial PC based analysis/design software packages is given in Table 1. The main features of each software package are identified. As shown in Table 1, the existing software packages are very specific and most of them only cover one or two joints geometries. For most of the softwares, the selection process is dependent on the previous experience of the designer, apart from those of da Silva et al. (2009c) and Dragoni et al. (2010).

The design philosophy associated to adhesive joints is radically different from that of other traditional methods of joining such as bolts or rivets. Therefore, it is not advised to take a joint initially designed for another type of joining method and modify it for adhesive bonding. The first point in design is to choose a suitable adhesive which will depend on the type of loading, the adherends to bond, and the environment (temperature and humidity). Adhesives, which are polymeric materials, are not as strong as the adherends they are joining such as metals or composites. However, when they are loaded over a large area such as in a single-lap joint, they can provide a high strength, sufficient to deform plastically the metal in some cases or to break the composite. That is why when designing an adhesive joint, the load must be spread over a large area and not concentrated in one point. Peel loads are the greatest enemy of the designer of bonded joints (Adams et al. 1997). The adhesive should be loaded in shear whenever possible and the peel and cleavage stresses should be avoided. However, there might be limitations in terms of manufacturing process, cost, consequences of failure, and desired final appearance that may complicate the designing process.

The strength of an adhesive joint in the absence of environmental factors is determined by the mechanical properties of the adhesive and adherends, the joint geometry, and the residual internal stresses. In effect, localized stresses are not always apparent and may occur as a result of differential thermal expansion of the adhesive and adherends. Another cause is shrinkage of adhesive during cure. These factors are all discussed and simple design guidelines are given. The joint strength can be improved by a number of techniques such as fillets, adherend shaping, and other geometric solutions. All these aspects are discussed in detail. Hybrid joints are increasingly being used for improving the strength of adhesive joints. Adhesive can be used in conjunction with a rivet, a bolt, or a spot weld. The advantages of such solutions are explained in this chapter. Repair techniques are also treated because joints may be damaged in some way and it is important to discuss methods to guarantee an efficient repair design. Finally, configurations are recommended for several types of joints such as butt joints, strap joints, cylindrical joints, and T joints.

**27.2 Factors Affecting Joint Strength**

The major factors that affect the joint strength of lap joints are the material properties (adherends and adhesive) and the geometry (adherend and adhesive thickness, and overlap). Residual internal stresses due to thermal effects should also be taken into account. The stress distribution in adhesive joints is not uniform (see ► [Chaps. 24, “Analytical Approach”](#) and ► [25, “Numerical Approach: Finite Element Analysis”](#)), therefore, the average shear stress (i.e., load divided by the bonded area) can be much lower than the local maximum stress. Failure always occurs at the stress concentrations and it is fundamental to decrease these stress peaks if a joint strength improvement is required. There are general guidelines to increase the joint strength by minimizing the stress concentrations:

- Use an adhesive with a low modulus and ductile behavior
- Use similar adherends or if not possible balance the stiffness
- Use a thin adhesive layer
- Use a large bonded area

Each of these factors is discussed next and detailed design guidelines are given. The residual stresses caused by thermal effects are also discussed. Note that the joint strength can be further improved by using adhesive fillets, adherend tapers, and adhesive bands along the overlap or hybrid joints. These solutions are described in Sect. 3.

**27.2.1 Adhesive Properties**

It is very important to distinguish adhesive strength and joint strength. The joint strength may not increase if a stronger adhesive is used. The joint strength depends not only on the adhesive strength but also on its ductility and stiffness. Adhesives with high ductility and flexibility have generally a low strength. However, when used in a joint, their ability to distribute uniformly the stress along the overlap (low stiffness) and deform plastically

**Fig. 1** Effect of the adhesive modulus on the adhesive stress distribution along the overlap

**Fig. 2** Effect of the adhesive ductility on the adhesive stress distribution along the overlap (Adapted from Hart-Smith (1973))

can give a joint strength much higher than with apparently strong but less ductile adhesives (da Silva et al. 2006). A low modulus adhesive gives a more uniform stress distribution compared to a stiff adhesive where there is a high stress concentration at the ends of the overlap (see Fig. 1). A ductile adhesive is able to redistribute the load and make use of the less stressed parts of the overlap, whereas a brittle adhesive concentrates the load at the ends of the overlap giving a low average shear stress (see Fig. 2). Adhesives are either strong, brittle, and stiff, or weak, ductile, and flexible. The ideal would be to have a strong, ductile, and flexible adhesive but this is very difficult to achieve, although the properties are independent. It is recommended to use ductile adhesives, but this also depends on the overlap, as will be seen in Sect. 2.4.

**Fig. 3** Adherend yielding in a single-lap joint

Ductile adhesives are also more resistant to crack propagation than brittle adhesives, giving a much higher toughness. The fatigue strength is generally lower for brittle adhesives. If the fatigue limit is measured in terms of a percentage of the static maximum joint strength, then the fatigue life of joints with ductile adhesives is considerably higher than that of joints with brittle adhesives. This is due to a more uniform stress distribution and also because of the higher damping energy associated to ductile adhesives. In the case of nonuniform loading such as peel, cleavage, or thermal internal stresses, a joint with a ductile adhesive will also give a better response.

### 27.2.2 Adherend Properties

Adherend properties also have a huge impact on the joint strength. The most important are the adherend modulus and its strength. The higher the adherend modulus, the lower will be its deformation at the ends of the overlap, where the load transfer takes place, and the lower will be the effect of the differential straining in the adhesive (Volkersen 1938). The adherend strength is also fundamental and can explain many joint failures. In the case of metallic adherends, the adherend yielding can cause a premature failure of the joint. As the load imposed on the joint increases, the stress imposed at the edge of the overlap increases. When the stress reaches the yield point of the steel, large plastic strains result, creating a plastic hinge as shown in Fig. 3. Although the stresses are limited, the strains associated with the stress in the plastic range are very large. As the maximum adhesive strain is limited, it therefore fails when the maximum adhesive strain is exceeded. In other words, it is the adherend yielding that controls failure.

In the case of composite laminate adherends, it is recommended to have the outer layers with a direction parallel to the loading direction to avoid intralaminar failure of these layers. In any case, the major problem is the low transverse strength (through the thickness) of composites that is of the same order or lower than the adhesive tensile strength. This is a major problem of adhesive joints with composites that tend to fail in an interlaminar manner due to the high peel stresses at the ends of the overlap, as shown in Fig. 4. If failure occurs in the composite, a failure criterion in the adhesive (maximum stress and maximum strain) overestimates the joint strength. Predictions based on the composite transverse stress at the interface compare very well with the experiments (da Silva et al. 2009b). One solution to decrease the peel stresses is by tapering the adherends, as will be discussed in Sect. 3.3.

**Fig. 4** Interlaminar failure of the composite in adhesive joints (Adapted from Hart-Smith (1973))

The use of dissimilar adherends decreases the joint strength due to a nonuniform stress distribution (see Fig. 5b). To reduce this problem, the joint should be designed so that the longitudinal stiffness of the adherends to be bonded are equal, i.e.,  $E_1 t_1 = E_2 t_2$ , where  $E$  is the longitudinal modulus,  $t$  the thickness, and the subscripts (1, 2) refer to adherend 1 and adherend 2.

### 27.2.3 Adhesive Thickness

The effect of the bondline thickness on single-lap joints is well-documented in the literature. Most of the results are for typical structural adhesives and show that the lap-joint strength decreases as the bondline increases (da Silva et al. 2006; Adams and Peppiatt 1974). Experimental results show that for structural adhesives, the optimum joint strength is obtained with thin bondlines, in the range of 0.1–0.2 mm. However, the classical analytical models such as those of Volkersen (1938) or Goland and Reissner (1944) predict the opposite. There are many theories that attempt to explain this fact and this subject is still controversial. Adams and Peppiatt (1974) explained that an increase in the bondline thickness increases the probability of having internal imperfection in the joint (voids and microcracks), which will lead to premature failure of the joints. Crocombe (1989) shows that thicker single-lap joints (SLJs) have a lower strength, by considering the plasticity of the adhesive. An elastic analysis shows that the stress distribution

**Fig. 5** Adhesive shear stresses in a metal/composite double-lap joint for the case where the composite has a lower longitudinal stiffness than the metal ( $E_{lc} t_c < E_m t_m$ ) under a tensile load and a thermal load, at adhesive yielding ( $\tau_y$ ) (Adapted from Hart-Smith (1973))

of a thin bondline is more concentrated at the ends of the overlap than a thicker bondline which has a more uniform stress distribution. A thin bondline will therefore reach the yielding stress at a lower load than a thick bondline. However, when yielding does occur in a thicker joint, there is a less “elastic reserve” to sustain further loading, thus yielding spreads more quickly (see Fig. 6). Gleich et al. (2001) showed with a finite element analysis on single-lap joints that increases in the interface stresses (peel and shear) as the bondline gets thicker cause the failure load of a bonded joint to decrease with increasing bondline thickness. They found that for the low bondline thickness range, an optimum distribution of stresses along the joint interface exists for maximum joint strength. Grant et al. (2009a) found a reduction in joint strength with increasing the bondline thickness when testing SLJs for the automotive industry with an epoxy adhesive. The strength reduction was attributed to the higher bending moments for the lap

**Fig. 6** Stress distribution in a thick (*top*) and in a thin (*bottom*) adhesive layer

**Fig. 7** Failure envelope for lap joints produced from sheet steel and an epoxy adhesive

joints with thick bondlines due to the increase in the loading offset. Figure 7 shows the failure envelope obtained by Grant et al. (2009a) for single-lap joints under tension and three-point bending with mild steel where failure is dictated by the adherend yielding. It can be seen that there is a clear relationship between the bending moment at the edge of the overlap at failure, and the tensile failure load. This forms an envelope of failure, where any combination of load and bending moment outside the envelope means that failure occurs, and any combination inside means that the joint will not fail. The limits are defined by the relationship between bending moment and failure load that can be deduced from the adhesive/adherend combination, and the maximum bending moment that can be sustained by the adherend. Further studies (Grant et al. 2009b, c) show that this failure envelope is also applicable to other types of joints (T joints) and environments (temperature).

## 27.2.4 Overlap

Increasing the joint width increases the strength proportionally. However, the effect of the overlap length depends on the type of adhesive (i.e., ductile or brittle) and on the adherend yielding strength. Three cases should be considered: elastic adherends (e.g., high-strength steel) and ductile adhesive, elastic adherend and brittle adhesive and adherends that yield. For elastic adherends and ductile adhesives (more than 20% shear strain to failure), the joint strength is approximately proportional to the overlap. This is because ductile adhesives can deform plastically, redistribute the stress as the load increases, and make use of the whole overlap. In this case the failure criterion is the global yielding of the adhesive. For adhesives with intermediate ductility, the adhesive fails because the strain in the adhesive at the ends of the overlap reaches the adhesive shear strain to failure (see Fig. 8). For elastic adherends and brittle adhesives, the joint strength is not proportional to the overlap and a plateau is reached. This is because the stress is concentrated at the ends of the overlap and a longer overlap does not alter the stress distribution along the overlap. For adherends that yield, the failure is dictated by the adherend yielding and again a plateau is reached corresponding to the adherend yielding.

Adams et al. (1997) proposed a simple methodology for designing single-lap joints under tension, which is represented graphically in Fig. 9. The upper limit is given by the load corresponding to the total plastic deformation of the adhesive (global yielding) which is

$$P_{GY} = \tau_y \cdot b \cdot l \quad (1)$$

where  $P_{GY}$  is the failure load of the adhesive due to global yielding,  $\tau_y$  is the yield strength of the adhesive,  $b$  is the joint width, and  $l$  is the overlap length. A lower limit

**Fig. 8** Failure due to adhesive shear strain (*left*) and due to global yielding (*right*).  $\tau_y$  is the yielding shear stress, and  $\gamma_p$  is the plastic shear strain at failure

**Fig. 9** Failure load vs. overlap length ( $P_{GY}$  is the failure load of the adhesive due to global yielding,  $\tau_y$  is the yield strength of the adhesive,  $b$  is the joint width,  $l$  is the overlap length,  $t$  is the adherend thickness,  $P_Y$  is the maximum load that can be carried which just creates adherend yield, and  $\sigma_y$  is the yield strength of the adherend)

is given when the adherends yield plastically. The direct tensile stress ( $\sigma_t$ ) acting in the adherend due to the applied load  $P$  is

$$\sigma_t = P/bt \quad (2)$$

where  $t$  is the adherend thickness. The stress at the inner adherend surface ( $\sigma_s$ ) due to the bending moment  $M$  is

$$\sigma_s = 6M/bt^2 \quad (3)$$

where ( $M = kPt/2$ ), according to Goland and Reissner (1944). The variable  $k$  is the bending moment factor which reduces (from unity) as the lap rotates under load. The stress acting in the adherend is the sum of the direct stress and the bending stress. Thus, the maximum load which can be carried which just creates adherend yield ( $P_Y$ ) is

$$P_Y = \sigma_y bt / (1 + 3k) \quad (4)$$

where  $\sigma_y$  is the yield strength of the adherend. For low loads and short overlaps,  $k$  is approximately 1. Therefore, for such a case,

$$P_Y = \sigma_y bt / 4 \quad (5)$$

However, for joints that are long compared to the adherend thickness, which is the case here ( $l = 15$  mm and  $t = 0.95$  mm), the value of  $k$  decreases and it is assumed that it tends to be zero. In this case, the whole of the cross section yields and

$$P_Y = \sigma_y \cdot bt \quad (6)$$

This criterion has been applied with successful results to thin bondlines and a conservative value has always been obtained (Adams et al. 1997). The prediction is

also conservative for thin bondlines (less than 1 mm) but overestimates the results of thicker bondlines (more than 1 mm). This could be explained by the fact that the model does not take into account strain hardening of the steel. For a more accurate solution, the bending moment factor  $k$  could be computed according to Hart-Smith's equation that takes into account the adhesive thickness (Hart-Smith 1973). Note, however, that Eq. (4) would now require a numerical solution because  $k$  also depends on the load applied  $P$ . Moreover, Hart-Smith's bending moment factor is inaccurate when the adherend deforms plastically.

For joints with ductile adhesives, the failure load is given by the load that causes adhesive global yielding along the overlap. This criterion works reasonably well provided the failure shear strain of the adhesive is more than 20%. However, for brittle adhesives, this methodology is not applicable (da Silva et al. 2008). For joints with a brittle adhesive, the Volkersen's model can be used (da Silva et al. 2009b) and the failure occurs when the maximum shear stress at the ends of the overlap exceeds the shear strength of the adhesive. Alternatively, the finite element method can be used.

## 27.2.5 Residual Stresses

One of the main advantages of using adhesive bonding is the possibility to bond dissimilar materials, such as carbon fiber-reinforced plastics (CFRP) to aluminum in many aeronautical applications. However, dissimilar adherends may have very different coefficients of thermal expansion (CTE). Thus, temperature changes may introduce thermal stresses in addition to the externally applied loads. The chemical process of adhesive curing as well as the thermal variations during cure can lead to shrinkage and may also introduce internal stresses. Deformations or even cracks can appear. It is important to consider thermal effects because these generally lead to a joint strength reduction, even though in some cases the opposite happens (da Silva et al. 2004). Several authors have found that the stresses caused by adhesive shrinkage have much less effect on the lap-joint strength than those generated by the adherend thermal mismatch. Thermal loads are especially important when bonding adherends with different CTEs (Hart-Smith 1973). For metal/composite joints for example, the metal tends to shrink as the temperature is decreased from the cure value (generally a high temperature) and this is partially resisted by the composite (lower CTE), thereby inducing residual bond stresses especially at the ends of the joint. One end has positive residual shear stresses and the other end has negative residual shear stresses (see Fig. 5a). The thermal stresses are beneficial at one end of the joint but have the reverse effect on the other side of the joint. The thermal load  $\Delta T$  is given by Eq. (7):

$$\Delta T = T_O - T_{SF} \quad (7)$$

where  $T_O$  is the operating temperature and  $T_{SF}$  is the stress-free temperature. It is reasonable to consider the stress-free temperature as the normal cure temperature of the adhesive for most cases.

## 27.3 Methods to Increase Joint Strength

### 27.3.1 Fillets

Various authors have shown that the inclusion of a spew fillet at the ends of the overlap reduces the stress concentrations in the adhesive and the substrate (Adams and Peppiatt 1974; Crocombe and Adams 1981; Adams et al. 1986; Adams and Harris 1987; Dorn and Liu 1993; Tsai and Morton 1995; Lang and Mallick 1998; da Silva and Adams 2007a). The load transfer and shear stress distribution of a single-lap joint with and without fillet are schematically represented in Fig. 10. It can be seen that there is a stress concentration at the ends of the overlap for the single-lap joint with a square end. Modification of the joint end geometry with a spew fillet spreads the load transfer over a larger area and gives a more uniform shear stress distribution. The fillet not only gives a smoother load transfer but also alters the stress intensity factors as shown in Fig. 11.

Adams and Peppiatt (1974) found that the inclusion of a 45° triangular spew fillet decreases the magnitude of the maximum principal stress by 40% when compared to a square end adhesive fillet. Adams and Harris (1987) tested aluminum/epoxy single-lap joints with and without fillet and found an increase of 54% in joint strength for the filleted joint. Adams et al. (1986) tested aluminum/CFRP single-lap joints and found that the joint with a fillet is nearly two times stronger than the joint without a fillet. Crocombe and Adams (1981) did similar work but included geometric (overlap length, adhesive thickness, and adherend thickness) and material (modulus ratio) parameters. The reduction in peel and shear stresses is greatest for a low modulus ratio (low adhesive modulus), a high adhesive thickness, and a low adherend thickness.

**Fig. 10** Load transfer and shear stress distribution in single-lap joints with and without fillet

**Fig. 11** Stress intensity factors in adhesive lap joints with different spew fillet geometry

Dorn and Liu (1993) investigated the influence of the spew fillet in plastic/metal joints. The study included an FE analysis and experimental tests and they concluded that the spew fillet reduces the peak shear and peel adhesive stresses and decreases stress and strain concentrations in the adherends in the most critical regions. They also studied the influence of different adhesive and different metal adherends. A ductile adhesive and a more balanced joint (aluminum/plastic instead of steel/plastic) give a better stress distribution.

Tsai and Morton (1995) studied the influence of a triangular spew fillet in laminated composite single-lap joints. The FE analysis and the experimental tests (Moire interferometry) proved that the fillet helps to carry part of the load, thus reducing the shear and peel strains.

The above analyses are limited to triangular geometry. Lang and Mallick (1998) investigated several different geometries: full and half triangular, full and half rounded, full rounded with fillet, oval, and arc. They showed that shaping the spew to provide a smoother transition in joint geometry significantly reduces the stress concentrations. Full rounded with fillet and arc spew fillets give the highest percent reduction in maximum stresses whereas half-rounded fillet gives less. Furthermore, increasing the size of the spew also reduces the peak stress concentrations.

The spew fillet is not beneficial in all situations. In effect, the spew fillet tends to generate more thermal stresses than a square-end geometry when used at low temperatures (da Silva and Adams 2007a).

### 27.3.2 Adherend Rounding

Adhesive single-lap joints may have several singular (infinite) stresses. The stresses tend to infinite at crack tips and at bi-material junctions. Fracture mechanics can be

applied to treat the singular points at crack tips. As regards the bi-material singularities, there can be two or three, depending on the joint geometry (see Fig. 11). For both situations, there is an abrupt change in slope giving a sharp corner. The stress field in the vicinity of a sharp corner depends on the mesh used. A stress limit criterion will therefore lead to arbitrary results. The first FE analyses 40 years ago used coarse meshes due to computer memory limitations and therefore did not capture the infinite stress at singular points. The joint strength predictions obtained with stress or strain limit-based criteria compared well with the experimental results (Harris and Adams 1984). With computer power development, finer meshes can be used which led to a better stress distribution description but also to stresses that tend to infinite at singular points. The stress or strain limit failure criteria give, in this circumstance, more conservative predictions and are therefore very arguable.

Groth (1988) used a fracture mechanics approach without considering a pre-existing crack. He formulated a fracture criterion based on an equivalent generalized stress intensity factor similar to that in classical fracture mechanics. Comparing it to a critical value, joint fracture may be predicted. However, the critical stress intensity factor needs first to be tuned with an experimental test which makes this approach questionable.

Another approach for dealing with the singularity points is to use a cohesive zone model (CZM). This approach is associated to interface elements and enables to predict crack initiation and crack growth. It is a combination of a stress limit and fracture mechanics approach and relatively mesh insensitive. Many researchers are using this tool with accurate results (de Moura et al. 2006). However, the parameters associated to the CZM require previous experimental “tuning” and the user needs to know beforehand where the failure is likely to occur. This subject is discussed in detail in ► Chap. 25, “Numerical Approach: Finite Element Analysis.”

In practical joints the sharp corners are always slightly rounded during manufacture and the singular points will not necessarily exist. Adams and Harris (1987) studied the influence of the geometry of the corners. Using a simplified model, the effect of rounding on the local stress was investigated. Rounding the corner removes the singularity. Therefore, small local changes in geometry have a significant effect. They also performed an elastic-plastic analysis by calculating the plastic energy density. They found that the stress distribution is more uniform with a maximum some distance from the corner. The reason they give is that as the corner is approached, although the normal stress increases, the rigid adherend restrains the adhesive in the transverse direction. The net hydrostatic component is increased and yield is suppressed so that close to the corner there is a reduction in plastic energy density. It should be borne in mind that the effects are local: far away from the corner the stress distribution is unaffected. Apart from the simplified model, Adams and Harris (1987) tested three types of aluminum/rubber-toughened epoxy single-lap joints so that local changes at the end of the joint could be assessed. They found excellent agreement between the predicted joint strengths, with the modified models, and the experimental values. Zhao et al. (2011a, b) developed further the initial work of Adams and Harris (1987) and studied the cases illustrated in Fig. 12. They found that for joints bonded with brittle adhesives, the effect of adherend corner radius is

**Fig. 12** Aluminum/epoxy single-lap joints with different degrees of rounding

larger than that with ductile adhesives. For the brittle adhesive, the joint strength with large-radius adherend corners increases about 40% compared with that of sharp adherend corners. For large-radii adherend corners, a criterion based on continuum mechanics can be used to predict joint strength because there is no stress singularity. For joints with sharp and small adherend corners, a new criterion based on an average value around the singularity was proposed and demonstrated to be accurate for joint strength prediction with ductile adhesives.

### 27.3.3 Adherend Shaping

Adherend shaping is a powerful way to decrease the stress concentration at the ends of the overlap. Figure 13 presents typical geometries used for that purpose. Some analytical models were proposed to have a more uniform stress distribution along the overlap (Cherry and Harrison 1970). However, the FE method is more appropriate for the study of adherends shaping. The concentrated load transfer at the ends of the overlap can be more uniformly distributed if the local stiffness of the joint is reduced. This is particularly relevant for adhesive joints with composites due to the low

**Fig. 13** Adherend shaping

transverse strength of composites (see Sect. 2.2). Adams et al. (1986) addressed this problem. They studied various configurations of double-lap joints where the central adherend is CFRP and the outer adherends are made of steel. They found with FE and experiments that the inclusion of an internal taper and an external fillet can triple the joint strength. The same geometry was studied at low temperatures and it was found that the thermal stresses reduce substantially the joint strength (da Silva and Adams 2007a).

Hildebrand (1994) did similar work on SLJs between fiber-reinforced plastic and metal adherends. The optimization of the SLJs was done by modifying the geometry of the joint ends. Different shapes of adhesive fillet, reverse tapering of the adherend, rounding edges, and denting were applied in order to increase the joint strength. The results of the numerical predictions suggest that, with a careful joint-end design, the strength of the joints can be increased by 90–150%.

The use of internal tapers in adherends in order to minimize the maximum transverse stresses at the ends of bonded joints has also been studied by Rispler et al. (2000). An evolutionary structural optimization method (EVOLVE) was used to optimize the shape of adhesive fillets. EVOLVE consists of an iterative FE analysis and a progressive removal of elements in the adhesive which are low stressed.

Other examples of joint-end modifications for joint transverse stress reduction but using external tapers are those of Sancaktar and Nirantar (2003) and Kaye and Heller (2005). Kaye and Heller (2005) used numerical optimization techniques in order to optimize the shape of the adherends. This is especially relevant in the context of repairs using composite patches bonded to aluminum structures (see Sect. 3.5) due to the highly stressed edges.

Tapers (internal or external), or more complex adherend shaping, are excellent methods to reduce the peel stresses at the ends of the overlap and, therefore, to increase the joint strength. Internal tapers with a fillet seem to be the more efficient way to have a joint increase, especially with brittle adhesives and when composites are used. The FE method is a convenient technique for the determination of the optimum adherend geometry; however, the complexity of the geometry achieved is not always possible to realize in practice.

**Fig. 14** Various forms of geometric complexity

#### 27.3.4 Other Geometric Solutions

Other complex geometrical features such as voids in the bondline, surface roughness, notches in the adherend, etc. can be used to increase the joint strength. Again, the FE method should be used to find the optimum adherend geometry, bearing in mind that the complexity of the geometry might not be practical (see Fig. 14).

Nakagawa et al. (1999) studied the effect of voids in butt joints subjected to thermal stresses and found that stresses around defects in the center of the joint are more significant than those near the free surface of the adhesive. Lang and Mallick (1999) and de Moura et al. (2006) studied the influence of gaps in the adhesive and found that a gap in the middle of the overlap has little effect on joint strength. That is because the stress is more concentrated at the ends of the overlap. However, if a ductile adhesive that makes use of the whole overlap is used, then a joint strength improvement is expected.

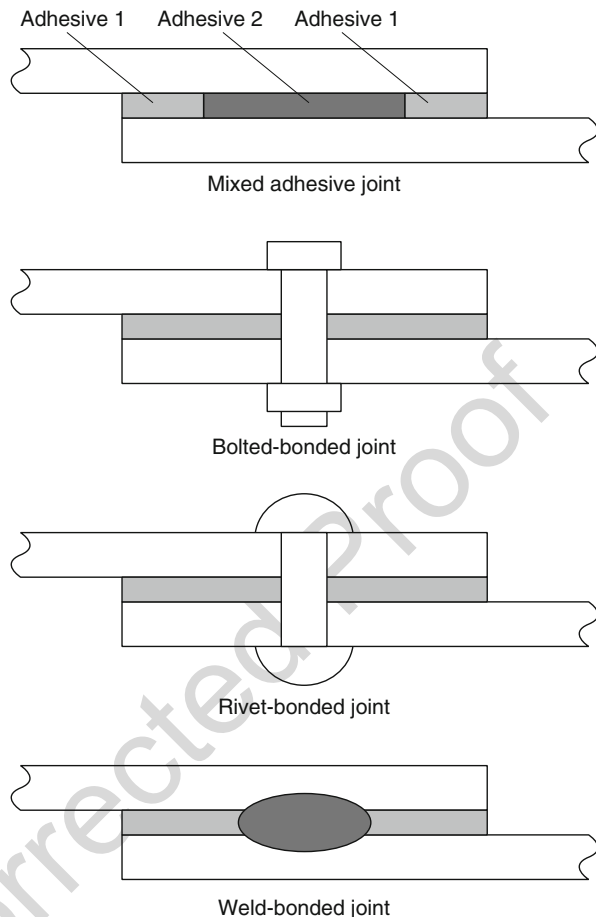

Kim (2003) proposed an analytical model supported by FE modeling to study the effect of variations of adhesive thickness along the overlap. The author showed that the variations found in practice have little effect on the adhesive stresses along the overlap.

Kwon and Lee (2000) studied the influence of surface roughness on the strength of tubular joints by modeling the stiffness of the interfacial layer between the adherends and the adhesive as a normal statistical distribution function of the surface roughness of the adherends. The authors found that the optimum surface roughness was dependent on the bond thickness and applied load.

Sancaktar and Simmons (2000) investigated the effect of adherend notching on the strength and deformation behavior of single-lap joints. The experimental results showed a 29% increase in joint strength with the introduction of the notches, which compared well with the FE analysis results.

### 27.4 Hybrid Joints

Joints combining different methods of joining are increasingly being used. The idea is to gather the advantages of the different techniques leaving out their problems. For example, the combination of friction stir welding with adhesive

**Fig. 15** Hybrid joints

bonding is able to overcome the inherent defects that occur when lap joints are  
 friction stir welded (Braga et al. 2016) and produce stronger joints. Another  
 possibility is to use more than one adhesive along the overlap or varying the  
 adhesive and/or adherend properties. All these cases have been grouped here  
 under a section called “hybrid joints” (see Fig. 15). It is important to note that  
 hybrid joints are especially well-suited for industrial applications, as they provide  
 immediate handling strength while the adhesive is not fully cured (da Silva et al.  
 2011c). Such joints are particularly difficult to simulate using analytical models for  
 obvious reasons, however, they can be tailor designed for a given application  
 (Moroni et al. 2010). The FE method is the preferred tool to investigate the  
 application of such techniques and find design guidelines. Campilho et al. (2012)  
 used finite element models to successfully optimize the geometry of hybrid spot-  
 welded/bonded single-lap joints, employing a CZM FE analysis.

#### 27.4.1 Mixed Adhesive Joints

Mixed modulus joints have been proposed in the past to improve the stress distribution and increase the joint strength of high modulus adhesives. The stiff, brittle adhesive should be in the middle of the overlap, while a low modulus adhesive is applied at the edges prone to stress concentrations. Sancaktar and Kumar (2000) used rubber particles to toughen the part of the adhesive located at the ends of the overlap and increase the joint strength. The concept was studied with the FE method and proved experimentally. Pires et al. (2003) also proved with an FE analysis and experimentally with two different adhesives that the mixed adhesive method gives an improvement in joint performance. Temiz (2006) used an FE analysis to study the influence of two adhesives in double-lap joints under bending and found that the technique decreases greatly the stresses at the ends of the overlap. Bouiadjra et al. (2007) used the mixed modulus technique for the repair of an aluminum structure with a composite patch. The use of a more flexible adhesive at the edge of the patch increases the strength performance of the repair. Das Neves et al. (2009a, b) have developed an analytical model that takes into account two adhesives along the overlap and permits to determine the best combination of adhesives and the optimum geometric factors (e.g., overlap) to have the maximum joint strength. The authors showed that the technique is more efficient for single-lap joints than for double-lap joints. More recently, da Silva and Lopes (2009) have studied single-lap adhesive joints maintaining the same brittle adhesive in the middle of the overlap and using three different ductile adhesives of increasing ductility at the ends of the overlap. A simple joint strength prediction is proposed for mixed adhesive joints. The mixed adhesive technique gives joint strength improvements in relation to a brittle adhesive alone in all cases. For a mixed adhesive joint to be stronger than the brittle adhesive and the ductile adhesive used individually, the load carried by the brittle adhesive must be higher than that carried by the ductile adhesive. Marques and da Silva (2008) studied mixed adhesive joints with an internal taper and a fillet. They show that the use of a taper and a fillet have little effect on the strength of mixed adhesive joints. The ductile adhesive at the ends of the overlap is sufficient to have an improved joint strength in relation to a brittle adhesive alone. The taper and the fillet are only useful when the brittle adhesive is used alone. One of the problems associated with the mixed adhesive technique is the adhesive proper separation. The best way to control the process is to use film adhesives. However, it is difficult to find compatible adhesives in the film form. This is a problem for the manufacturers to solve. Meanwhile, the physical separation of the paste or liquid adhesives can be achieved by using polymer wires or with the use of silicone strips even though a small portion of the load-bearing area is necessarily reduced.

The technique of using multi-modulus adhesives has been extended to solve the problem of adhesive joints that need to withstand low and high temperatures by da Silva and Adams (2007b, c). At high temperatures, a high temperature adhesive in the middle of the joint retains the strength and transfers the entire load while a low temperature adhesive is the load-bearing component at low temperatures, making the high temperature adhesive relatively lightly stressed. The authors studied various configurations with the FE method and proved experimentally that the concept works, especially with dissimilar adherends. The work of Marques et al. (2011)

expanded the use of this concept demonstrating its use for even higher temperatures, using ceramic and metal substrates.

## 27.4.2 Adhesive Joints with Functionally Graded Materials

The mixed adhesive joint technique can be considered a rough version of a functionally graded material. The ideal would be to have an adhesive functionally modified with properties that vary gradually along the overlap allowing a true uniform stress distribution along the overlap. One of the earlier works attempting to achieve this effect was performed by Sancaktar and Kumar (2000). Their work used rubber particles to modify locally the adhesive at the ends of the overlap but this technique does not create a truly gradually modified adhesive. Gannesh and Choo (2002) and Apalak and Gunes (2007) have used functionally graded adherends instead of functionally graded adhesives. Gannesh and Choo (2002) used a braided preform with continuously varying braid angle and the variation of the braid angle measured to realistically evaluate the performance of adherend modulus grading in a single-lap bonded joint. An increase of 20% joint strength was obtained due to a more uniform stress distribution. Apalak and Gunes (2007) studied the flexural behavior of an adhesively bonded single-lap joint with adherends composed of a functionally gradient layer between a pure ceramic ( $\text{Al}_2\text{O}_3$ ) layer and a pure metal (Ni) layer. The study is not supported with experimental results and the adhesive stress distribution was not hugely affected. The work of Carbas et al. (2014) was the first to achieve joint strength improvements with a gradually modified adhesive. The authors have employed induction heating to achieve a gradually modified cure of the adhesive in single-lap bonded joints, reducing stiffness at the ends of the overlap and increasing it in the central section, with good results. This is an area that is still being intensively studied and where modeling at different scales is essential.

## 27.4.3 Rivet-Bonded Joints

Liu and Sawa (2001) investigated, using a three-dimensional FE analysis, rivet-bonded joints and found that for thin substrates, bonded joints, riveted joints, adhesive joints, and rivet-bonded joints gave similar strengths while for thicker substrates the rivet-bonded joints were stronger. They proved this experimentally. Later, the same authors (Liu et al. 2004) proposed another technique similar to rivet-bonded joints: adhesive joints with adhesively bonded columns. Strength improvements are also obtained in this case. The advantage of this technique is that the appearance of the joint is maintained in relation to an adhesive joint. Grassi et al. (2006) studied through-thickness pins for restricting debond failure in joints. The pins were simulated by tractions acting on the fracture surfaces of the debond crack. Pirondi and Moroni (2009) found that the adhesive layer strongly increases the maximum load and the initial stiffness in comparison to a joint with a rivet alone. When failure of the adhesive occurs, the joint behaves as with only a rivet.

#### 27.4.4 Bolted-Bonded Joints

Chan and Vedhagiri (2001) studied the response of various configurations of single-lap joints, namely bonded, bolted, and bonded-bolted joints by three-dimensional FE method and the results were validated experimentally. The authors found that for the bonded-bolted joints, the bolts help to reduce the stresses at the edge of the overlap, especially after the initiation of failure. The same type of study was carried out by Lin and Jen (1999).

#### 27.4.5 Weld-Bonded Joints

Al-Samhann and Darwish (2003) demonstrated with the FE method that the stress peaks typical of adhesive joints can be reduced by the inclusion of a weld spot in the middle of the overlap. They studied later (Darwish and Al-Samhann 2004) the effect of adhesive modulus and thickness and concluded that for rational design of weld-bonded joints, adhesives of low Young's modulus are recommended with the largest possible bondline thickness. Darwish (2004) also investigated weld-bonded joints between dissimilar materials and found that the introduction of an adhesive layer resulted in an increased joint strength and a better stress distribution.

---

### 27.5 Repair Techniques

Adhesively bonded repairs are generally associated to complex geometries and the FE method has been extensively used for the design and optimization of the repair, especially with composites. The literature review of Odi and Friend (2002) about repair techniques illustrates clearly this point. Typical methods and geometries are presented in Fig. 16. Among the various techniques available, bonded scarf or stepped repairs are particularly attractive because a flush surface is maintained which permits a good aerodynamic behavior. Gunnion and Herszberg (2006) studied scarf repairs and carried out an FE analysis to assess the effect of various parameters. They found that the adhesive stress is not much influenced by mismatched adherend layups and that there is a huge reduction in peak stresses with the addition of an over-laminate. Campilho et al. (2007) studied scarf repairs of composites with a cohesive damage model and concluded that the strength of the repair increased exponentially with the scarf angle reduction.

Bahei-El-Din and Dvorak (2001) proposed new design concepts for the repair of thick composite laminates. The regular butt joint with a patch on both sides was modified by the inclusion of pointed inserts or a "zigzag" interface to increase the area of contact and improve the joint strength.

Soutis and Hu (1997) studied numerically and experimentally bonded composite patch repairs to repair cracked aircraft aluminum panels. The authors concluded that the bonded patch repair provides a considerable increase in the residual strength.

**Fig. 16** Repair techniques

Tong and Sun (2003) developed a pseudo-3D element to perform a simplified analysis of bonded repairs to curved structures. The analysis is supported by a full 3D FE analysis. The authors found that external patches are preferred when the shell is under an internal pressure, while internal patches are preferred when under an external pressure.

## 27.6 Configurations Recommended for Various Types of Joints

In an ideal joint, the adhesive must be loaded in shear and the load-bearing area must be as large as possible. These are two golden rules for the design engineer. However, this is not always possible to achieve for any type of joint such as a T joint, for example. Design guidelines are given next for butt joints, lap joints, cylindrical joints, corner joints and T joints.

### 27.6.1 Butt Joints

The simplest joint to manufacture is the butt joint. However, this type of joint does not resist bending loads because that puts the adhesive in cleavage. In the case of thick adherends, the joint strength can be improved by using the designs represented in Fig. 17. All the modifications presented in that figure reduce the cleavage stresses in the adhesives. The tongue-and-groove joints are particularly efficient because they

**Fig. 17** Butt joints (Adapted from Petrie (2000))

are self-aligned and act as reservoir for the adhesive. Nakagawa and Sawa (2001) studied scarf joints using photoelasticity and a 2D FE model. One of the conclusions is that under a static tensile load, an optimum scarf angle exists, where the stress singularity vanishes and the stress distributions become flat near the edge of the interface, but under thermal loads, the optimum scarf angle is not found. Dvorak et al. (2001) showed with an FE analysis and experimental results that adhesively bonded tongue-and-groove joints between steel and composite plates loaded are stronger than conventional strap joints.

**27.6.2 Lap Joints**

Lap joints are the most common type of joint because they are easy to manufacture and the adhesive is mostly loaded in shear. However, the load is not collinear, especially in single-lap joints, and this leads to peel stresses at the ends of the overlap (see ► Chap. 24, “Analytical Approach”). Some solutions have been proposed in Sect. 3 to decrease the peel stresses for single-lap joints. Another solution is to alter the lap joint as shown in Fig. 18. The joggle joint is the simplest solution to have load aligned if the adherend is easy to deform. The double-lap joint has a more balanced construction, which decreases drastically the bending moment. However, even with this type of joint, there are internal bending moments that cause peel stresses at the ends of the central adherend, as shown in Fig. 19. Other more recent solutions include the “wavy” joint and the “reverse bent” joint. Ávila and Bueno (2004) analyzed the “wavy” configuration. An FE analysis and experiments show that great strength improvements can be obtained with this technique.

**Fig. 18** Lap joints

Fessel et al. (2007) also studied this type of joint as well as joints with bent substrates along the overlap. An FE analysis and experiments show great joint strength improvements. Sancaktar and Lawry (1980) also demonstrated with photoelastic experiments up to 71% increase in load-carrying capacity in single-lap joints with 15° prebent adherends.

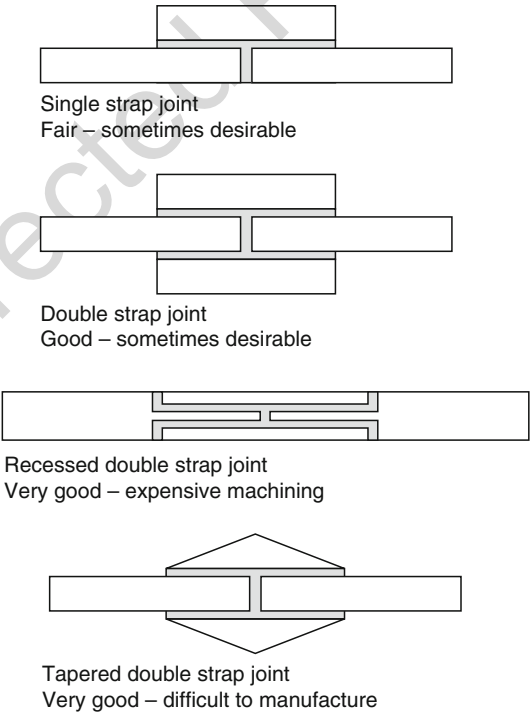

### 27.6.3 Strap Joints

Various configurations are presented in Fig. 20. As in the case of single-lap joints, the strap joint with only one strap is subjected to peeling stresses because the load is not collinear. The joint with two straps reduces the bending moment and is therefore stronger. The straps with a taper and the recessed joints are the most efficient but require a lot of machining. This type of joint is used in the context of repairs in the fuselage of aeronautical structures with patches made of aluminum or composite (Kaye and Heller 2005).

**Fig. 19** Peel stresses in the adhesive in a double-lap joint

**Fig. 20** Strap joints (Adapted from Petrie (2000))

**Fig. 21** Methods to decrease the peel in adhesively bonded joints with a thin adherend and a rigid base (Adapted from Kohen (1954))

#### 27.6.4 Reinforcements

The loading of joints where a thin plate is bonded to a thick component leads generally to peel, as shown in Fig. 21a. Figure 21b–c present solutions to reduce the peel by increasing the resistant area. It is also common practice to bond reinforcements to the thin adherends in order to increase its rigidity. However, in this case, the bending loads can induce cleavage in the adhesive. In Fig. 22, some solutions are presented to reduce the cleavage of joints with reinforcements. The joint strength can be improved with increases in the bonded area, the flexibility of the edges, and the rigidity of the base.

#### 27.6.5 Cylindrical Joints

Adhesive bonding is very convenient to bond tubes. The loading can be axial or in torsion. In case of axial loading, there are stress concentrations at the ends of the overlap as in lap joints with plane adherends. In the case of torsion, there is only the effect of differential straining. In the case of axial loading, the square end can be substituted by a taper, as shown in Fig. 23. Figure 24 presents some cylindrical joints that are commonly used in bars and tubes. These solutions are advantageous in

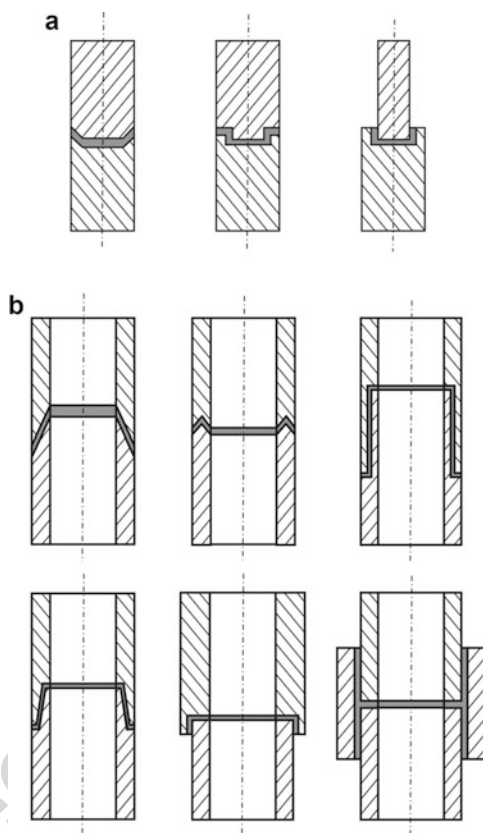

**Fig. 22** Solutions to decrease the cleavage in joints with a reinforcement (Adapted from Kohen (1954))

**Fig. 23** Tubular joint with square end (a) and with a taper (b)

**Fig. 24** Cylindrical joints with bars (**a**) and tubes (**b**) (Adapted from Petrie (2000))

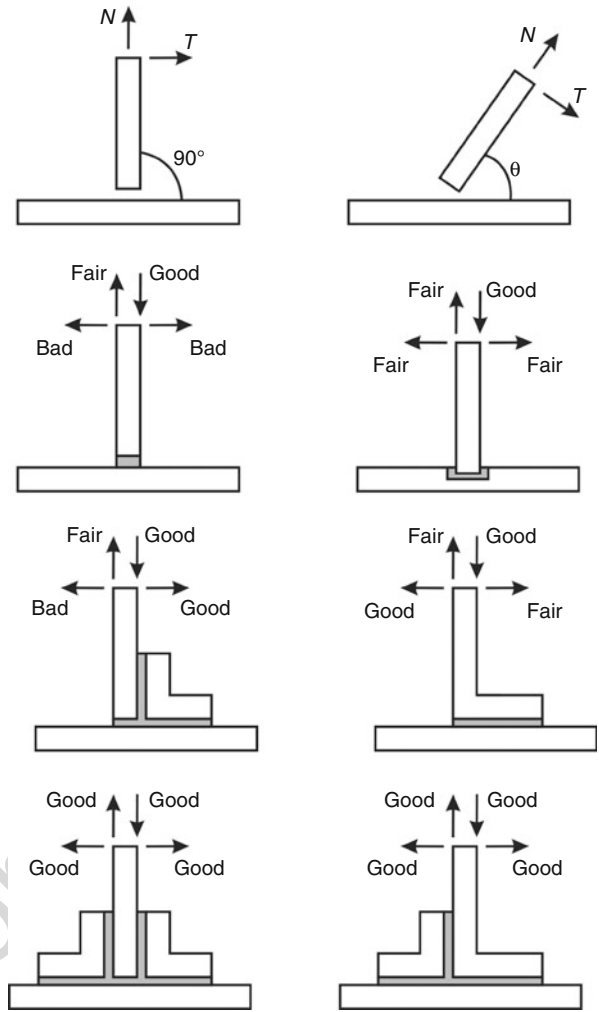

relation to the butt joints because a larger bonded area is obtained and the peel stresses are reduced. However, most of the solutions presented in Fig. 24 require heavy machining, which obviously renders the process expensive.

Several analytical models can be used to find the optimum design such as those of Lubkin and Reissner (1956) for tubular joints under axial loading and Adams and Peppiatt (1977) for torsion. Other loading modes have also been studied: internal and external pressure (Terekhova and Skoryi 1973) and asymmetric moments and forces (Kukovyakin and Skoryi 1972). Kim et al. (1992) studied various configurations of tubular joints (single overlap, double overlap, adherends tapering) and found with an FE analysis and experimentally that the double-lap configuration is the strongest joint.

## 27.6.6 T Joints

In T joints (see Fig. 25), two adherends are orientated perpendicularly ( $\theta = 90^\circ$ ). However, components with an orientation different from  $90^\circ$  are also included

**Fig. 25** T joints (Adapted from Adams et al. (1997))

in this type of joints. The loading can be in the plane of the plate ( $N$ ) or transverse to it ( $T$ ). The analysis of this type of joint is more difficult than lap joints or tubular joints and there are no analytical models for design purposes. Some configurations are presented in Fig. 25. The main objective of the proposed solutions is to minimize the peel loading and increase the shear loading. da Silva and Adams (2002) have shown experimentally that a strong base decreases the peel in the adhesive and enables to increase drastically the failure load in relation to a flexible base. Apalak (2002) studied the geometrical nonlinear response of T joints and obtained similar results. Design guidelines are given in terms of the length of the support, fillet, and other geometrical factors. Marcadon et al. (2006) studied T joint for marine applications and found that both the

overlap length and also the distance between the T plywood and the base have an influence on the tearing strength.

### 27.6.7 Corner Joints

Corner joints are similar to T joints. Figure 26 presents the solutions usually used to decrease the peeling stresses in the adhesive. These solutions are similar to those adopted for T joints. More elaborate constructions are presented in Fig. 27 proposed and tested by Keimel (1966). Apalak and Davies (1993) studied different types of corner joints using a linear FE analysis and proposed design guidelines based on the overall static stiffness and stress analysis. They found that in terms of stress and stiffness, the transverse loading ( $T$  in Fig. 26) is the most critical. The support length, the thickness, and length of the reinforcements increase the stiffness of the joint and decrease the peak stresses at the adhesive. Feih and Shercliff (2005) modeled simple corner joints with composites. Experimental testing showed an increase in joint strength of up to 100% by altering the fillet shape.

---

## 27.7 Conclusions

Simple design rules for single-lap joints were proposed as a function of the main variables that influence joint strength: adhesive and adherend properties, adhesive thickness, overlap, and residual stresses. The main rules are:

- Use an adhesive with a low modulus and high ductility
- Use similar adherends whenever possible
- Use a thin adhesive layer
- Use a large bonded area

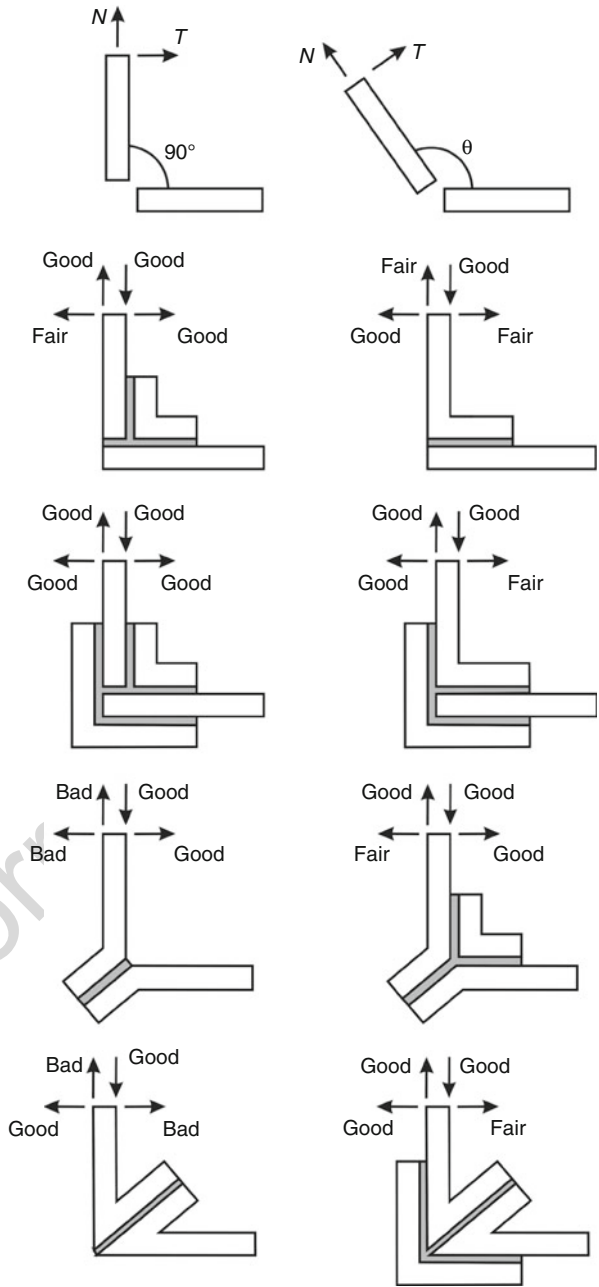

Several methods to increase the joint strength were discussed for lap joints: fillets, adherend shaping, and other geometric solutions. The designer should always bear in mind that when designing an adhesive joint, the load must be spread over a large area and not concentrated in one point. Peel loads are the greatest enemy of the designer of bonded joints.

Adhesive in conjunction with other methods of joining were explained: rivet, bolt, and welding. The idea is to get a synergetic effect and combine the advantages of two methods. Mixed adhesive joints and functionally graded joints are also very promising techniques.

Various types of repairs are discussed in order to obtain the maximum strength recovery. The scarf joint is particularly efficient and aesthetically attractive.

Finally, configurations are recommended for various types of joints: butt joints, lap joints, reinforcements, T joints, and corner joints. The philosophy behind all the designs is to spread the load over a large area and decrease the peel stresses.

## Abstract

This chapter describes the many factors to go into the design of reliable sealant joints. Common causes of sealant joint failure are addressed. The various joint types are discussed and illustrated, and their critical dimensions and materials are described. Sealant properties critical to joint assembly, cure, function, reliability, and aging are discussed. These include chemical, physical, mechanical, and adhesion properties. Proper measurement of these properties is also presented. Finally, calculation of the differential movement of the substrates in a sealant joint, the accommodation of which is the primary mechanical requirement of a sealant joint, is discussed.

## 28.1 Introduction

The use of sealant joints is prevalent in building design and construction, aerospace, automotive, electronics, tank fabrication, and construction industries. There are two major purposes of sealants in joints: (1) the sealant fills space, creating a seal, and must maintain that seal throughout the useful life of the structure; and (2) the sealant provides a barrier to the transfer of fluids. Secondary functions of sealants can include electrical and/or thermal insulation, noise reduction, vibration dampening, surface smoothing, providing a protective coating, and providing protection from tampering. There is an important distinction to be made between an adhesive joint and a sealant joint. Whereas adhesive joints are designed to inhibit the movement of the substrates, sealant joints are designed to allow and accommodate the inservice movement of the substrates.

Proper design of sealant joints is critical to the reliability of the joints. The general types of sealant joints and the critical geometric parameters that must be considered in joint design will be discussed in detail. Because the proper selection of materials is absolutely critical to the reliability of sealant joints, the critical sealant properties will also be discussed.

When designing sealant joints, an understanding of the most common causes of sealant joint failure is important in order to eliminate as many of the causes as possible. The four most common causes of sealant joint failure are: poor adhesion of the sealant to the substrate, poor joint design, poor workmanship in creating the joint, and aging. Poor joint design will be eliminated through the proper selection of sealant material and joint critical geometric parameters discussed in later sections. Aging is a function of sealant material selection and the selection of other materials that go into a sealant joint. Chemical compatibility among the various materials is essential to the long life of a sealant joint and will be discussed in detail in Sect. 3.

Achieving adequate adhesion of the sealant to the substrates is normally accomplished by ensuring that there is nothing on the substrate surfaces to inhibit or preclude a strong bond. This not only means ensuring that the bond surfaces are dry and free from oil, other contaminants, or from release agents (especially important when bonding to concrete), it also means that the surface must be free from dust and loose, friable material at the substrate surface. Elimination of loose substrate material at the bond surface may require a fresh cut of masonry or concrete. Many primers applied to porous substrate bond surfaces reinforce the substrate and fix any remaining loose material strongly to the surface.

Excellent surface preparations for porous surfaces include blasting with oil-free compressed air, abrasive media, or high pressure water (dry time is a must in this case) and grinding or wire brushing followed by oil-free dry compressed air blasting. For nonporous substrates, solvent wiping with clean cloth following immediately by a clean cloth dry wipe is the preferred approach. Solvent wiping of porous substrates is not recommended, because the solvent can wash the contaminant into the porous substrate where it is free to diffuse back to the surface or interface over time.

In addition to substrate bond surface preparation, poor workmanship can also negatively affect mixing and insertion of the sealant into the joint. Thorough mixing is important for solvated or waterborne sealants and two-part sealants. Thorough mixing of the solvated and waterborne systems ensures even distribution of the sealant within the solution, and improper mixing can lead to less than adequate sealant remaining in the joint. Improper mixing of two-part systems will lead to the areas of uncured sealant that will not reliably perform as a fluid barrier. Insertion of the sealant needs to be done by forcing the sealant into the joint so that it fills the space and wets the substrate surfaces. In order for this to be accomplished well, the sealant must be forced to flow into the joint in advance of the applicator. Following application of the sealant, it is also good practice to tool the sealant, i.e., push the sealant into the joint using a convex-shaped screed. Tooling the surface further compresses the sealant against the substrate surfaces, creates an attractive smooth sealant surface, and creates a slight concavity to that surface which is beneficial from a structural design standpoint.

An additional note of caution is given at this point regarding the application of sealant at low temperature. At the temperatures lower than normal use temperature, the joint will be more open than normal. Care should be taken to tool the sealant surface sufficiently to avoid extrusion of the cured sealant from the joint at normal operational temperature. Also important is the fact that at lower temperatures, the sealant cure rate or solvent evaporation rate will be slower. This will likely require additional fixturing time to not disturb the joint prematurely. Finally, water-based sealant emulsions should always be kept above 5 °C to avoid freezing.

In addition to this text, there are several other references dealing with the design of sealant joints (Amstock 1973; Prane 1977; Panek and Cook 1984; Petrie 2007). Also, ASTM International has a written standard on the use of sealants in joints, standard C-1193.

---

## 28.2 Joint Types and Their Critical Dimensions

There are four main types of sealant joints with variations within each type. They are butt joints, lap joints, angle or corner joints, and seam or edge joints. The two most prevalent are butt and lap joints. Both are used for joining substrates parallel to one another. In selecting one over the other, one must consider access to the joint for sealant insertion. Because the butt joint is more accessible, inserting the sealant into a butt joint is generally easier to do. An exception to this is joining substrates in a factory where at least one substrate can be readily moved into place after applying sealant to the other substrate. In such factory-made sealant joints, accessibility is not an issue. For much of sealant joint assembly in the field, accessibility dictates the use of butt joint. Where practicable, however, the lap joint has better weather and environment protection of the sealant than the butt joint.

Each of the four joint types and their variations will now be discussed. The critical dimensions and supporting materials crucial to the joint design will also be discussed.

## 28.2.1 Butt Joints

Common butt joints are depicted in Fig. 1. In all its variations, the substrates of a butt joint are both parallel and aligned. The overriding design feature of the simple and complex butt joints is that there must be sufficient sealant in the joint to handle the joint elongation and contraction and the recovery of the sealant following the extremes of elongation and contraction. It is also extremely important to understand that even though the load on the sealant can be unidirectional in line with the substrates, the stress state in the sealant, especially at the interfaces of the sealant with the substrates, is highly complex.

Sealants are in general nearly incompressible. Thus, they will change their shapes to accommodate the joint expansion or contraction, but they will not change their volume. Because the sealant remains firmly fixed at the substrate bond interfaces, it is the center region of the sealant in a butt joint that deforms the most when the joint is loaded. Correspondingly, the stresses are the highest at the edges of the bond surfaces where the restriction of the deformation is the greatest, as depicted in Fig. 2. In fact, bondline stress is a function of the elongation of the sealant-free surface, increasing with increasing elongation. As can be seen in Fig. 2, deeper butt joints have significantly higher bondline stresses than shallow butt joints, because the increased volume of sealant requires increased sealant-free surface elongation in order to maintain a constant sealant volume.

Two other design considerations are pertinent to generalized width versus depth guidelines for reliable simple sealant butt joints. At very low depths, there is usually insufficient bond area of the sealant to the substrates to have reliable adhesion. On the other hand, at very large width-to-depth ratios, buckling of the sealant can occur when the joint contracts. This can cause the sealant to be extruded from the joint where abrasion of the sealant can occur, drastically reducing the sealant life. Extruded sealant can also be a safety hazard in some instances.

With these design considerations in mind, the following are standard guidelines for the preferred depth of the sealant as a function of the joint width:

**Fig. 1** Butt joints: (a) simple thin-substrate butt joint, (b) simple thick-substrate butt joint, (c) compound butt joint, (d) sealant bead seal, and (e) sealant tape seal

**Fig. 2** Sealant deformation in simple shallow and deep butt joints subjected to elongation

- For width less than or equal to 0.5 in (13 mm), the depth should be equal to the width, but not less than 0.25 in (6 mm)
- For width greater than 0.5 in (13 mm) and less than or equal to 1 in (26 mm), the depth should be 0.5 in (13 mm)
- For width greater than 1 in (26 mm), the depth should be half the width

There are other practical considerations regarding the maximum width desirable. Sealant slump from the joint can occur in shallow simple butt joint geometries. The tendency of the sealant to slump increases as the joint width increases. Also, some sealants either require moisture to cure or require solvent evaporation for the sealant to set. With these materials, increased time is required for sealant solidification to occur. This increases the tooling time and the overall manufacturing time.

In order to regulate the depth of the sealant fill, the butt joint gap must have a bottom. Having a bottom is also important from two practical standpoints: it ensures the sealant properly flows into the joint – forcing sealant to flow into the joint ahead of the applicator, and it forces the sealant to wet out the substrate bond surfaces for good adhesion. Creating a bottom in a simple butt joint is accomplished by inserting backing material (or backing rod) into the joint to the proper depth. Materials commonly used for this application are typically soft and resilient such as closed- or open-cell urethane foams, closed-cell butyl rubber or polystyrene foams, polyethylene rod or solid rods of neoprene, or butyl rubber. A desirable feature of the backing material is that it creates a water barrier as a secondary seal in case of sealant joint failure. Open-cell backing materials may be needed for many one-part sealant systems that require moisture exposure to initiate cure even though the open-cell structure does not provide a moisture barrier. Closed-cell backing materials have the added benefit that they hold their shape better, ensuring that they remain in place

during sealant insertion. A commonly used backing material good for most applications is closed-cell polyethylene foam rod, which provides a nonadhering surface for the sealant, doesn't slip after placement, and forms a moisture barrier. In order to keep the backing material from slipping, closed-cell foam rods should have a diameter 25–35% greater than the joint opening, and open-cell rods should have a diameter 40–50% greater than the joint opening.

There are two important chemical considerations in selecting a backing material. The selected material must be chemically compatible with both the substrate and sealant materials and the sealant carrier solvent in solvated sealant systems. There should also be a minimum amount of chemicals that can diffuse from the backing material over time in order to preclude staining of the sealant.

An issue with complex butt joints and simple butt joints containing backing material is termed three-sided adhesion. If the sealant is allowed to bond to the backing material or the bottom member (in the case of the complex joint), the sealant will be bonded on three sides. This allows sealant deformation on only one surface. Because of the incompressible nature of sealants, the elongation under joint extension subjected to the free surface of the sealant and the consequent bondline stress at the sealant-free surface corners is roughly doubled in comparison to sealant joints bonded on just the two sides. This will likely result in peeling of the sealant from the substrate surface, destroying the joint seal. In order to avoid this, the adhesion of the sealant to the backing material should be minimal. In the case of complex butt joints, bond breaker material (typically polyethylene or Teflon™ film or tape or a carefully applied chemical release agent) is applied to the surface of the bottom member of a complex joint that will contact the sealant. Teflon™ film is easily placed in position, but care must be taken to ensure that it stays in place during sealant insertion. Liquid release agents can be easily painted onto the appropriate surface. Aerosol release agents should be used with caution. While they are easily applied to the surface prior to securing the bottom member in place, application with the bottom member already in place requires careful masking of the bond surfaces of the two substrates. Use of bond breaker materials is especially critical in joints with large gap widths subjected to significant joint opening.

It is mechanically advantageous to create an hourglass shape in the sealant of a butt joint (see Fig. 1b) prior to sealant solidification. This will allow greater deformation at the center of the sealant during its operational life, transferring less stress to the bondline when the joint expands. The hourglass shape is achieved by using a rod-shaped backing material to produce a concave bottom surface and by tooling the exposed upper surface. Care should be taken to keep the tooling concavity to 1/8 in (3 mm) in order to preclude buckling of the sealant in the center when the joint contracts.

### 28.2.2 Lap Joints

Sealant is used in lap joints in two different ways. Sealant may be used between the two parallel off-set substrates forming a sandwich lap joint similar to adhesive in adhesive lap joints. A bead of sealant may also be used as a fillet or a sealant tape can

be applied that spans both substrates at the end of the joint to provide a fluid barrier. These variations of sealant use in lap joints are shown in Fig. 3.

For the sandwich lap joint, the substrates must be held in place during sealant cure or setting. This can be done with mechanical fasteners such as rivets or bolts. In the automotive industry, specially formulated sealants are used that allow spot welding through the sealant layer as a means of greatly increasing the manufacturing rate. In Fig. 3, rivets are shown as the fixturing mechanism. The elongation of the sealant-free surface in a sandwich lap joint can be easily calculated as shown in Fig. 4 (Thompson 1990). If the differential movement of the two substrates in termed  $M$ , and the thickness of the sealant is termed  $d$ , then the sealant-free surface length after the differential movement ( $d'$ ) is given by the following relationship:

$$d' = (M^2 + d^2)^{1/2}, \quad (1)$$

and the elongation of the sealant-free surface ( $e$ ) is:

$$e = (M^2 + d^2)^{1/2} - d. \quad (2)$$

This relationship shows the importance of the sealant layer thickness. By increasing the thickness, higher differential movement can be accommodated in a sealant with a given elongation capability or extensibility.

If one makes the simplifying assumption that the shape change in a butt joint can be neglected (valid only for small substrate movements), one can easily compare the free-surface elongations of sealant in a butt joint with that in a sandwich lap joint. For example, if the differential movement in the joints is 1/8 inch (3 mm) and the thickness of the sealant in a sandwich lap joint or width of the sealant in a butt joint is 1/4 inch (6 mm), the sealant-free surface elongation in the lap joint is 12 percent compared with

**Fig. 3** Lap joints: (a) sandwich, (b) sealant bead fillet with bond breaker, (c) sealant bead fillet with backing material, and (d) sealant tape fillet

**Fig. 4** Free sealant surface elongation ( $d'$ ) in a sandwich lap joint

50 percent for the butt joint. When one considers that the sealant shape change in the butt joint increases the free-surface elongation, the difference is even greater.

From this simple relationship, it is seen that the sealant-free surface elongation is always significantly less in the sandwich lap joint than that in the butt joint. Thus, from a mechanical perspective, the use of the lap joint is preferable. It is mainly the accessibility of the sealant in the butt joint that makes it preferable in main practical situations.

When using a sealant bead as the sealing fillet, the use of backing material or bond breaker can reduce the sealant bondline stresses, greatly enhancing the reliability of the joint. In order for sealant tapes to be effective, the tape must form a moisture or fluid barrier and resist chemical attack by the moisture or fluid. The bond of the pressure-sensitive adhesive used to bond the tape to the substrates is typically very sensitive to the surface condition of the substrate. Ensuring that these bond surfaces are clean, dry, and dust-free will usually ensure a good sealant tape bond and a subsequent seal. It is important to consider that sealant tape provides only a two-dimensional seal as opposed to the three-dimensional seal of a sealant bead fillet. Thus, a breach in the tape seal can allow fluid exposure to the entire joint length, whereas a bead fillet breach allows only local fluid exposure.

### 28.2.3 Corner or Angle Joints

When corners of structures need to be sealed, a designer has several options. These are shown in Fig. 5. If the thickness of the substrates is sufficient, it may be possible to use a butt joint with proper backing material. This is termed a simple angle or corner joint in Fig. 5. Although simple to make, there are usually better options from a structural point of view in cases where the sealant loading is significant. Applying a sealant bead fillet on the interior corner allows the substrates to support the sealant material, increasing performance of the joint. This type of joint is especially useful in

**Fig. 5** Corner or angle joints: (a) simple, (b) sealant bead with bond breaker, (c) sealant bead with backing material, (d) sandwich seal supported, and (e) bead seal supported

tank fabrication. By placing the sealant bead internal to the tank, the fluid pressure acts to augment the seal. Because the opposite is also the case, a designer should not use a sealant fillet on the outside of a tank. When using a sealant bead, proper use of bond breaker or backing rod materials reduce bondline stresses significantly. Supported corner joints can also be sealed with a sealant bead on the interior of the joint. By using the sealant in a sandwich configuration between the corner-forming substrates and the support, a lap-like sealant joint is formed. Although this joint geometry can be more labor-intensive to create, the structural benefits of a lap joint are inherent in this design geometry.

**28.2.4 Seam or Edge Joints**

The use of sealants and sealant tapes in seam or edge joints requires only that a seal be created and maintained. In this type of joint, there is no significant differential movement between the substrates. Figure 6 shows the four different methods available for sealing a seam. The most fail-safe method is pressing putty into the internal seam opening. As in the corner or angle joint, the internal fluid pressure will tend to enhance the seal in this type of joint. The other method for creating an internal seal is to apply a sealant tape that spans the two joined substrates. The use of sealant tape in this geometry carries with it the same limitations and required bond surface cleanliness as in the lap joint case.

**Fig. 6** Various uses of sealants in seam or edge joints

## 28.3 Critical Sealant Properties

There are many sealant properties that are critical to the design and assembly of reliable sealant joints. These critical properties include chemical, physical, and mechanical aspects of the sealant material.

### 28.3.1 Chemical Properties

Critical chemical properties of sealants include cure rate and its related properties of pot life, working life, tack-free time, depth of cure and skinning, cure shrinkage, chemical resistance, and weatherability. Chemical compatibility is also a major issue that must be addressed.

The rate of the cure reaction affects sealant use in different ways depending on the cure mechanism. For two-part sealants in which a curing agent is mixed into the sealant base, the rate of cure determines the allowable time between mixing and when the sealant must be inserted into the joint. Two different terms are used for this allowable time: pot life and working life. The pot life is typically determined from viscosity measurements and is often considered to be the time between the end of the mixing operation and the point at which the initial end-of-mix viscosity doubles in magnitude. Working life is typically determined by monitoring the ability of the sealant to be spread onto a substrate surface and wet that surface properly. Thus, the working life is a more subjective measurement than the pot life, but it is more representative of the actual use of the sealant.

The rate of cure for a one-part sealant material in which cure is initiated upon contact with moisture is important in determining the depth of cure. One-part sealants cure from the outer surface that is exposed to surface or environmental moisture, and the cure proceeds inward, toward the center of the sealant material. Curing beyond the outer surface depends on moisture diffusing into the sealant material. This diffusion process is slowed significantly or stopped completely when the sealant cures sufficient to create the desired “tight” moisture barrier. Because the sealant underneath the cured surface remains uncured due to the exclusion of water from the bulk of the sealant, the phenomenon is often called “skinning.” Once the sealant forms a cured skin, only the water molecules already within the sealant will be able to initiate further sealant cure. After consuming the available water molecules in additional sealant cure, no water is available to drive to cure to completion. In this way, the rate of reaction determines the maximum depth of cure by setting a limit to the amount of cure-initiating water that can diffuse into the sealant.

For solvated sealant formulations that require diffusion of the solvent or water to the surface of the sealant where it can evaporate, solidifying the sealant, diffusion, and evaporation rates are also important in determining the depth of sealant that can be fully solidified. Rapid loss of solvent or water at the sealant surface can create a skin not unlike that in the curing sealant system. In this case, the skin prohibits or significantly slows the further diffusion of solvent or water from the bulk of the sealant to the sealant surface where it can evaporate. This keeps the bulk of the sealant from solidifying, effectively creating an analogous depth of cure.

The tack-free time is that time necessary to cure or solidify the sealant to a sufficient degree that the surface is no longer sticky or tacky. This occurs near complete sealant surface cure or solidification. Tack-free time is especially important in sealant joints where physical appearance is important. Until the point where the surface is no longer tacky, the sealant surface must be kept dust free in order to preclude dust from sticking to the surface and ruining the appearance of the joint. The tack-free time is also often used as the time required before the joint has achieved sufficient handling strength to allow manufacturing or assembly with the sealant joint to continue.

Cure shrinkage is important to the structural capability of sealant joints. If cure shrinkage is excessive it may cause the sealant to pull away from the substrate surface, thus destroying the seal. In less dramatic fashion, cure shrinkage in joints where the seal is not broken creates stress and strain on the sealant that is additive to the thermal and structural loads that the sealant must accommodate to maintain the seal of the joint. Cure shrinkage in sealants that solidify through a chemical reaction is typically less than 10%. Shrinkage occurring in solvent-borne sealants can be greater than 10% as the sealant solidifies. It is in these sealants systems that shrinkage can be especially detrimental to the reliability of the joint seal.

The resistance of the sealant to chemical and environmental attack is the principal property that determines the ultimate life of most sealant joints. During the life of a sealant joint, the sealant may be subjected to hot and cold temperature extremes, thermal cycling, moisture, and UV and solar radiation. Many sealants are also exposed to chemicals such as petroleum-based fuel, alkali or acidic solutions or fumes, ozone, and salt water spray. Chemical and/or environmental exposure can cause sealants to soften, harden, contract, swell, embrittle, crack, craze, and dissolve or disintegrate. Such exposure can also inhibit sealant solidification or cause the sealant to debond from the substrate.

Solar radiation causes the most widespread damage of sealants used outdoors. The majority of this damage is in the form of breaking chemical bonds within the sealant polymer molecules. Water and water vapor can degrade sealants chemically by hydrolysis of the chemical bonds or physically by cyclical swelling and contracting of the sealant caused by moisture absorption and desorption (Wolf 2009).

In general, polysulfide sealants resist attack from fuels and water and have good chemical resistance. Polyurethane sealants are especially resistant to alkali exposure. Polyurethane, acrylic, and polychloroprene (neoprene) are all moisture-resistant. Polychloroprene and butyl rubber sealants both have good general chemical resistance. Silicones, although expensive, are often the sealant of choice, because they are strongly resistant to moisture and all chemicals. Silicones are also the most resistant sealants to UV and solar radiation.

Chemical compatibility among the various materials used in a sealant joint is also paramount to a long life for the joint. The sealant and substrates must not only be chemically compatible, but the choice of primer, bond breaker, and backing materials, where used, must take into consideration the chemical compatibility. The most typical offenders when it comes to chemical compatibility are plasticized sealants that contain species that are not chemically bound within the sealant and are free to diffuse into other surrounding materials (e.g., butyl rubber) and solvated sealants.

The cure reaction for many silicone sealants is initiated by acid added at low levels to the sealant formulation. Acids are chemically incompatible with concrete, marble, and limestone. When acid-containing silicone sealants are used in joints with these substrate materials, the acid reacts with the substrate bond surfaces creating salts at the bond interface. These salts destroy the sealant/substrate adhesion and cause debonding and loss of the seal. In order to use a silicone sealant with these substrates, a silicone formulated without acid is required. Another known chemical incompatibility is silicone and polychloroprene. Use of these two materials together in a sealant joint is to be avoided. Solvated sealant use in joints containing plastic or rubber materials should be undertaken only after chemical compatibility studies of the sealant with these materials are performed. Typical incompatibility will manifest itself over time by causing the sealant or substrate to soften, harden, crack, and/or craze. A standard test method for determining chemical compatibility is ASTM D-471.

### 28.3.2 Physical Properties

The important physical properties of sealants include the rheology, permeability, hardness, and thermal capability. They are distinct from the mechanical properties which are material responses to external loading.

Rheology refers to the fluid character of a material. There are two basic fluid forms of sealants: self-levelling and non-sag. Self-levelling sealants have sufficiently low viscosity to allow the sealant to flow and create a horizontal free surface. Non-sag sealants are typically thixotropic, or shear thinning. At high rates of shearing, these materials have low viscosity relative to their viscosity at low rates of shearing. Thus, a non-sag sealant will exhibit lower viscosity when being mixed – allowing thorough mixing, but will exhibit a high viscosity that allows the sealant to stay in place and hold its form once the mixing is completed and the material is inserted into the joint. There are two important standards relating to fluid sealant rheology. ASTM C-639 standardizes the differentiation between self-levelling and non-sag fluid sealant designations. The quantification or measurement of the degree of sag-resistance is covered in ASTM D-2202.

Some sealants have a very high viscosity under all conditions. These putty-like sealants are often called mastics. A formal definition of a mastic material is a fluid with a viscosity greater than 500,000 cP.

Permeability, a measure of the ease with which fluids can move through a solid material, is a critical characteristic of sealants. Because all sealants have low permeability, permeability is typically not a selection criterion in choosing among various sealant formulations. Measurement of permeability can be difficult, and there is no standardized method for measuring permeability that is specific to sealants. Therefore, the designer is usually left to using the permeability data available in the technical data sheets for specific sealant formulations.

The thermal capability of sealants can often be a crucial selection criterion. Both the temperature extremes that a sealant will experience over its lifetime and the daily and seasonal fluctuations of temperature can be important. For exterior sealant joints,

the joint may typically see 25 °C temperature differences within a day and upward of 50 °C temperature seasonally. External joints loaded primarily by the thermal expansion and contraction of the substrates will experience tension in the cold winter months and compression in the hot summer months.

The upper temperature limit is especially critical, because it is at higher temperatures that sealant materials soften and/or break down, leading to failure of the sealant joint. Determination of thermal capability of sealants is standardized in ASTM D-573. As a rule of thumb, acrylic and polysulfide sealants are generally good to 95 °C, while silicones can usually handle 200 °C. A special class of fluorosilicone sealants can operate to temperatures as high as 260 °C.

On the lower end of the temperature capability, the glass transition temperature can be important. When the temperature drops below the glass transition of the sealant, the sealant acts like an adhesive, rather than a sealant, restricting the movement of the substrates. Low temperatures also cause the sealant in butt joints to be loaded in tension due to thermal contraction of the substrates. When the temperature drops below the glass transition of the sealant, the tensile stress in the sealant, the bondlines, and the substrates increases tremendously. This can result in failure of any of the three.

Typical values for the glass transition temperature of acrylic and polyvinyl acetate sealants are in the range -15 °C to -20 °C. The glass transitions of neoprene and fluoro-polymer sealants range from -22 °C to -32 °C. Polysulfide and polyurethane sealants exhibit glass transitions at approximately -40 °C. Silicone sealants have the best low-temperature performance with glass transitions of approximately -65 °C.

Hardness is a very important property of a sealant. Changes in hardness over time reflect chemical changes internal to the sealant. Hardening can indicate that additional cure or solvent or plasticizer loss is occurring. Softening can be indicative of chemical or physical breakdown of the sealant. Due to these factors, measuring the hardness of the sealant over time is important to monitoring its useful life.

Hardness is inversely related to the flexibility of the sealant. Flexibility is, of course, crucial to a functioning sealant joint where substrate movement is accommodated. From this standpoint, low hardness is good. However, softer materials tend to have low resistance to abrasion and tearing. Depending on the requirements of a given sealant joint, the sealant selection may be preferential to softer or harder sealant formulations.

Because hardness is easy to measure and indicative of many performance capabilities, hardness is typically used as a quality conformance test. ASTM standards C-661 and D-2240 govern hardness measurements.

### 28.3.3 Mechanical Properties

Mechanical properties of sealants are those properties that define how sealants react to external loading. It is important to keep in mind that sealant materials are viscoelastic in nature; thus, many of these critical properties are rate and temperature dependent.

The tensile strength of a sealant is typically measured using a specimen commonly referred to as a dogbone. Tensile strength determination has been standardized in ASTM D-412. Also covered in this standard are determinations of the elongation capability of sealants and their modulus of elasticity. The elongation capability is the maximum extension a sealant will accommodate prior to rupture, and it is usually expressed as a percentage of the original length. Elongation is such a critical parameter for sealants that ASTM C-920 uses this property to classify different sealants. For example, a sealant that can elongate between 12.5% and 24% is termed a Class 12.5 sealant, while one that can elongate more than 25% is a Class 25 sealant. Measurement of the elongation is fairly simple. Sealants have such low stiffness that the crosshead displacement of the test device can be used for the elongation measurement without resorting to the use of extensometers or strain gages. Use of electromechanical extensometers or strain gages is not appropriate for sealants, because their use significantly affects the measured values. Laser or optical extensometers should be used when higher precision measurements are desired.

The technical term for stiffness is modulus of elasticity or Young's modulus. The modulus of elasticity is defined as the ratio of stress to strain. The stress is the load applied to the specimen divided by its cross-sectional area. The strain is the ratio of the extension or elongation of the specimen divided by its original length. It is the low modulus of elasticity of sealants combined with their high elongation capability that allows them to accommodate the differential movement of the substrates. In comparison with adhesives that are used in joints to restrict the substrate movement, the modulus of elasticity is typically one or two orders of magnitude smaller, and the elongation capability is 2–10 times greater.

The modulus of a sealant can change dramatically over time due to environmental or chemical exposure, additional cure, or solvent diffusion and evaporation from solvated sealants. Additional cure or solvent loss leads to increase in the modulus of the sealant over time. With increasing modulus, the ability of the sealant to accommodate the differential movement of the substrates is reduced. Environmental and chemical exposures of sealants tend to reduce the modulus over time. This would not typically be a problem, if all other properties remained the same. Unfortunately, they do not. The reduction in modulus is typically brought about by chemical degradation of the sealant, making the sealant more permeable and less able to maintain a seal. With enough degradation, the cohesive strength of the sealant and the adhesion of the sealant to the substrates will deteriorate.

The compressive strength of sealants is the maximum compressive stress a sealant can withstand without deteriorating. Although compressive strength is an important property, the tensile strength is generally lower and can be used as a conservative estimate of the compressive strength. For this reason, and also because failure of a sealant loaded in compression is much more difficult to determine than failure under tensile loading, there is no ASTM standard for determining the compressive strength of a sealant. To perform compressive strength testing, a short cylinder molded from sealant can be used. Care should be taken to keep the length-to-diameter ratio near one to avoid buckling of the cylinder during testing. Careful review of the load versus displacement data can reveal the failure load or the load at which the sealant starts to deteriorate.

Compression set is a term relating to the inability of many sealants to recover to their original dimensions following prolonged compressive loading. Compression set is not a favorable property, and it is very undesirable property in cases where the sealant joint is subjected to cyclic loading. Thus, fatigue resistance can be directly related to compression set. Compression set usually occurs in sealant formulations that cure slowly over time or that degrade over time due to environmental exposure. In general, oleoresinous caulking compounds and polybutene-based sealants are very susceptible to compression setting, while polysulfides, polyurethanes, and silicones are not. Acrylic, butyl rubber, and polychloroprene (neoprene) sealants can experience compression setting depending on the magnitude of the compressive load and the environmental conditions.

Tear and abrasion resistance are related properties. The measurement of both is standardized in ASTM D-624. As was stated earlier, harder materials, in general, exhibit greater resistance to both tearing and abrasion. Polyurethane sealants are particularly resistant to tearing and abrasion.

Stress relaxation is defined as the time-dependent relaxation of stress in a material subjected to a fixed displacement. Stress relaxation is observed in all viscoelastic materials and is directly related to creep. Creep is the time-dependent elongation of a material subjected to a fixed load. Excessive creep can result in failure of a material when the elongation due to creep exceeds the elongation capability of the material. The term for this type of failure is creep rupture. The magnitudes of creep and stress relaxation that a material will experience are inversely proportional to the crosslink density of the material. Creep rupture generally occurs in materials that do not crosslink or that have a very low-crosslink density. Stress relaxation testing can be performed using dogbone specimens subjected to a given elongation, typically between 20% and 80% of the elongation capability of the material.

### 28.3.4 Adhesion

The overriding consideration with respect to the adhesion of sealants is that the sealant and surface preparation should be selected to ensure that the adhesion strength exceeds the cohesive strength of the sealant. This can necessitate that extra care be used in the substrate bond surface preparation or that a primer be used, but ensuring that any failure that occurs will be cohesive in the sealant rather than adhesively to the substrate is a primary design consideration.

ASTM C-1135 can be used to determine the tensile adhesion strength of a sealant bond. Although there is no ASTM standard that specifically addresses the measurement of the adhesion or bond strength of sealants loaded in shear, the standards in place for adhesive bonds can be used (single-lap shear – ASTM D-1002; notched-lap shear – ASTM D-3165; and double-lap shear – ASTM D-3528). Much of the adhesion testing that is performed in the industry is testing to determine the effects of environmental and chemical exposure on sealant adhesion. This exposure can be either static or cyclic (Gutowski and Cerra 2009).

## 28.4 Differential Movement Tolerances

The ability of a sealant to accommodate the differential movement of the substrates in a sealant joint is the primary mechanical performance requirement of a sealant. There are many sources of this differential movement. In the use of sealants in building construction, the sources include changes in temperature that cause the substrates to expand or contract, changes in moisture content that can cause porous substrates such as concrete and masonry to swell or shrink, building loads including those induced by the settling of the building over the first two-to-three years, and environmental loads due to wind and earthquakes. Sealant joints should generally not be load-bearing in nature. To be so is counter to the primary mechanical purpose of the sealant joint, accommodating the differential movement. For this reason, the overall design of a building should limit vertical movement through the use of structural reinforcements and key and tongue-and-groove joints.

The differential movement caused by the various mechanisms is additive. Calculation of movement caused by building loads, building settling, and environmental loads are the providence of structural engineers and are beyond the scope of this chapter. Suffice it to say that these loads can be significant, and the input of a competent structural engineer in determining their magnitude is essential to the design of the sealant joints.

The calculations of differential movement caused by temperature changes, though straightforward, must consider all of the following aspects: ambient temperature and the temperature of the sealant material and substrates when the joint is assembled, any movement of the substrates during the processes of sealant insertion and cure, the joint geometry and material used, the substrate mechanical constraints that limit movement, any expected compression set that the sealant may experience, and the expected temperature extremes throughout the sealant joint lifetime.

The total joint movement due to temperature changes can be calculated from the following equation:

$$M_{total} = (T_{max} - T_{min}) \cdot \alpha_{substrate} \cdot l_{substrate} \quad (3)$$

In the equation,  $M_{total}$  is the total joint movement,  $T_{max}$  is the maximum temperature the joint will experience due to ambient heating and the absorption of radiant heat,  $T_{min}$  is the minimum temperature the joint will experience including wind chill,  $\alpha_{substrate}$  and  $l_{substrate}$  are the coefficient of thermal expansion and the unrestrained length of the substrates. Accounting for the absorption of radiant heat can be very important. A dark metal substrate that is in direct sunlight can have a temperature 40 °C higher than the ambient temperature, greatly increasing the joint movement.

For butt joints, this total joint movement should be broken down into movement that will expand or contract the sealant width. The movement creating joint expansion ( $M_{exp}$ ) is:

$$M_{exp} = (T_0 - T_{min}) \cdot \alpha_{substrate} \cdot l_{substrate}, \quad (4)$$

571 where  $T_0$  is the temperature of the substrates at the time of sealant insertion and cure.  
 572 The movement creating joint compression is:

$$M_{comp} = (T_{max} - T_0) \cdot \alpha_{substrate} \cdot l_{substrate} \quad (5)$$

573 The sealant in the joint must accommodate these movements considering the  
 574 actual joint width when the sealant is inserted and cured or set. The necessary joint  
 575 widths to accommodate joint expansion and contraction are easily calculated from  
 576 the elongation capabilities of the sealant in tensile and compression. These values are  
 577 standard information in the technical data sheets of sealants, often using the term  
 578 dynamic movement capability and expressed as a percentage. Where only one value  
 579 is given, it should be used for both tension and compression. Calculation of these  
 580 minimum widths is accomplished using the following relationships:

$$w_{exp} = (100 \cdot M_{exp}) / S_{ten}, \text{ and} \quad (6)$$

$$w_{comp} = (100 \cdot M_{comp}) / S_{comp}. \quad (7)$$

581 In these relationships,  $w$  is the minimum joint width expressed in mm,  $M$  is also in  
 582 mm and is calculated from the preceding equations, and  $S_{ten}$  and  $S_{comp}$  are the  
 583 elongation capabilities of the sealant, in tension and compression respectively, and  
 584 expressed in percent.

585 The movement due to moisture extremes in porous substrates can be calculated in  
 586 much the same way, once the coefficient of moisture expansion is determined for the  
 587 substrate. The movement due to moisture and any movement due to building and  
 588 environmental loads can be added to the thermally induced movement when they are  
 589 significant. The overall required joint width can then be calculated using the relation-  
 590 ships above, and the smaller of the two calculated joint width, with an appropriate  
 591 safety factor, is used for the minimum joint width. From a practical perspective, it is  
 592 important to remember the differences between the as-designed sealant joints and the  
 593 as-built sealant joints and the effects these differences may create. Both geometric  
 594 tolerances and the accuracy of substrate placement must be considered in the design  
 595 of the joints.

596 For lap joints, the differential movement can also be easily calculated. In these  
 597 joints it is the minimum thickness of the joint that must be calculated in the design of  
 598 the joint geometry. This is done by ensuring that the elongation of the sealant-free  
 599 surface does not exceed the elongation capability of the sealant. This is done by  
 600 setting the free surface elongation ( $e$  Eq. (1) discussed in Sect. 2.2) equal to the  
 601 sealant elongation capability and solving the equation for the minimum sealant  
 602 thickness ( $d_{min}$  in the following equation).

$$S_{ten} = (M_{exp}^2 + d_{min}^2)^{1/2} - d_{min} \quad (8)$$

$$S_{comp} = (M_{comp}^2 + d_{min}^2)^{1/2} - d_{min} \quad (9)$$

## 28.5 Conclusions

The proper use of sealants and design of sealant joints must entail consideration of the chemical, physical, and mechanical properties of the sealant and substrate materials and the joint geometry. There are four main sealant joint geometries: butt joints, lap joints, corner or angle joints, and seam or edge joints. Corner and seam joints typically have very limited or no mechanical requirements; they must simply create a lasting seal. The main mechanical requirement of butt and lap joints is to accommodate the differential movement of the substrates. This differential movement dictates the minimum width of butt joints and the minimum thickness of lap joints. The calculation of the substrate differential movement due to temperature and moisture extremes is straightforward, while the influence of external loading on this movement can be complex and will require the services of a structural engineer.

Butt joints are typically chosen over lap joints due to the accessibility of the sealant for repairs and replacement. The use of backing material and bond breaker is essential to creating reliable butt joints. Creating an hourglass shape in the cure or set sealant can greatly decrease the stresses a sealant bond is subjected to.

Most failures of sealant joints can be eliminated by careful selection of the sealant and proper preparation of the substrate bond surfaces. In selecting the sealant, consideration of the chemical, physical, and mechanical properties within the framework of the joint geometry is essential. For joints that require a large volume of sealant, solvated systems and curing systems that require moisture to initiate the cure should not be selected, because they will likely not completely solidify. Chemical compatibility of all materials that will be in contact in the assembled joint, sealant, primer, substrates, bond breaker, and backing material, and the fluids to which the sealant joint will be subjected is essential. Hardness, permeability, and thermal capability of the sealant are the principal physical properties that should be considered in the sealant selection. The mechanical properties of the sealant must match the end use of the sealant joint. Compression set and creep rupture are factors somewhat unique to some sealants that can dramatically reduce the lifetime of a sealant joint.

## Abstract

Design methods of adhesively bonded joints subjected to impact loading are discussed in this chapter. Methodologies to treat the dynamic responses of structures are shown. In these cases, it is necessary to analyze the stress distribution considering stress wave propagation because inertia effects of the structures are more significant than those in quasi static conditions. Constitutive relations of materials are discussed. The relations are highly dependent to the stress and strain rates. Thus, the dependence should be considered for the dynamic analysis of materials. Some examples of stress analysis are shown, where closed-form
